On the other hand, it is idle to deny the direct advantages which man for man, and at the point where the attack occurs the defence has gained by the development of the effectiveness of fire. Since during the time that a man is moving forward he cannot be shooting, it follows at once that the man who is shooting from a fixed position gains in proportion to the effectiveness of the fire which can be delivered during the time taken by his assailants to move over the ground. So great is the advantage which, from this cause, the new weapon confers on the defendant, that were it not for two considerations it might almost be considered decisive. The first is, that in the best situation which can be selected for taking up a defensive position there is always some point which is weaker than the rest, more exposed, that is, to the assailants' fire, and the access to which is less under the fire of the defendant; and that while the defendant necessarily has to be prepared for attack at every point, the assailant is able to gather his forces against the point which he selects as the most vulnerable. The other is the enormous power of modern artillery, which enables an assailant to bring against the position he assails an overpowering fire long before his infantry are ready to move to the assault. This leads us naturally to the next consideration in regard to armament—that which relates to the big guns. There are some further points in the question of attack and defence which are connected with the effective employment of the infantry arms, but they are much more easily understood when we consider them with reference to the "drill" which has been devised in order to enable armies to take advantage of the power of their weapons, that I shall leave them until this part of the subject is brought under consideration.

TECHNICAL DRAWING.—LXIV.

DRAWING FOR BRICKLAYERS.

FIG. 525.—The design of the floor given in this example is of a very simple character, and consists of octagonal and square floor-tiles. Tiles of this character, and of varied manufacture, are now made by several firms in this country, and may be had to suit any building, or adapted to any sized floor. Numerous beautiful specimens of these may be seen in the South Kensington Museum. To draw this pattern, divide the whole width into three equal parts, and draw lines dividing the surface into three equal strips, or as many as may be required in the design. Next draw lines at right angles to these, thus dividing the whole surface into squares.

In one of these, as A B, draw diagonals, and from the angles, with a radius extending from the angle to the centre (C), describe arcs cutting the sides of the square in D, E, F, G, H, I, J, K. Join E H, I K, J G, and F D, and an octagon will be inscribed in the square, as shown in Fig. 525, or on a larger scale in Fig. 526. Now measure the distance from the angle of the square to I or K, and set off the length on each of the four lines meeting at the angles of all the squares. Join these points; the design will then be completed, and may be coloured according to taste. The squares may be formed of four triangular pieces, or may consist of complete squares.

In the following study (Fig. 527) another design for a tiled floor is given, the forms of the tiles being hexagonal and lozenge. In order to guide the student in drawing this pattern, the annexed elementary figure (Fig. 528) is given, from which the precise construction will be seen.

Draw the regular hexagon A B C D E F. Divide each of the sides into three equal parts, as G, H; I, J, etc.

From the various points draw lines across the hexagon, parallel to the respective sides. These intersecting, as at K, L, M, will give a smaller hexagon in each angle of the original figure, leaving the star in the middle, and a triangle, as G H M and I K J, in each of the sides. These triangles are the halves of the lozenges of six surrounding stars.

Fig. 527.—In commencing this pattern, draw the hexagon A B C D E F, and adjoining it construct the others, which are to contain the smaller hexagons. Finish each in the manner shown on the previous figure, and colour according to taste.

FREEHAND DRAWING.

It has in all the previous lessons been urged on artisans, to whatever branch of industry they may belong, that *all* drawing cannot be executed by the aid of instruments, and that it is therefore indispensable that they should acquire some power in drawing by freehand, guided only by the eye. The question

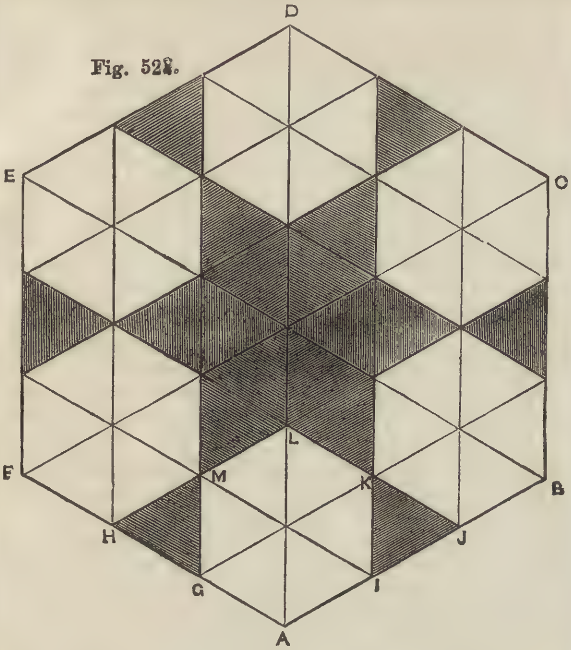

Fig. 528.

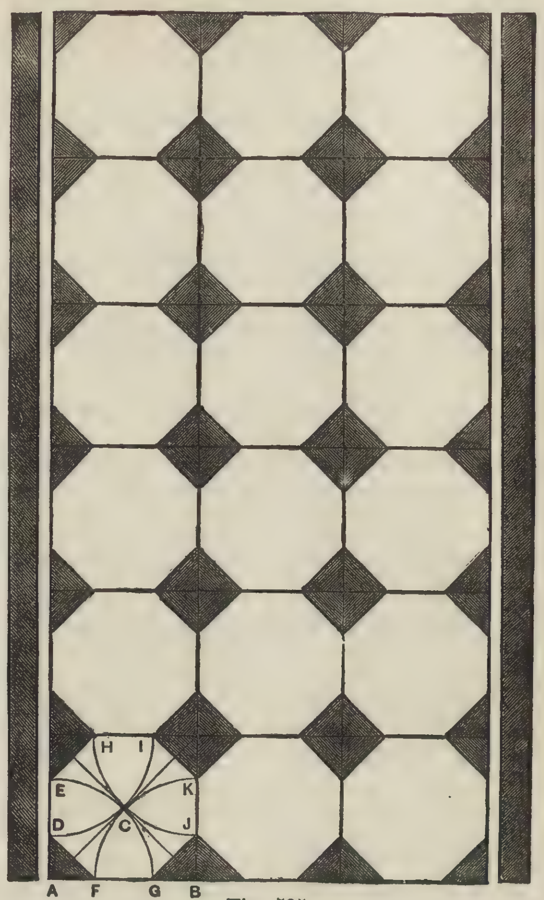

Fig. 525.

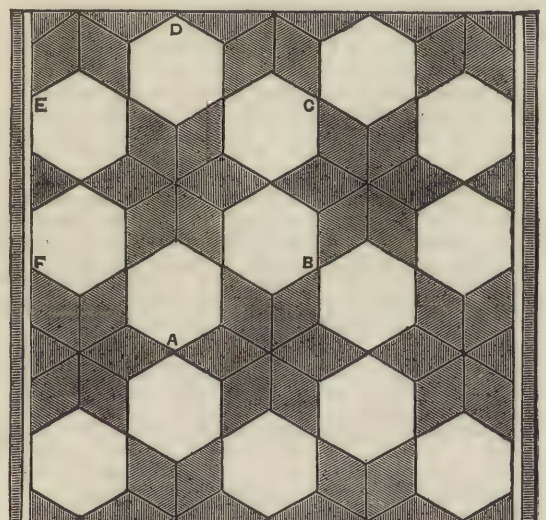

Fig. 527.

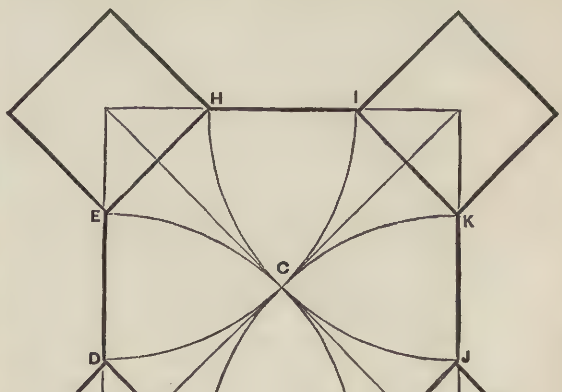

Fig. 526.

should not be asked, "Does a bricklayer ever require freehand drawing?" for although education should as far as possible be thoroughly practical in its character, still it is unwise for the young to study in such a narrow track. A bricklayer may not absolutely require freehand drawing in his work; but, for all that, the contemplation of graceful and beautiful forms refines and elevates his taste; and the accuracy of perception obtained by the practice of drawing rigid forms is such that it frequently enables him to check the work done by means of instruments, and to detect where an error has been made. Besides this, a bricklayer need not always draw bricks only; he will in time draw buildings, with their decorations; he will, by the aid of a knowledge of object drawing, be able to make sketches of any building or place he may visit; so that, from every point of view, the student is urged to follow the elementary course here laid down as a stepping-stone to higher subjects.

In order to avoid repetition in these lessons, and to economise space, the subjects of the freehand exercises in "Drawing for Stonemasons" may be used at this stage; they will be found at page 265, Vol. II., of THE TECHNICAL EDUCATOR.

Assuming then that these have been satisfactorily accomplished, we proceed with

LINEAR DRAWING BY MEANS OF INSTRUMENTS.

FOUNDATION OF BUILDINGS IN GOOD SOIL.

The meaning of the term and the general principles of foundations have been treated of in lessons on "Building Construction." The subject is here continued in order to give the student a further insight into it.

The ground on which a building is to be erected should be carefully examined to a considerable depth, and if it proves to be good throughout, such as rock, gravel, or soil of a sound, uniform quality, not liable to be altered from time to time, either entirely or in part, by the effects of water acting below the surface, a trench is cut all round, and carefully levelled; in this the walls are commenced, giving, however, to each wall a base somewhat thicker than that part of it which is to appear above ground.

If the ground to be built on should happen to be very irregular, such as the side of a hill, which often occurs in practice, instead of cutting the whole trench intended for the building to one general horizontal level, it is usually cut to several levels in steps or terraces, or, as it is technically termed, "benched out." When a building is to be erected, the ground should not on any account be cut to an inclined plane, although this method is sometimes used in low boundary walls, as in the north enclosure of the infantry barracks at Chatham, where the courses of bricks are all laid sloping. In any other description of wall this arrangement would be perfectly inadmissible.

PHOTOGRAPHY.—VIII.

By J. C. LEAKE.

DRY PLATE PROCESSES.

ALTHOUGH for excellence and certainty of result the wet collodion process already described is unrivalled, yet the difficulty and inconvenience of at all times carrying the necessary chemicals and a portable dark room to the scene to be photographed; are such that a process by which plates capable of receiving an impression, and which can be prepared and developed at home, has always been a desideratum to the out-door worker. Much attention has been given to the production of sensitive dry plates, and at length several processes have been invented, which are as nearly as may be expected equal to that upon wet collodion, although the same amount of sensitiveness or certainty cannot be at all times secured. Enough, however, has been done to render these processes exceedingly useful where the subject will allow of a moderately long exposure; and in some cases, such as dimly lighted interiors, where the exposure would be too long for the proper keeping of wet plates, those prepared as we are about to describe will enable the operator to obtain pictures which it would be impossible to produce by any other method.

There are, as we have before remarked, various processes by which sensitive dry plates may be prepared, but their number may be reduced to two or three for practical purposes, the others being for the most part merely modifications. Of these standard processes, that known as the collodio-albumen stands first, both as regards delicacy and certainty, as well as for its extraordinary keeping properties. As may be implied from its title, this is a combination of the albumen and collodion processes, both of these substances playing an important part in the production of the picture. For the production of sensitive plates by this process two nitrate-of-silver baths will be required; and we may here remark that as a rule the silver baths required for exciting the collodion film in dry-plate work should never be of less strength than forty grains to the ounce of water, and should be kept slightly acidulated with acetic acid.

It is also advisable to keep separate bath solutions for wet and dry plate work, as the conditions required are mostly different; attention to this point will save much trouble and vexation. For exciting the collodion film a bath should be mixed containing forty grains of nitrate of silver to the ounce of distilled water. To each pint of this solution add two or three grains of iodide of potassium and enough acetic acid to freely redden litmus paper. The second nitrate bath which will be required for exciting the albumen must be prepared as follows: nitrate of silver, thirty grains; distilled water, one ounce; dissolve and add one ounce of glacial acetic acid to each pint of solution. These baths must be kept each for its own purpose, or failure will result. Next prepare the following solution: distilled water, one and a half ounce; pure albumen (from fresh eggs), five ounces; iodide of potassium, twenty grains; bromide of ammonium, five grains. Dissolve the salts in the water, and add to the albumen in a large bottle, as before described for the preparation of albumenised paper; and after a few minutes' shaking add from forty to fifty drops of strong liquor-ammoniæ; again agitate until the whole becomes converted into froth, after which it should be allowed some hours to settle. It must always be carefully filtered before use. With these solutions prepared we may pass on to the manipulative details.

Any good bromo-iodised collodion will answer, but a sample should be selected which adheres well to the glass, and it should be remembered that a highly-bromised collodion will be most successful in all dry processes. After coating allow the film to become well set before immersion in the nitrate solution, and allow at least four or five minutes for the conversion of the iodide contained in the film. When removed from the nitrate bath, wash the film well first with distilled and afterwards with common water, in order to remove the whole of the free nitrate of silver. Pour into a flat dish, which must be scrupulously clean, enough of the following solution to amply cover the plate: iodide of potassium, three grains; water, one ounce; and allow the plate to remain in this four or five minutes, or while a second plate is in course of preparation. Wash well with clean water, drain, and pour over a portion of the iodised albumen, allowing it to soak well into the film. Allow the first quantity of albumen to flow off the plate into the sink, and repeat the operation with a fresh supply of solution, reserving the surplus for the first coating of the next plate. Set the coated plate to drain upon blotting-paper. It is a good plan to provide a clean box or cupboard in which the plates may be set to dry, as the albumen is exceedingly liable to attract particles of dust, which would produce spots in the finished picture. When the plate is dry (and it may be dried by artificial means if required, being in its present condition nearly, if not quite, insensitive to light), it will be ready for immersion in the second nitrate-of-silver bath. Before this immersion, however, it is better to thoroughly dry the film before a fire, making the plate quite hot, or blisters will probably ensue, and the film may be broken. After immersion in the second bath for one or two minutes the plate should be removed, again thoroughly washed in clean water and dried, when it will be ready for exposure in the camera. Respecting the exposure little advice can be given, except that as a rule plates prepared as above described will require at least four times that necessary for wet collodion, and frequently even more. One of the great faults of inexperienced dry-plate workers is that they frequently under-expose their pictures. Over-exposure can mostly be remedied in the development, but nothing can possibly be done with a plate if the detail in the darker portions be not properly impressed.

The usual developer for plates prepared as above described is composed of a saturated solution of gallic acid, made by pouring boiling water upon the crystal and agitating, pouring off the solution when cold. A quantity of this solution should be

prepared and filtered, and a small proportion of a ten-grain solution of nitrate of silver added before pouring over the plate, which should previously be wetted, in order to facilitate the flowing over the surface.

In the case of small plates, a sufficient quantity of the developing solution may be poured into a dish and the plate immersed, but care will be required in order to avoid stains, if the solution be not kept in motion, and as soon as any discolouration of the solution is observed the plate should be well washed and a fresh quantity applied. To those accustomed to the rapid development of collodion negatives the process in the case of dry plates may seem long and tedious, a collodio-albumen plate seldom developing in the way we have just described under half an hour. Care must be taken, however, not to make the negative too intense, as the deposit in this case is of a peculiar yellow non-actinic colour, so that a negative which appears to the eye thin and translucent is chemically sufficiently dense to yield a vigorous proof, while if the density were carried to anything like that usually necessary in a wet collodion negative the print would be hard and utterly useless. In case of under-exposure, or if the development should be unusually tardy, it may be hastened or completed by the use of a solution of pyrogallic acid, as follows: pyrogallic acid, two grains; water, one ounce; glacial acetic acid, twenty minims. This solution must be poured on and off the plate, and not used in a dish, as its action is extremely rapid, and must be carefully watched. Of course the usual addition of a few drops of nitrate-of-silver solution must be made before applying it to the plate. Sometimes the development is effected by means of pyrogallic acid solution entirely, and this is the modern practice, but it is not so safe in the hands of the tyro as the slower method by means of gallic acid; and we would therefore suggest that its use be deferred until the operator has gained some experience in the development of dry plates. When the operation of development is completed the plate may be washed, and fixed in a saturated solution of hyposulphite of soda as usual. The process we have now described is one which may be easily and safely worked, and although there are others which are more rapid and perhaps more simple, it is the one which the beginner should always commence with, as being likely to produce less failure and disappointment than those of a more delicate character, such as we shall describe in our next paper.

SANITARY ENGINEERING.—XVIII.

CISTERNS AND ECONOMY OF WATER—VENTILATION OF PIPES.

In two preceding papers (XVI. and XVII.) we briefly dealt with the methods of water-supply for villages and towns; and we now proceed to give the detail of various inventions for storing and also for economising the supply thus obtained. In the last century cisterns were almost invariably made of lead, in some cases cast solid of sufficient thickness to be fixed without external casing; the outside was often decorated with panelling in designs, and sometimes with coats of arms. The usual mode, however, was to provide a strong wooden cistern, which was subsequently lined with lead soldered together at the angles, either cast in sheets or rolled in a mill, described in the first case as "cast," and in the latter as "milled" lead; and this latter system is still extensively in use.

Within the present century, however, several other materials have been adopted for the purpose—*e.g.*, cast iron in one piece for small cisterns, and in a number of plates jointed together with flanges and bolts for those of larger dimensions, the joints being rendered water-tight with cement. Examples of this class of construction may be seen in the water-tanks for the supply of the engines at most railway stations.

The introduction of slate is, however, the most important feature of modern times in the construction of what may be termed household cisterns, and as it is much cheaper than lead, it has almost entirely superseded its use for all common purposes. The increased facility in obtaining what is called slab slate of late years, renders it possible for all, except very large cisterns, to be constructed with the ends, sides, and bottom each consisting of one single piece of slate. These are rabbeted together at the angles, confined in their place if necessary by small iron bolts, and the joints rendered water-tight with red lead. As slate, from the density of its texture, is scarcely affected by atmospheric changes, when the work is once properly executed, these cisterns are perfectly efficient. They are also free from an objection that applies to lead of all descriptions, and that is, that especially with soft water, when the water remains for any considerable time in contact with the lead, a chemical action takes place by which the water holds a certain quantity of lead in solution; and if this be allowed to proceed to any extent, the result when the water is used for drinking is very deleterious, producing the symptoms which are well recognised as those of lead poisoning.

Another material recently introduced for this purpose is sheet iron, which should always be galvanised to protect it from rust. The sheets are riveted together, and, where the size is so large as to require it, strengthened with iron cross-braces. This material is largely used for ships' tanks, as well as for household cisterns, and most of the large workhouse infirmaries erected recently, and also the large groups of buildings carried out within the last two or three years for the Metropolitan Asylums' Board, have been provided with cisterns of this construction.

Where, however, as is often the case in country houses, the general storage for the water is below the level of the ground, a brick tank is the usual receptacle. This can be made perfectly water-tight by a lining of cement within, and when the size is unusually large and the depth considerable, an outside coating of asphalte may be employed with advantage.

Having thus described the materials for the construction of cisterns in ordinary use, we now give the detail of various contrivances for economising the water-supply.

In districts where the supply is limited, or in houses where the cistern accommodation is comparatively small, it becomes important that the requisite flushing should be done with the minimum quantity of water, and for this purpose various inventions have been introduced. The one shown in Fig. 10 is Hooker's pattern, divided into a smaller and larger compartment, with levers and valves so arranged that the contents of the smaller cistern only are discharged for flushing purposes; the same action that releases the water closing for the time the connection between the two, which is restored when the operation is complete; the main store being thus retained intact, and the smaller portion refilling itself immediately.

Our second illustration (Fig. 11) shows a flushing cistern of somewhat similar construction, but so arranged as to be independent in itself, and to be attached to any ordinary larger cistern already fixed or otherwise, the same object being attained.

Our third sketch (Fig. 12) shows another adaptation of the same principle, but with a horizontal instead of a vertical division, the whole construction in this case being of cast iron.

In a previous paper we have had occasion to call attention to the difference between "constant" and "intermittent" supply, and our next illustration (Fig. 13) shows a contrivance for the economical supply of water to a closet where there is a *constant* supply at a considerable pressure, for which purpose only it is adapted. The air-chamber, which is of cast iron, must be connected with the main, and perfectly air-tight. The weight of the head of water compresses the air within the chamber, and fills it with water up to a certain point, the quantity being sufficient for the thorough service of the closet. When the closet is used the connection with the air-chamber is opened, the compressed air regains its original volume, discharging the water forced in by the pressure, the same action severing the connection with the main, which by the return action is again opened, when the air-chamber again charges itself as before, about two minutes being the time required, or even less.

This apparatus, which is called Common's patent high-pressure closet, has been used extensively and successfully in Brighton and other large towns where the constant supply is in operation. In a subsequent paper of this series we propose going in fuller detail into the various descriptions of closet apparatus, and therefore omit at this point any description of the remaining portion of the sketch, which is only introduced as an illustration of a certain class of methods for economising water-supply.

Regulators, of which Howard's patent is perhaps the best of its class, are another means of attaining the same object. They are attached to the water-service at its junction with the apparatus, and not to the cistern, and consist of a brass valve so arranged that the delivery of the water can be regulated by

a screw at pleasure, in accordance with the head or body of water to be dealt with. The rush consequent upon the working of the ordinary closet is thus avoided, sufficient water only being delivered to do the work thoroughly without waste. When the water, however, is charged with any foreign matter, the small aperture in the valve is apt to clog, and thus its efficiency is interfered with. In these cases Underhay's system may be adopted with advantage. Here the supply of water is received into a valve constructed with leather, like a bellows, the same result as before—a gradual discharge—being obtained; the leather, however, is perishable, especially if it be exposed to damp externally.

Having thus briefly described some of the methods in ordinary use for economy in the use of water-supply in connection with drainage, before going further into the detail of valves and closets, which will form the subject of our next paper, we wish to call especial attention to a matter we venture to think not generally understood, and that is the ventilation of pipes. meter, and then the pipe itself becomes as it were the flue by which the remainder of the system with which it is connected is ventilated; and in some cases this is so completely carried out, where unusual care is required, that the space between the bottom of the valve and the water in an ordinary valve-closet has a small air-pipe running into the ventilating soil-pipes. We may mention Sandringham House as an instance of the adoption of this precaution. The next point is to prevent any foul air from becoming what is technically called *water-bound*, *i.e.*, that when flushing takes place, a free escape should be provided for the air displaced, which, unless this is done, bubbles up through the water by which it is supposed to be hermetically confined, with the usual unpleasant results; and sometimes even when the plumbers' work is perfect in itself, a want of attention to this same point of water-bound air in the drains will produce the same result. Objections are frequently made to erecting closets in confined situations from fear of the want of general ventilation; but if the above cautions are carefully attended to

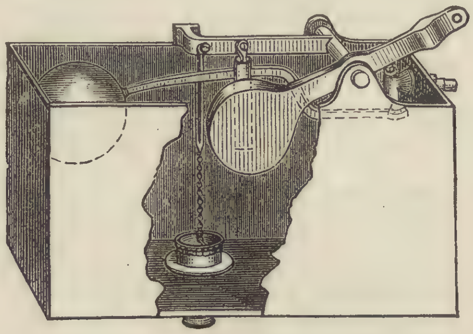

Fig. 11.

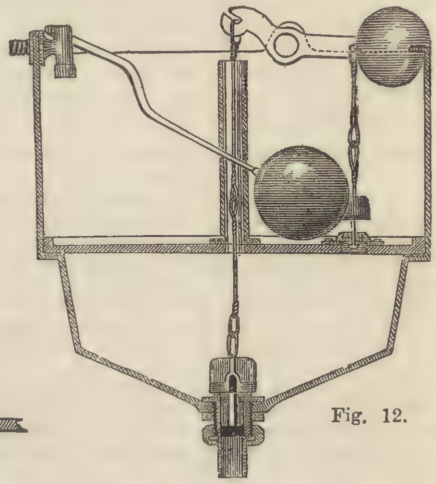

Fig. 12.

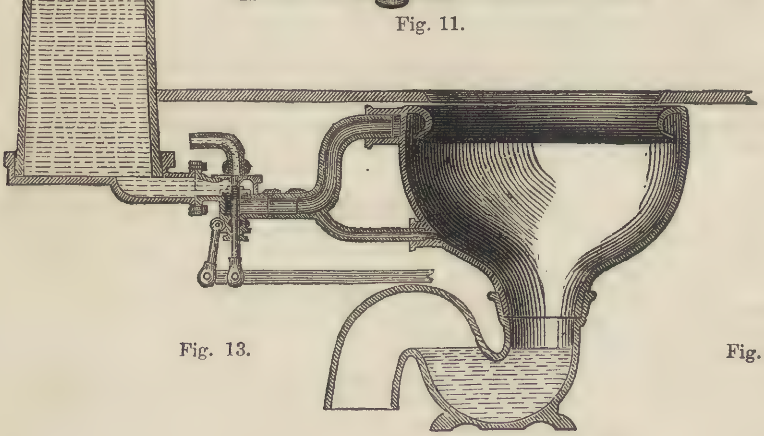

Fig. 13.

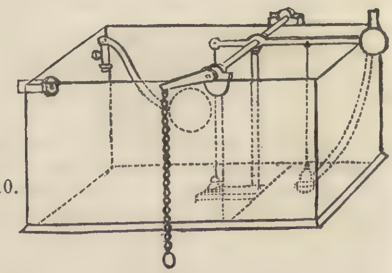

Fig. 10.

Lead is still the material generally in use, and will probably continue so to be; but whether of lead or of iron, or of any other material, our remarks will equally apply. One of the most important sanitary requisites in buildings of any kind is good plumbers' work; and there are two all-important requirements. The first is, that the strength of the material shall be sufficient, and the work well executed, as in no trade is perfection of workmanship more absolutely necessary, the least defect revealing its presence by its unpleasant and unhealthy consequences. But the second is equally important, and that is ventilation, as we shall proceed to explain, for the work may be perfectly well executed, and yet if this second requirement be either neglected or misunderstood, unsatisfactory results ensue, the cause of which is often obscure and difficult to trace. The great secret is to provide for the escape of all foul vapours to the outside air by means of the pipes themselves. Ordinary building specifications, as drawn even by the best professional men, are often wanting in explicit detail in this respect. The common wording is, "provide all necessary air-pipes," the details being too often left to the discretion of the working man. Every soil-pipe should have a ventilating-pipe from its topmost point, communicating with the external air, of not less than two inches in dia- by an expert, they ought to be absolutely and perfectly free from smell in whatever position they are placed.

This question of ventilation is all important in matters connected with drainage. Miss Nightingale says, "I have met just as strong a stream of sewer air coming up the staircase of a London house as I ever met with at Scutari, and this sewer air is retained in the bedrooms. No house with an imperfectly trapped pipe communicating with the sewer from the sink, can ever be healthy, and may at any time spread a fever among the inmates of a palace." The recent (1871-2) illness of the Prince of Wales has given only too striking confirmation to this well-founded observation. In our present paper we have given, as far as our limits have allowed, some guidance as to the general principles to be adopted for the complete avoidance of all danger as far as internal construction is concerned; and as we proceed with the subject, we hope in some subsequent paper to show how by the proper trapping of drains external to the house, with ventilation always kept in view, the evils which we fear are only too common may be effectually guarded against, and the noxious gases evolved from sewerage harmlessly discharged into the external air, and typhoid fever, with its cognate disorders, effectually kept at bay.

MINING AND QUARRYING.—XXI.

BY GEORGE GLADSTONE, F.C.S.

COPPER (*continued*).

PROPERTIES — ROLLING — HAMMERING — WIRE-DRAWING — PLATING—ALLOYS—SALTS OF COPPER.

PURE copper is easily recognised by its red colour, which is so familiarly known as not to need description; there is, indeed, no other simple metal with which it can be confounded. It is capable of receiving a high polish, but does not retain its brilliancy long, as it is liable to be affected by the atmosphere, under the influence of which it turns green, or a dark brown. This circumstance detracts considerably from its utility, except when combined with other metals which reduce its liability to tarnish. It melts at about 2000° Fahrenheit. It expands but slowly under the influence of heat; the calculation being that its linear expansion between the temperature of ice and that of boiling water amounts to $\frac{1}{552}$. Its power of conducting heat is, however, about $2\frac{1}{2}$ times that of iron. Its elasticity is only slight; but it is very tenacious, and can therefore be rolled or hammered out into thin sheets, or drawn into fine wire; and it becomes harder under these processes.

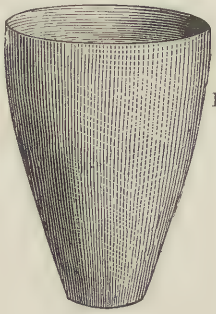

Fig. 1.

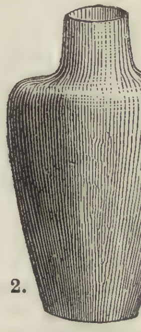

Fig. 2.

On account of its high value, it is never used in an unmixed state for large works; but it is applied to a great variety of purposes, in which its special advantages outweigh the question of cost. Some of these must now be briefly alluded to.

The bottoms of ships are sheathed with copper, or an alloy of this metal, for the purpose of protecting them from the attacks of worms, which would otherwise bore holes in the wood; as well as from barnacles, which would attach themselves to the surface. The former would impair the strength of the vessel, and cause her to leak; the latter would interfere with her sailing powers by preventing the free passage of the hull through the water. The gentle corrosion of the copper caused by the sea-water prevents any of these creatures from adhering to it. In making the sheathing the metal is rolled out into large sheets between heavy cylinders driven by steam. The cakes of copper while red-hot are passed between the first pair of rolls, and are then re-heated before the second rolling, and so on, until the plate has acquired the thinness desired; each successive pair of rolls being set closer together than the preceding. During these successive heatings the copper becomes oxidised on the surface; to free it from which it is dipped into a bath of urine, then heated afresh, and while hot plunged into a tank of cold water. The ammoniacal salts, having entered into combination with the oxide, form a scale, which is detached by the water, leaving the surface of the metal quite bright.

Fig. 3.

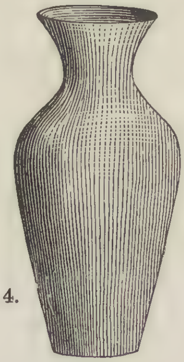

Fig: 4.

Copper sheets, thinner than those used for marine purposes, are sometimes employed in roofing. The spires and roofs of old churches and other public buildings are not unfrequently to be seen coated with copper, which may be recognised by its dull greenish hue; but this application is passing out of date, as lead, zinc, and tinned or galvanised iron are found to be more economical.

Many vessels used for culinary and manufacturing purposes —such as moulds and stewpans, urns and kettles, stills and coppers—are made of hammered metal. For making such articles a circular sheet of copper of the required diameter and thickness is taken, and beaten on one side until it assumes a hollow conical form; and by continuing the hammering on the inner side it can be beaten out to almost any shape that may be desired. From time to time the metal has to be warmed or annealed in order to prevent its becoming brittle; and this has to be attended to all the more carefully as the work proceeds, as the tendency to brittleness increases the longer the hammering is carried on. Figs. 1, 2, 3, 4, in the accompanying illustration, will serve to illustrate the intermediate forms assumed by a flat disc of metal under the hands of a workman in hammering it out into the shape of a vase. In this manufacture it is highly important to test the copper to see whether it contains any, or what foreign ingredients, as some of those which are commonly found in it greatly affect its malleability. Thus antimony and arsenic are highly objectionable, even when present in very small quantities; silver, on the other hand, is rather beneficial than otherwise. A careful chemical analysis should be made, as small quantities of tin, iron, and other metals besides those above named, may often be found in merchantable copper.

The tenacity of this metal renders it very suitable for wire-drawing; and this application of it may be found in almost every household, bell-wires being usually made of copper. In drawing it out, the same tendency to become hard and brittle is experienced, as when under the action of the hammer; it is, therefore, necessary to anneal it from time to time during the manufacture, in order to restore its softness and toughness. In making very fine wire the heat of a flame from burning straw is sufficient for the purpose.

Copper wire has within the last few years received other very important applications, on account of its high power as a conductor of electricity. As compared with silver wire, which is the best conductor known, and is therefore taken as the standard, it ranks as 94 to 100; none of the other metals can at all compare with these two in this respect. Only the very purest copper should be used for this purpose, as the smallest admixture of alloy or other foreign matter greatly interferes with its efficiency. In its application as telegraph wires there are several other reasons why none but the very best material should be employed; such as the immense length to which the wires extend, and the importance of rapidity of action, and of sensitiveness, in order to economise the electric power. According to the very careful experiments of Sir Charles Wheatstone, a copper wire will transmit electricity at the rate of 288,000 miles per second; but in practice nothing like this speed can be attained, as the insulators and the medium through which the wire passes become affected by induced currents, which cause a loss both of speed and power; the inferior conductors being still more liable than copper to suffer from these causes.

The same principles which suggest the use of copper wire in telegraphy also indicate the propriety of using it as a protection against thunder-storms. In shipping, where lightness as well as efficiency has to be studied, this metal is always employed. A thin strip or wire is carried up to the masthead, which by its superior conductivity will effectually protect the mast from the effects of the lightning, and that without risk of being fused by the electricity; its power of resisting fusion being in proportion to its power of conduction.

Silversmiths very frequently make use of copper as the foundation of their manufactures, and then coat the goods over with a thin film of the more valuable metal. This is done by rubbing it over with a composition made of nitrate of silver, chloride of sodium, and the acid tartrate of potash, when a

decomposition of the former salt takes place, and a film of the metallic silver is deposited upon the surface of the copper. A heavier plating is made by a mechanical process. A sheet of silver is laid upon one of copper, a little powdered borax being placed between them; they are then heated in a furnace nearly to the melting-point, and while in that state are passed between heavy rollers, which bring the surfaces of the two metals into actual contact. These plates, consisting of copper on the one side and silver on the other, are then worked up into various useful articles for the table.

Copper was formerly used in making our coins of the lowest denominations, until superseded by the bronze coinage; but it also finds its way into the gold pieces, a certain per-centage of copper being mixed with the precious metal to give it increased hardness. Our standard gold contains 8·33 per cent. of copper. The red gold of jewellers is still more highly alloyed with it; sometimes to the extent of 25 per cent.

Copper forms the principal ingredient in several alloys of very considerable value for industrial purposes. The various combinations of this metal with tin have already been described in Article XVII.; while those with zinc will form the subject of the next paper. Those with nickel, lead, and other metals, will be described hereafter when treating of those different elements. Sometimes it is mixed in small quantities with iron; the addition of about 5 per cent. of copper to grey pig-iron yields an alloy of very considerable hardness, which is therefore recommended for anvils, and other implements which have to endure rough usage.

Phosphorus also forms some definite chemical combinations with copper. It yields two phosphides, the one containing six equivalents and the other three equivalents of copper to one of phosphorus; giving 14·1 and 7·5 per cent. of the latter element respectively. Both these alloys are very hard and brittle, with a crystalline structure; but if the proportion of phosphorus be reduced to about 1½ per cent., just the opposite effect is produced. This compound is much more readily fused than pure copper, becomes very limpid, and makes excellent castings when poured into chills or iron moulds. It greatly contracts in cooling, and can only be rolled and hammered when cold. It will endure a weight more than 50 per cent. greater than pure copper, without breaking; being in this respect superior even to gun-metal.

It will now only remain to consider the principal salts of copper of importance in the arts. Their uses are so varied that they will continually be found mentioned in other series of articles, such as those which treat of glass-making, colours, dyeing, alum, and many others.

The manufacture and uses of verdigris, or the basic acetate of copper, have been described under the article "Acetic Acid" ("Chemistry applied to the Arts."—XV.), to which the reader is referred. The normal acetate, $CuC_2H_3O_2$, sometimes called crystallised verdigris, is produced by taking some of the ordinary verdigris, or some of the oxide of copper, and dissolving it in acetic acid. It can also be made by precipitating a solution of acetate of lead with sulphate of copper. The salt is poisonous; a common characteristic of all these compounds, the best antidote for which is white of egg or albumen.

The *sulphate* ($CuSO_4 + 5$ water) is more familiarly known as blue vitriol, and is very extensively used in making both blue and green pigments, as well as in electrotyping, and in medicine; it possesses highly astringent properties. The water pumped up from the bottom of copper mines often consists of a solution of this salt, but it is always charged with impurities. The commercial article is most generally made in one of the following manners. Old copper is taken and heated to redness in a reverberatory furnace, after which some sulphur is thrown in and the doors closed, when combination of the two ingredients takes place, and the metal is converted into a sulphide. On admitting the air this is again changed into a sulphate, along with some oxide. The charge is then thrown while still hot into water containing some sulphuric acid; and it is then evaporated down so as to crystallise out the sulphate of copper. It may also be made by the roasting and lixiviation of the common pyrites, the sulphide of copper and iron; but it is liable to be contaminated with a little of the sulphate of the latter metal. This, however, can readily be separated by the application of a small quantity of nitric acid. A very pure salt may also be made by boiling the oxide with dilute sulphuric acid, and then allowing the liquid to cool, when the sulphate of copper will crystallise out; or by heating metallic copper in presence of strong acid, and digesting the resulting mass with hot water, which dissolves out the sulphate of copper, from which crystals of the salt are thrown down as it cools. The former of these methods is commonly adopted in manufactories. Strong wooden tanks lined with lead are used for the purpose, and the boiling is caused by forcing steam in through a lead pipe near the bottom of the tank. From this the liquor is driven off into other leaden vessels to crystallise out, which occupies from five to six days. After being drained dry from the mother liquor, the crystals are packed in casks for sale.

The arsenite of copper, commonly called "Scheele's Green," is prepared by precipitating a copper salt, such as the foregoing, with arsenite of potassium; or with arsenious acid itself, neutralised by ammonia.

The aceto-arsenite of copper is also used as a pigment, under the name of "Schweinfurt Green." It produces a splendid colour, but it has a bad reputation on account of being a highly poisonous substance, though it is not volatilised at any ordinary temperature. It is made by taking 5 parts of verdigris or the acetate of copper, making this into a paste, and then boiling it up in an aqueous solution of arsenious acid, containing at least 4 parts of acid to 50 of water. If it should turn a yellowish-green during the process, it indicates a deficiency of acid, which must be increased, and the boiling continued for a short time longer, until the full colour has been attained.

Azurite, or the blue carbonate of copper, which has been already described when speaking of the different kinds of ores, is made into a pigment, by grinding it into a fine powder. It goes by the name of "blue verditer;" but its value in the arts is impaired to some extent by its liability to turn green on exposure to the influence of the atmosphere. It can also be made artificially. The simplest process is that of working up a quantity of chalk or carbonate of lime with a solution of nitrate of copper, when double decomposition takes place, forming nitrate of calcium and carbonate of copper. The latter settles to the bottom, and is washed with water several times till quite pure. Before the precipitate is dried, from 8 to 10 per cent. of caustic lime is added, and intimately mixed with it, when the compound acquires a beautiful blue colour, and the process is complete.

The more usual plan is to grind up a quantity of the sulphate of copper, along with a slight excess of chloride of sodium, into a fine powder, and then work them up into a paste with water. Into this small bits of thin sheet-copper, which have just been thoroughly purified from any oxide by first dipping them in acid and then washing them with pure water, are inserted; the weight of metal employed should be about equal to that of the sulphate used in making the paste. The copper is left in the paste for about three months, but in order that all parts should be equally acted upon, the whole contents of the chest are turned out and then back again about once a week. The product of this operation is carefully washed with water, and then treated with hydrochloric acid, in order to convert it into a soluble chloride of copper, from which it is again re-converted into the oxide by the agency of caustic lime. The precipitate is subsequently washed and filtered, and then laid out to dry in the air, but the temperature should not be allowed to exceed that of ordinary summer weather. When thoroughly dry the product will possess a beautiful blue colour.

CHEMISTRY OF THE FINE ARTS.—VII.

By Professor CHURCH, Royal Agricultural College, Cirencester.

THE RESTORATION AND PRESERVATION OF MURAL PAINTINGS—CHEMISTRY OF THE MATERIALS OF SCULPTURE AND ARCHITECTURE—MOSAICS—MARBLE—STONE, BRICK, AND TERRA-COTTA—WOOD.

IT is often desirable to preserve, for artistic or archæological reasons, the remains of those mural paintings with which, in mediæval times, our English churches were so profusely decorated. But great difficulties generally stand in the way of such preservation. Sometimes the plaster below the painting is in a thoroughly decayed state, crumbling on the slightest pressure, and in some cases the weakness is apparent in the

layers of pigment themselves. Under the former conditions the only process of conservation involves the entire removal or transference of the painting to canvas or cloth: in the latter case, where the plaster is sound but the pigments loose, there is no plan which answers more thoroughly, and is easier of execution, than that of fixing the crumbling paint by means of a spray of some preservative solution. Before giving details of the successful application of this process, we must recur for a brief space to the process of transference before mentioned. When a mural painting has been cleared of the layers of white-wash which concealed it, and shows a good firm surface, though the plaster below is uneven and crumbling, it may, after careful dusting, be gradually transferred to a piece of cloth, which is to be wetted with smooth flour-paste just as it is gradually applied to part after part of the surface of the picture. Other materials of an adhesive nature, such as resin, have been employed for this purpose with success. When the cloth or canvas is quite dry, it may be loosened, together with its adherent painted layer, by the insertion of appropriate instruments (palette knives, etc.) between the layer to be removed and the plaster below. The other operations necessary to restore the picture are of a simple mechanical nature, involving the preparation of a bed of fresh plaster for its reception, and the final removal of the cloth on the face of the work by means of hot water. It may then be allowed to dry thoroughly, and finally submitted to the following treatment, which is equally appropriate in those instances where the paint on the surface is in a powdery and fragile condition, though the wall behind remains sound. All dust must be first removed by the bellows, or by a soft brush if the picture will bear it. Then the surface is to be dried, by means of a brazier or by burning spirit of wine upon it, but slowly and carefully, so that no flakes of colour curl up and separate. While still warm the surface is to be syringed (by means which we have pointed out in our remarks on Stereochromy) with a preservative liquid. A good preparation for this purpose is the wax or paraffine medium described in the last lesson. This material requires to be diluted with a good deal of the proper solvent (benzole or turpentine) before it is used for syringing. The liquid spray as it dries up fixes the loose particles and flakes of paint to each other and the wall, and though it darkens the colours a little, enriches them somewhat at the same time, while it exerts, it must be allowed, an unsatisfactory effect upon the whites and high lights of the picture. Preparations of parchment size or isinglass may be similarly employed in lieu of the paraffine or wax medium, but in a damp position these substances are likely to introduce a new element of decay, as they favour the growth of mildew upon the surface to which they have been applied. Nor is it usually safe to apply any preparation of the soluble silicates to an ancient mural painting executed in tempera or fresco, though such a proceeding has been once and again recommended. In trials made by the author of these papers it was found that water-glass solution produced the most undesirable changes of colour and surface in some fragments of mural decorations to which it was carefully applied. The process which we have described and recommended, and in which a spray of a chemically inert solution of paraffine or wax and resinous substances is used, seems to leave very little to desire. In some cases, where the colours and surface of the painting are firm and good, it may be simply painted over with a soft broad brush with such solutions as we have named. A simpler liquid preparation may even be used, of which paraffine and mineral turpentine are the sole constituents.

In now turning our attention to mosaic and tessellated work, we would first notice an erroneous idea which seems to prevail widely on the subject of the permanence of works executed in this manner. In wall and floor mosaics materials of very different degrees of texture and stability were and are employed as tesseræ—the little cubes or angular masses which constitute the materials at the disposal of the mosaicist. These coloured substances are either natural stones and marbles, or preparations of burnt clay or terra-cotta, or true porcelain, or else glass and enamel. While some of the natural stones and marbles of the most compact and insoluble kinds are but little influenced by damp and air, other sorts of an absorbent or mixed nature are very liable to disintegration and decay from frost and adverse atmospheric agencies. The older pottery tesseræ are not usually satisfactory, owing to their porous texture and the comparative ease with which they relapse into a soft mass not unlike the original clay from which they were made. The more modern tesseræ are of a much improved nature, especially those manufactured from nearly dry clay intensely compressed before burning. But the tesseræ of the hard porcelain, containing neither bone-ash on the one hand, nor excess of alkali on the other, leave nothing to desire in point of hardness and permanence, while they may be stained throughout their substance or near their surfaces only by those metallic oxides which are employed in glass and porcelain painting. Of the glass and enamel tesseræ a less satisfactory report must be given. The materials of which they are composed are generally remarkable for the quantity of alkaline and lead compounds which they contain. The carbon dioxide (carbonic acid) of the atmosphere acts upon these substances, in the course of time producing either a flaking off of the material itself, or else an incrustation upon its surface. No better illustration of this fact can be given than that afforded by the beautiful ruby glass which was occasionally employed in the Roman tessellated pavements found in this country. The tesseræ made of this glass are covered with a crust of green carbonate of copper and white carbonate of lead arising from the action just named. Thus the colour they now show is scarcely that which they were used to represent by the original artists. In the well-known and beautiful pavement at Corinium (Cirencester), the red poppies in the hair of Flora, and the blood dropping from the wounds of Actæon are of a malachite green. The very iridescence which often renders ancient glass so exquisitely beautiful is of itself no doubtful sign of decay. Film after film of the glassy surface becomes minutely streaked and pitted by the gradual removal of the alkaline bases of the vitreous material, until at last the whole substance of a vase, perhaps a quarter of an inch thick in parts, crumbles under the fingers to a mass of rainbow-tinted films. Enamels are no better than glass in this respect, often containing as they do still larger proportions of those constituents which aid in the process of decay. The oxide of tin which is introduced into them to confer opacity, exerts little or no favourable influence on their preservation, though in itself unalterable. We fear that we shall soon have evidence—in the fate of some mosaics recently executed in this country, and placed in positions where they are exposed to the weather—of the changes to which the apparently lasting materials of such works are really liable; and we must mention another matter in relation to mosaic work which hardly seems to have attracted attention. What guarantee have we of the permanence and continued binding power of the cement with which each tessera is held in its place? Without entering into details about such cements, which would indeed involve us in too long a digression, it may suffice to remark that the pure slaked but still caustic cream of lime which the Romans used for this purpose generally remains perfectly hard and firm after the lapse of 1,600 or 1,700 years. And it is reasonable to anticipate that if a hard and insoluble cement be once secured, it would be an admirable plan to saturate it when dry with a small quantity of pure and unalterable white paraffine, which might readily be driven by the aid of heat into the surface of the finished mosaic picture. A similar plan has sufficed in the hands of the author to restore to brilliancy, to waterproof, and to preserve from further change some fragments of Roman tessellated pavements which were rapidly falling to pieces.

The saturation of marble, especially of white statuary marble, with purified beeswax is an ancient practice which has been revived in modern times with some measure of success. But the bas-reliefs of the Wellington arch by Apsley House, which were thus treated under the direction of Faraday, and with every care, such as previous drying and warming, have not been able to resist very long the corrosive influence of a London atmosphere charged highly with the acid products of the combustion of coal. There can be no doubt that solid paraffine similarly used for the saturation of the marble would have exercised a much more lasting, if not a completely permanent effect. We have said enough in preceding lessons as to the selection and solution of the paraffine to be employed for such purposes as the present. Here, however, it may be convenient to note that it may be applied to stone not only in solution, but also in the state of fine powder laid on with a little water as a kind of paste, then allowed to dry, and finally driven in by the

aid of heat. If it be desired to tint the marble, this may be done by previously incorporating the necessary pigment with the paraffine employed. This process is applicable not only to statuary marble, but to stone, wood, and many other materials. In the case of a font of alabaster which was gradually being dissolved away and corroded by the solvent action of the water in it, this fatal action was arrested by saturating the interior of the bowl with a fine coat of paraffine by means of heat. For decayed stonework and marble in ancient buildings the paraffine process forms perhaps a more complete and safe preservative than any of those numerous and varied aqueous solutions which have from time to time attracted public notice. It is also peculiarly adapted to the preservation of metallic surfaces from rust and corrosion; and in the case of iron objects of early date it has been used with great success by the author for many years past to preserve them without further alteration or disruption. For this purpose it is best to dry and warm the objects to be coated; they are then to be suspended in pure melted paraffine at a temperature of about 120° Centigrade, till all bubbles of vapour have ceased to be given off. The objects when lifted out and allowed to drain and harden will no longer admit of corrosion, while the scales or fragments of which they consist will be cemented together.

In default of any perfect process of waterproofing and hardening brick, terra-cotta, and stone, we may direct attention, though in a very brief manner, to that one method of which the writer of these papers has had most experience, and which indeed he gradually elaborated by experimental trials on public buildings. This process consists in the successive application of three solutions to the material to be waterproofed and hardened. Solution No. 1 is one of pure hydrate of baryta; No. 2 contains monocalcic phosphate, or soluble phosphate of lime; and No. 3 is a double water-glass mixed with some quantity of a dialysed solution of pure silica. Solutions 1 and 2 are applied alternately many times until no more can be absorbed; then, after a lapse of a day or so, one or two coats of No. 3 are given. The great feature of this process lies in the entire absence of any soluble salt. No such compound is formed in consequence of the changes which go on between the solutions themselves or between the solutions and the stone, etc. The surface of the stone is rendered smooth and slightly translucent in appearance, but is not discoloured, except it be of dark tint originally. In such a case, and where brick has to be treated, some suitable pigment, any of those which may be employed in stereochromy, should be mixed with the last coat of No. 3 solution just before it is laid on. Not only have brick walls and chimney stacks in the neighbourhood of the sea been rendered waterproof by this process, but it has been employed in the interior stonework of public buildings for the purpose, on the one hand, of preventing the soiling of stone by grease, soot, and clothes, and, on the other hand, for preventing the stone itself from being abraded by friction, and coming off in powder upon objects which may touch its surface. The drawback of the process is the tedious series of applications of three liquids which it involves. Neither water-glass, nor hydrofluosilicic acid, nor phosphoric acid, nor any of the other preparations which have been used or suggested for the purposes of preserving stone, actually fulfil the necessary conditions of success, as they are either ineffective, or else injure and disfigure the surfaces to which they are applied. A great desideratum would be supplied if a hardening, preserving, and waterproofing preparation could be obtained, which in one operation, or at all events by its use in the form of a single fluid only, could be readily applied to our stone and brick buildings. It must not discolour them, nor must it be of the nature of a paint. A solution of this kind is necessary in some places and under certain conditions, not only for stone, but also for terra-cotta. It is a mistake to suppose that this substance is practically impenetrable even when made of a satisfactory clay, well burnt, and with the kiln-face left untouched. Saline efflorescences and frost may exert upon it, as upon all materials not destitute of porosity, the most injurious disruptive influence. Under such circumstances it is of little use coating the surface with a repellant and waterproofing material; the sides and back of each block must be similarly treated before they are placed in position, that the entrance of the injurious liquids, etc., from behind may be effectually prevented. For the same reason the proper treatment of damp walls is seldom hit upon. And here another difficulty presents itself: the ashes used in the preparation of the plaster and mortar of such walls, instead of being clean and fresh, have often been used previously as absorbents of various decaying matters of animal and vegetable origin, and have become charged with the nitrates and sulphates which occur amongst the decomposition products of such matters. Where such ashes have been used in plaster, the task of rendering the wall sound and free from efflorescence is almost hopeless. Coating it with a water-glass cement after a thorough cleansing with warm rain-water has been attended in some cases with fair success.

Though there is no doubt that in many directions, not noticed in these papers, chemistry has rendered service to the fine arts, or is capable of doing so, yet we trust that the facts and suggestions which we have laid before our readers, even if incomplete, will yet aid those who work with the beauties of form and colour. It is certain that science and art will each benefit by a legitimate union.

SHIP-BUILDING.—XI.

BY W. H. WHITE,

Fellow of the Royal School of Naval Architecture, and Member of the Institution of Naval Architects.

THE SKINS OF WOOD AND COMPOSITE SHIPS (*continued*).

In the preceding paper the disposition and fastenings of a wood skin, formed of one thickness of plank, were described at length, that being the common plan: we will now proceed to notice an arrangement where the skin is made up of three thicknesses of plank, as shown in Fig. 31. The planks in the two inside thicknesses, B, C, will be seen to be placed diagonally and to cross each other at right angles, whilst the outside layer, A, is worked longitudinally. With a skin so formed there is obviously no want of resisting power against strains tending to cause longitudinal sliding or shearing, such as exists in the skin of an ordinary wood ship. In fact, we have here a wood skin capable of transmitting and resisting strains in all directions, and requiring much less stiffening and framing than an ordinary skin. The system of construction is commonly known as the "diagonal" or "bread-and-butter" system. It has been used in many cases where the chief object has been to combine lightness with strength to an exceptional extent. The royal yacht *Victoria and Albert* and several of the light swift vessels of the Royal Navy have been constructed on this plan, as have also many merchant vessels, and it has given great satisfaction after full trial.

The framing in vessels built on the diagonal system is much lighter than that of ordinary ships. The middle-line arrangements are in some cases very similar to those previously described, but there are generally no timbers standing upon the floors, so that the spacing of the frames above the floor-head is much greater than in the usual plan. In other cases the frame is still further lightened, and iron braces are used to strengthen the skin. The work of building is no doubt made more difficult by adopting the diagonal arrangement, and this fact probably accounts for the comparatively limited use made of it. A skin so formed also requires great care in its fitting and fastenings. When the first layer of diagonal planking has been worked, it has to be secured to the timbers by a few fastenings, and lightly caulked before the second layer can be brought on; and this in its turn has to be secured to the timbers as well as to the inner layer, and caulked before the longitudinal planking can be fitted. All three thicknesses are ultimately bound together by through-bolts clenched inside and outside, and are secured to the timbers by metal screws, dumps, or through-bolts. But when properly fitted and fastened the united layers form a thoroughly efficient skin, and with comparatively little weight give great strength of hull.

Large boats for the Government service are commonly built upon a plan slightly differing from that illustrated in Fig. 31. Their skins are formed of two thicknesses of planking, wrought diagonally just as B and C are in the diagram. Their only framing consists of light floors stretching out to the bilge, and yet so great is the strength of the skin that they are found capable of bearing rough usage and carrying very heavy weights, without any sensible change of form or other serious damage. It should be added that in building these boats the planking is wrought upon a light framework of suitable form, capable of being removed with ease when the work is sufficiently advanced.

A few light river steamers have been built with one thickness of planking, the strakes of which were worked longitudinally as on the ordinary plan, and connected together by numerous edge-bolts. Frames were almost entirely dispensed with, strong diagonal iron riders and straps being employed to strengthen the skin. This plan is said to have answered fairly in the vessels so built, but it scarcely appears capable of successful application in sea-going vessels, which are necessarily subjected to much more severe strains than those river steamers have to bear.

Considerable importance attaches to the *caulking* of the skins of wood ships, and a few words respecting it will not be out of place. The operation consists simply in driving threads of oakum, the number of which varies with the thickness of the planking, into the spaces between the edges and butts of adjacent planks. These spaces or "seams" should be so formed as to taper gradually toward the inner surfaces of the planks, where the adjacent edges should touch each other; and when the oakum is driven in the seams should be compactly filled and made water-tight. The latter object is partly attained by "paying" over the seams with pitch after the oakum is in place. Pieces of plank are sometimes cut out at different parts of the bottom of a ship in order to test the efficiency of the caulking. However tightly the oakum may have been driven at first, it will probably become slack after a vessel has been a few years at work, this slackness being due in part to shrinkage in the planking, and in part to the unavoidable working of the vessel when at sea. One of the most common features in the refit of wood ships is consequently the re-caulking of their bottoms, which renders them not only tighter, but also stronger.

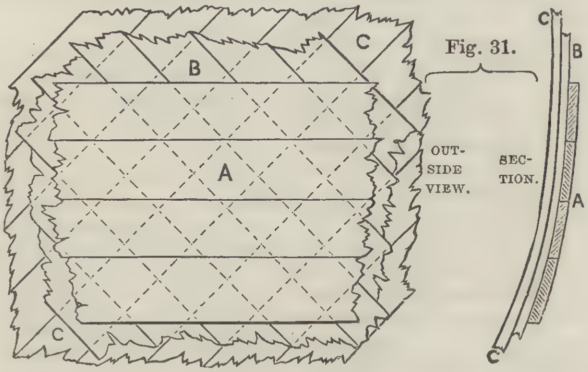

Fig. 31.

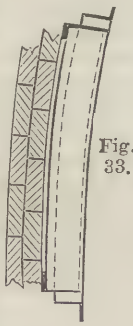

Fig. 33.

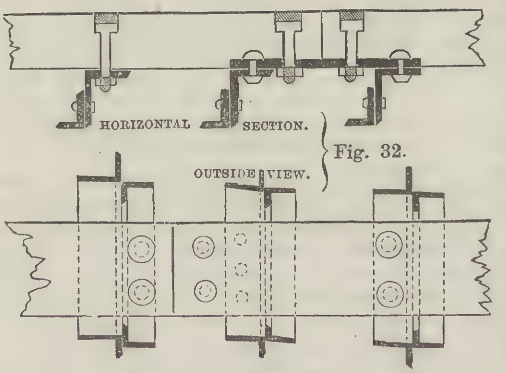

Fig. 32.

Turning next to the skins of composite ships, it will be proper to take first the most common arrangement where the planking is in one thickness. So far as the general disposition and the shift of butts is concerned, there is no difference between this plan and that illustrated by Fig. 27, page 256. Three passing strakes occur between consecutive butts, and "steps" are carefully avoided. Instead of being placed *upon* the frames, however, the butts are placed *between*, and usually secured as shown in Fig. 32, a plate of iron, termed a "butt-plate," being riveted to the adjacent frames in order to support the butt and receive its fastenings. This plate is of the same breadth as the planks it helps to connect. Each butt-end is secured by two bolts, with nuts hove up, inside the butt-plate, on screw-threads cut for that purpose. The heads of these bolts are formed as shown to give good holding power, and are sunk into the planking, so that they may be covered with wood plugs. Great care should be taken in driving the bolts and fitting the plugs in order to make the bottom tight. The sketch shows also how the planking is secured to the frame angle-irons, by means of nut-and-screw bolts similar to those at the butt, the nuts being hove up inside the flange of the angle-iron. Double fastening is shown in this case, and it is that suggested by Lloyd's Committee for planks more than 10 inches broad; double and single fastening alternately would be allowed in planks from $8\frac{1}{2}$ inches to 10 inches broad, and single fastening in planks under $8\frac{1}{2}$ inches in breadth. In all cases, however, double-butt fastenings like those in Fig. 32 are required; and it will be clear that this method of securing the butts gives greater strength against tensile strains than that usual in wood ships. The butt-plate, in fact, straps or "fishes" the butt in a far better way than the frame-timber of a wood ship; and the butt-bolts are better arranged in the composite skin. But even with this improved connection it cannot be expected that a butted-strake, such as is shown in Fig. 32, can be thoroughly efficient against severe tensile strains, the ultimate effect of which would undoubtedly be to open the butt by tearing away the short-grained wood left between the bolts and the butt. It should be added that in some few composite vessels butt-plates have not been used, but plain scarfs employed instead of butts, in order to make a good connection.

Composite ships with one thickness of planking obviously require to be strengthened by diagonal ties on the frames, just as wood ships require diagonal riders. The usual plan is to have two sets of diagonal tie-plates riveted upon the outside of the frames, and crossing each other at right angles. The upper ends of these tie-plates are connected with a strake of plating, named the "sheer-strake," fitted in wake of the upper deck beams, and their lower ends are secured to a strake of plating worked near the bilge at the height where the floor-plates end. By this means the skin is much aided in resisting longitudinal sliding or shearing, against which the caulking, when tight, is also a great help.

The composite system was devised in order to combine greater strength than wood ships possess, with an equal freedom from foulness of bottom, and for the latter purpose metal sheathing, usually of copper or Muntz metal, is nailed to the planking up to a few feet above the load water-line. It has already been remarked that the great danger incurred by this plan is the setting up of galvanic action between the metal sheathing and the iron portions of the hull, which action necessarily leads to the more or less rapid deterioration of the iron. Experience proves that even with the greatest precautions it is difficult to avoid metallic connection between the sheathing and the iron portions of the hull, especially when only one thickness of planking is used; and in cases where less care is taken the damage to the iron is often both serious and rapid. For example, it is very common to use iron bolts in fastening the planking, their surfaces being often "galvanised" or coated with zinc to protect them from rust, and their heads let into the planks and covered by plugs, as shown in Fig. 32; and in such cases the wasting of the bolts to a very serious extent is not at all unusual after a short period of service. Copper or metal bolts are sometimes used instead of iron, and are, on the whole, much to be preferred; but they are not free from disadvantage, because, as usually fitted, they form a direct metallic connection between the sheathing and the iron frames, and may cause damage to the latter; besides which they are much more expensive than iron. In fact, after full trial, many ship-builders have formed the opinion that it is necessary to employ two thicknesses of planking in the skins of composite ships with copper or metal sheathing, in order to prevent serious galvanic action and to secure proper durability. Others have advocated the disuse of such sheathing, and the substitution for it of zinc, urging that the bottoms would thus be kept clean, while no evil would result to the iron portions of the hull if galvanic action

were set up, the zinc sheathing then wasting instead of the iron, and being easily replaced. The balance of opinion appears at present to be in favour of the continued use of metal sheathing, and we will therefore glance at some of the arrangements adopted when the skin planking is worked in two thicknesses.

One of the most common plans is illustrated in Fig. 33; both thicknesses being worked longitudinally, and the seams of the planks in one layer being brought upon the centres of the planks in the other layer, the two sets thus mutually supplying the direct edge connection which is wanting in a wood skin worked in one thickness.

Another arrangement consists in working both layers of planking diagonally (like B and C in Fig. 31). Diagonal tie-plates are not fitted on the frames when this plan is followed, and they are obviously unnecessary, the skin being capable of acting alone in resisting longitudinal shearing strains.

Still another plan consists in working one layer (either the inner or outer) diagonally, and the other longitudinally; in most cases the outer planks are worked longitudinally. In all three plans both thicknesses of planking must be caulked, and between the two it is usual to fit felt, waterproof glue, or some similar material. The inner thickness is fastened to the frame angle-irons by iron nut-and-screw bolts; and the outer thickness is secured to the inner by short copper or metal bolts, either with nuts on the inner ends or clenched upon rings on the inside of the planking. The fastenings of the outer thickness are placed in the frame-spaces, clear of the frames and the fastenings of the inner thickness, so that the probability of any galvanic action being set up between the metal sheathing and the iron frames, etc., is much reduced. The cost of building a vessel with two thicknesses of planking is of course greater than that of building with one thickness; but there is reason to believe that the additional outlay is more than repaid by the increase in durability and efficiency.

It is usual to have the garboard strakes in one thickness, even when the greater portion of the skin is in two thicknesses; and it is by no means uncommon to terminate the double thickness at a moderate height above the load water-line of the vessel, the remainder of the upper works being covered with one thickness of planking. The latter practice has no such attendant disadvantages as the use of a single thickness under water entails, and it lessens the cost of construction. In some cases this topside planking is replaced by iron plating down to six or eight feet from the load line, but this is not a common plan, nor does it seem on the whole preferable to the other.

Some eminent authorities have expressed great doubts as to the efficiency of the skins of composite ships, and the general strength of their structure. As compared with the skins of iron ships, those of composite ships are undoubtedly inefficient against some classes of strains; but they compare favourably with those of wood ships, especially when wrought in two thicknesses. Severe and extended trials have, moreover, shown that composite ships are fully capable of resisting the strains brought upon them when at sea; and the fact that the far-famed China tea-ships which race home yearly under an enormous spread of canvas, continue to perform their duties satisfactorily without displaying signs of working or weakness, furnishes a very strong argument in favour of the sufficiency of the strength of composite ships. In short, their continued use or their disuse is likely to be settled rather by considerations of cost and durability than by those of structural strength.

The arrangements of the inside planking or ceiling of composite ships are identical in character with those of ordinary iron ships, and it will consequently be preferable to defer any remarks on that subject to a later paper.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXVI.—DAVID MUSHET.

BY JAMES GRANT.

Though the existence of ironstone in the Scottish coal measures was known for many years before the year 1760, when, as we have related in the memoir of Dr. Roebuck, the Carron works were established, no attempt was made, until then, to turn it to account. Only one kind of ironstone was then used, viz., the argillaceous, or "clay-band;" for the more valuable and carbonaceous was unknown until the year 1801, when it was discovered by David Mushet, a native of the little town of Dalkeith, six miles from Edinburgh. He was born there in 1772, and though but the son of a labouring man, was descended from an old historical stock, the Mushets who resided in Kincardine, on the estates of the Montrose family. In the time of Charles II., all these Mushets, save two, perished of the plague, and one of these, the Rev. George Mushet, who accompanied the great Marquis of Montrose in nearly all his campaigns as chaplain, died early in life, and is buried in the churchyard of Kincardine; but the name can be traced far back in Scottish history, as they are descended from William de Montefixo, who held the lands of Uchreardore under Robert I., and others in the thanedom of Cluny under David II.

At the age of nineteen, David Mushet, who like most of his family had been brought up as a metal founder, obtained employment at the Clyde Iron Works, near Glasgow, as accountant of the company, which had then but two blast-furnaces at work. Though he had nothing to do with the mechanical operations of the firm, being of a thoughtful and speculative turn of mind, the remarkable conversions undergone by iron in the various processes of manufacture soon began to occupy his attention, and he joined in the occasional discussions of that subject held by the more intelligent of the young men employed about the works, and Fourcroy's book was frequently referred to by them with reference to certain questions of difference which arose among them in the course of their inquiries.

In 1793, when the establishment of the company was reduced, David Mushet finding that he was almost the only occupant of the office, resolved to commence a few experiments, and to acquire a perfect knowledge of assaying as the true key to the method of iron-making. "He first set up his crucible upon the bridge of the reverberatory furnace used for melting pig-iron," says Mr. Smiles, "and filled it with a mixture carefully compounded according to the formula of the books; but notwithstanding the shelter of a brick, placed before it to break the action of the flame, the crucible generally split in two, and not unfrequently melted and disappeared altogether. To obtain better results, if possible, he next had recourse to the ordinary smith's fire, carrying on his experiments in the evening after office hours. He set his crucible upon the fire on a piece of fire-brick, opposite the nozzle of the bellows, covering the whole with coke, and then exciting the flame by blowing. This mode of operating produced somewhat better results; but still neither the iron nor the cinder obtained resembled the pig or scoriæ of the blast-furnace, which it was his ambition to imitate. From the irregularity of the results, and the frequent failure of the crucibles, he came to the conclusion that either his furnace or his mode of fluxing was in fault, and he looked about him for a more convenient mode of pursuing his experiments. A small square furnace had been erected in the works for the purpose of heating the rivets and for the repair of the steam-engine boilers. The furnace had for its chimney a cast-iron pipe of 6 or 7 inches in diameter, and 9 feet long. After a few trials with it, he raised the heat to such an extent that the lower end of the pipe was *melted off*, without producing any very satisfactory results on the crucible, and his operations were again brought to a stand-still."

For two years Mushet continued to make experiments in the art of assaying, and during that time he wrought entirely in the method detailed by past experimentists in their books; but certain that all his results were somewhat negative, he cast books aside, and resolved to work upon a system of his own, the result of which, he was assured, would be similar to those produced by the blow-furnace. All these repeated attempts had to be made in the night, as all the hours of the day were fully occupied by quill-work in the company's office; but he eventually succeeded, and he became acknowledged as a well-skilled assayer in iron, and whenever a difficulty occurred in the smelting of any new ironstone, "the manager himself resorted to the book-keeper for advice and information; and the skill and experience he had gathered during his nightly labours enabled him readily and satisfactorily to solve the difficulty, and suggest a suitable remedy."

He was now permitted by the company to have an assay-furnace of his own, at which he continued to make his experiments, while at the same time he instructed the son of the

manager in the art of assaying, devoting, at times, entire nights to experiments in assaying, in roasting and cementing iron ores and iron stones, decarbonating cast iron for steel and bar iron; working thus till three a.m., and leaving instructions with the engine-man to call him at half-past five, so that he might be at his desk by six!

In the midst of his arduous career of investigation, as he tells us in his "Papers on Iron and Steel," published in London in 1840, without any cause or motive being assigned, but probably through some whim or caprice, he was ordered to stop; and, by direction of the manager, his furnaces were demolished, with an edict that they were not to be erected again! This ended all his hopes of research at the Clyde Iron Works. However, he erected, with the consent of a friend, an assay and cementing furnace, on a piece of ground two miles distant from these works, and thither the unwearying Mushet was wont to repair in the night, and during the hours allotted by others to their meals, for a whole summer; but the labour proved too great, and the results too uncertain to be continued longer. At the close of 1798 he quitted the Clyde Works, and constructed several furnaces, and for two years continued his investigations in connection with the alloys of metals.

"Though operating in a retired manner, and holding little communication with others, my views and opinions," he relates, "upon the *rationale* of iron-making, spread over the establishment. I was considered forward in affecting to see and explain matters in a different way from others who were so much my seniors, and who were *content* to be satisfied with old methods of explanation, or with no explanation at all. . . . . Prejudices seldom outlive the generation to which they belong, when opposed to a more rational system of explanation. In this respect Time, as my Lord Bacon says, is the greatest of all innovators. In a similar manner *Time* operated in my favour in respect to the black band ironstone."

In the year 1801, when crossing a stream called the Calder, in Old Monkland, in the Middle Ward of Lanarkshire—a soil abounding in mineral treasures—Mushet picked up a specimen of this most valuable description of ore, which chanced to attract his eye as it lay in the bed of the river. He subjected it to his crucible, and on being fully satisfied as to its properties, he next proceeded to discover its geological position and relations, and finding that it belonged to the upper part of the coal formation, he designated it carboniferous ironstone; and he further discovered that rich beds of the mineral were in most of the western counties of Scotland. Analysis proved it to contain over 50 per cent. of protoxide of iron; while the coaly matter it contained was not its least valuable ingredient, as by the aid of the hot-blast it may be smelted without *any* addition of coal.

In the year of his discovery, Mushet was engaged in erecting for himself and his partners the Calder Iron Works, and great prejudice was excited against him by all the ironmasters at the time, for daring to class "the wild coals" of the country, as black band was called, with ironstone fit and proper for the blast-furnace. Yet that discovery enabled Scotland to take a high rank among the iron-working nations of Europe; and seams of the same coal have since then been discovered in North Wales and in Staffordshire.

From the establishment of the Carron Works in 1760 till 1788, the quantity of iron produced by Scotland did not exceed 1,500 tons per annum; but it has steadily risen since then, and the total quantity made in the year 1867 amounted to 1,031,000 tons; but ten years previous, the largest quantity of ore put out in one year was 2,500,000 tons. Now, thanks to the discovery of David Mushet, the west of Scotland, more particularly the district about Old Monkland, has made an unparalleled advance in population and prosperity. To this, of course, the introduction of the hot-blast and the increasing demand for iron for railway purposes have added. In that district which was once so pastoral and lonely, there is everywhere heard the brattling of machinery, the sonorous strike of mighty hammers, and the hissing and clanking of the steam-engine. Dense clouds of smoke roll over it incessantly; a coat of black dust lies over everything, and the flames of the blast-furnaces, for ever belching with wild and weird effect, but chiefly at night, have won for that district the somewhat appropriate title of "the Land of Fire."

"Fortunes have been realised there in the iron trade," says a statist, "with a rapidity equalled only by the sudden and princely gains of those who accompanied Pizarro to Peru. It is understood that the clear profits of a single establishment in this line during the year 1840 alone were £60,000; though less than twenty years previous the co-partners of this company were earning their bread by the sweat of their brow, in following the agricultural vocation of their fathers."

"Such," says Mushet himself, "are the consolatory effects of time, and the discoverer of 1801 is no longer considered the intrusive visionary of the laboratory, but the acknowledged benefactor of his country at large, and particularly of an extensive class of coal and mine proprietors and iron masters, who have derived, and are still deriving, great wealth from this important discovery, and who, in the spirit of grateful acknowledgment, have pronounced it worthy of a crown of gold, or a monumental record on the spot where the discovery was first made." But he adds elsewhere, with some bitterness of heart, "whilst the exploits of the conqueror and the intrigues of the selfish demagogue are faithfully preserved through a succession of ages, the persevering and unobtrusive efforts of genius, developing the best blessings of the Deity to man, are often consigned to oblivion!"

David Mushet, in addition to many papers in the *Philosophical Journal*, contributed largely to other scientific works. He wrote the article "Iron" for Macvey Napier's supplement to the Edinburgh edition of the *Encyclopædia Britannica*, and the articles "Blast Furnace" and "Blowing Machine" for Rees' *Cyclopædia*, both of which were frequently quoted in Parliament when, in 1807, it was proposed to levy a tax on iron.

Mushet discovered a mode for the preparation of bar-iron by a direct process, combining iron with carbon; he discovered also the beneficial effects of oxide of manganese on iron and steel; the uses of oxide of iron in the puddling-furnace in various modes of appliance; the application of the hot-blast to anthracite coal in iron-smelting, and the production of pig-iron from the blast-furnace suitable for puddling without the intervention of the refinery.

In 1800 he patented his process for combining iron with carbon for the production of steel; and afterwards, when he discovered the beneficial effects of oxide of manganese on steel, "Mr. Josiah Heath founded upon it his celebrated patent for making cast steel, which had the effect of raising the annual production of that metal in Sheffield alone from 3,000 to 100,000 tons. His application of the hot-blast to anthracite coal, after a process invented by him and adopted by the Messrs. Hill, of the Plymouth Iron Works, South Wales, had the effect of producing savings equal to £20,000 a year at those works; and yet," says Smiles, "strange to say, Mr. Mushet himself never received any consideration for his invention."

While David Mushet lived he was a leading authority on all matters connected with steel and iron, and he closed a laborious and useful life in 1847, at the age of seventy-five years.

PRINCIPLES OF DESIGN.—XXIX.

BY CHRISTOPHER DRESSER, PH.D., F.L.S., ETC.

HARDWARE (*continued*).

In ironwork the manifestation of a true constructive principle is beyond all things desirable. Iron, being a strong material, should not be formed into heavy masses unless immense weight has to be sustained or very great strength is required. If we form lamps, candelabra, and such works of iron, it is obvious that the portions of metal employed in their construction may be thin, as the material is of great strength. Were we to form such works of wood, then a greatly increased thickness of material would be necessary, in order that the same strength be secured, as wood is not nearly so strong as iron.

My remarks will have special reference to wrought iron, as cast iron cannot so fully be said to have a constructive character. A small railing (Fig. 133), which we engraved in our last article (page 217), is an admirable illustration of a true constructive formation, as the parts are all held together, and strengthened to a wonderful degree, by the introduction of a horseshoe-shaped member. This railing is worthy of the most careful study, for its strength is great. Besides strength we have also beauty. The horseshoe form, especially when judiciously applied, is far from being offensive. Utility must come

first, and then beauty, and so it does in this particular railing, but here we have great simplicity, and a correct structural character has been arrived at in its production rather than any elaboration of the principles of beauty.

From the catalogue of J. W. Dovey, of John Dalton Street, Manchester, I select an illustration of structure in the form of a candelabrum which is highly satisfactory in character as a simple work (Fig. 138). There is a solidly-formed heavy base, an upright stem terminating in a candle-holder. There is an arrangement for catching waste grease, and extra strength is given to the stem by four slender buttress-like brackets, which are securely and well attached to the base below and to the stem above; and these are strengthened by two hoops, which prevent their bending under pressure.

Figs. 139 and 140, the former being a ridge or wall cresting, and the latter a stair railing, are each illustrations of a correct treatment, inasmuch as strength (a structural quality) and beauty (an art quality) are secured at the same time. Fig. 139, it may be noticed, is admirably constructed, only it is a little slender above the middle horizontal line. These two illustrations are also from Mr. Dovey's excellent catalogue.

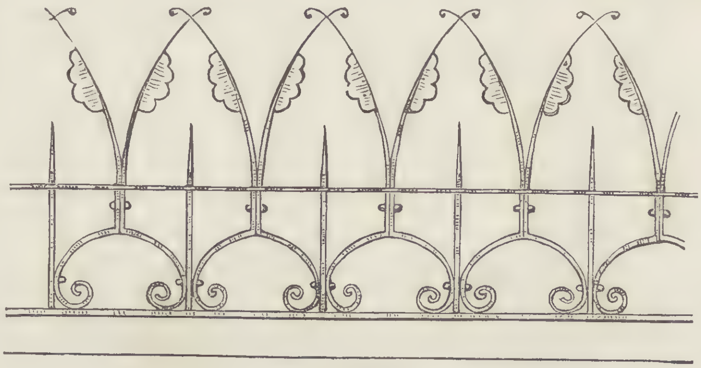

Fig. 139.

In the catalogue just named, and in those named in my last article also, many good examples may be found illustrative of the successful combination of true structural qualities with a considerable amount of beauty, and also acknowledging the strength of the material by the lightness of the parts.

Those who reside in or visit London, will do well to go to the South Kensington Museum, and study a large and splendid candelabrum of Messrs. Hart, Son, and Peard, which is well worthy of consideration. It is rather heavy, and is of enormous strength,

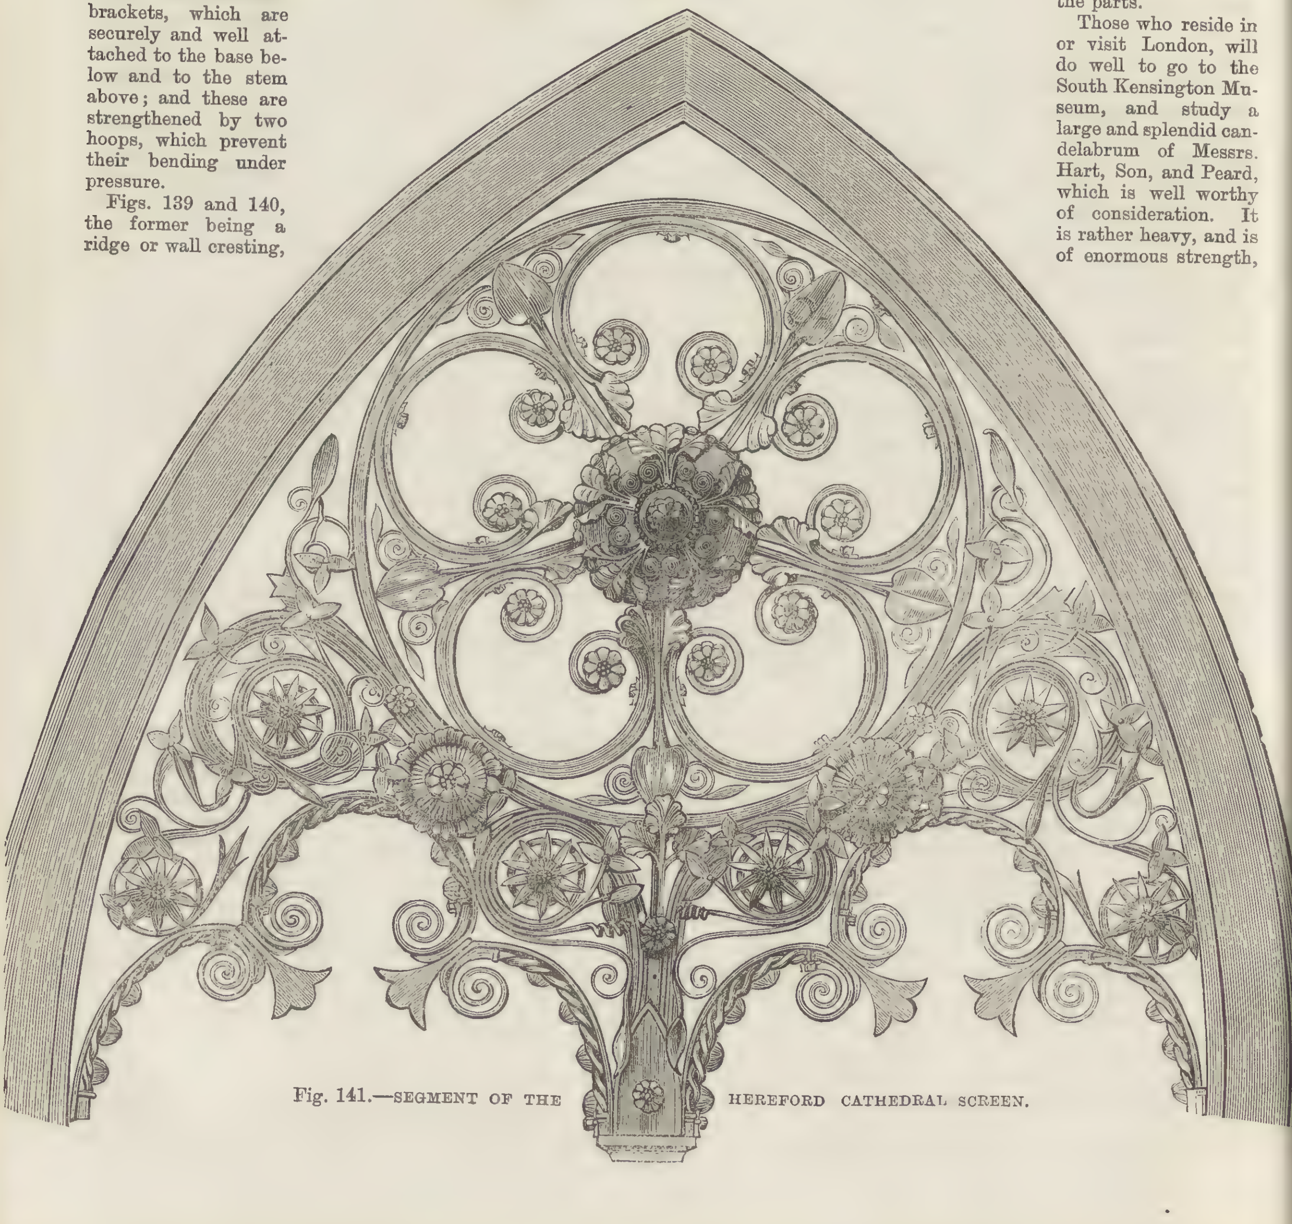

Fig. 141.—SEGMENT OF THE HEREFORD CATHEDRAL SCREEN.

but in most other respects it is highly commendable. It is beautiful, well proportioned, and illustrative of a correct treatment of metal. Besides this, it exemplifies the manner in which stones or jewels may be applied to works in hardware with advantage. As a further illustration of a correct and very beautiful treatment of metal we give one segment of the Hereford Cathedral Screen (Fig. 141), the work of that most intelligent of metal-workers, Mr. Skidmore of Coventry. This screen was shown in the International Exhibition of 1862, in London, and was from there removed to its place in the cathedral. All who can will do well to view this beautiful work, which is one of the finest examples of artistic metal-work with which we are acquainted. Notice the ease with which iron may be treated if a correct mode of working be employed. Let a bar of iron be taken which is about half an inch thick, by 1¼ broad. This can be rolled into a volute (the filigree mode of treatment), or its end can be hammered out into stems and leaves, and to it can be attached other leaves by rivets, screws, or ties, or it can be bent into any structural form. To the student I say, study the shapes into which simple bars of iron can be beaten, both mentally, and by observing well-formed works.

Brass, copper, and other metals may be associated with iron in the formation of any works. If well managed, brass and other bright metals may act as gems—that is, they may give bright spots; but where the bright metals are used with this view, care must be exercised in order that the bright spots be formed by beautiful parts, and that their distribution be just, for that which is bright will attract first attention.

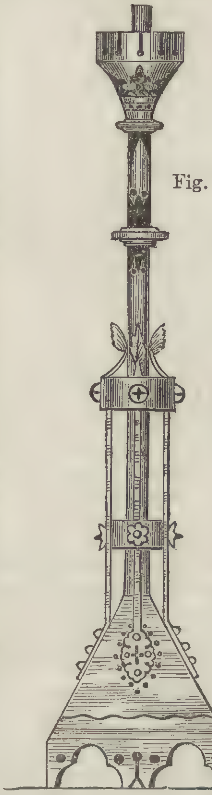

Fig. 138.

Fig. 140.

Before leaving this part of our subject, I must call attention to a hinge by Hardman, of Birmingham, which was shown in the International Exhibition of 1862, as it is both quaint and beautiful (Fig. 142). The door to which this hinge was applied opened twice; the first half opened and folded back on the second half, and then the two halves opened as one door, as will be seen from our illustration. It is very desirable that we have a little novelty of arrangement in our works. We are too apt to repeat ourselves, hence it is a sort of relief to meet with a new idea.

It is impossible that I take up each article of hardware and consider it separately. All I can do is to point out principles, and leave the learner to consider and apply them for himself—a principle which, once understood, may result in the construction of many excellent works, and may lead to the formation of a correct judgment respecting such objects as may be brought forward for criticism. I will, however, just call attention to gas-branches, as they are often wrongly constructed. A gas-branch is a duct through which gas is to be conveyed. It must be strong if it is to be exposed to pressure, or if it runs the chance of coming in collision with the person, as do standard lights in public buildings. The main part of a gas-branch is the tube or pipe which is to convey the gas, but this may be supported in many ways, as by such buttress-like brackets as in the candelabrum shown in Fig. 138; and if there are branch tubes for several lights, these may well be connected with the central tube, not only by their own attachment, but by brackets of some sort, or with one another by some connecting parts. Whether the gas-branch be pendent or standard, this mode of strengthen-

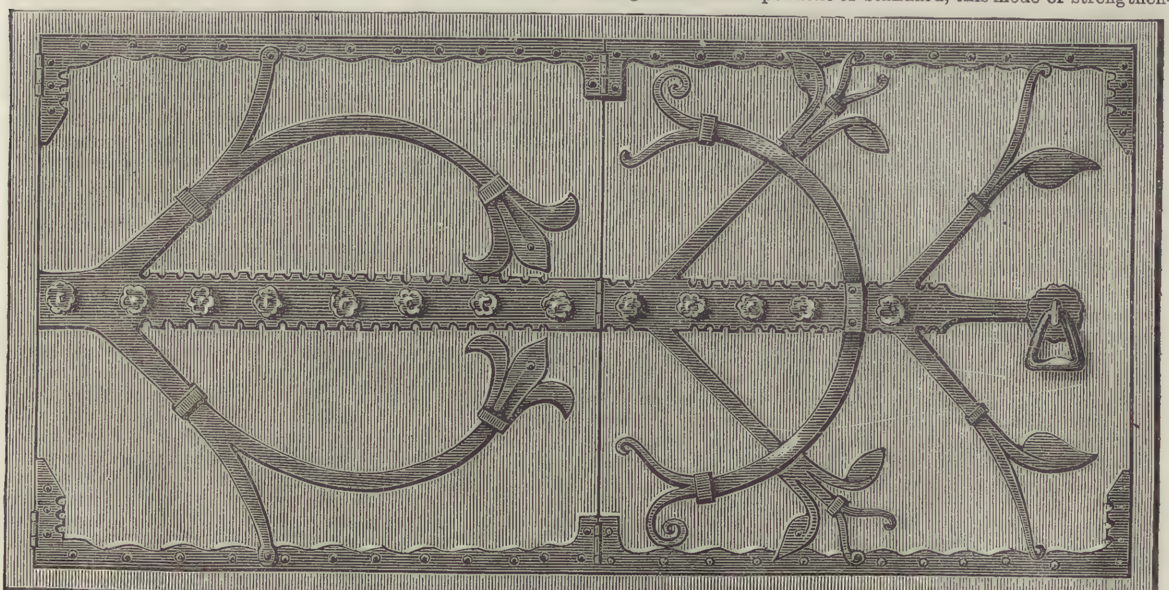

Fig. 142.

ing the tube-work should be employed, for the tubes themselves are but slightly held together, and by pressure being brought to bear upon them, a dangerous and expensive escape of gas may result.

In the manufacture of gaseliers one or two Birmingham houses have certainly distinguished themselves by the production of works both beautiful and true; and these lead me to think that a better day is dawning for Birmingham, in which its art shall be exalted rather than degraded, and shall be such as will win to it the esteem of the world rather than call forth the execrations of art-loving people.

As to the colouring of iron I can say little. In my judgment the best modes of colouring metals were originated by Mr. Skidmore of Coventry, of whom I have before spoken. His theory is this, that metals are best coloured by the tints of their oxides. When a metal, especially brass, is seen in a furnace in a molten condition, the flames, where the oxygen of the atmosphere is uniting with the vapour of the metal, present the most resplendent tints. The same thing in a lesser degree occurs in the case of iron, but here the colours are less brilliant, and are more tertiary in character. Mr. Skidmore applies to a metal the colours seen in the flames of the furnace where it melts. Without attempting to limit the colourist to any theory whereby his ideas might be restricted, I must say that Skidmore's colouring of the metals is very good.

SEATS OF INDUSTRY.—XXV.

NEWCASTLE-UPON-TYNE.

BY WILLIAM WATT WEBSTER.

The importance of coal as an agent in modern domestic, manufacturing, and commercial economy can hardly be exaggerated, and no country in the world has reaped so much benefit from its possession and use as Great Britain. It is to the richness of our coal-fields, and to the industry and skill with which they have been worked, that we owe in a great measure our manufacturing and commercial prominence among the nations. "We are living," as Robert Stephenson once said, "in an age when the pent-up rays of that sun which shone upon the great carboniferous forests of past ages are being liberated to set in motion our mills and factories, to carry us with great rapidity over the earth's surface, and to propel our fleets, regardless of wind and tide, with unerring regularity over the ocean." It is calculated that about 70,000,000 tons of coal are now annually raised in the United Kingdom, and the coal-mines of Durham and Northumberland produce about one-third of this total. Newcastle-upon-Tyne is the capital of Northumberland, and the port from which the coal excavated in that county, and in the neighbouring county of Durham, is exported to other parts of Great Britain and to foreign countries. It is the principal centre of the coal-trade in England, and to a great extent it is indebted for its prosperity to the convenience of its situation as a port of shipment for the coal found in the neighbouring districts.

The history of Newcastle stretches back to the time of the Roman occupation. It was one of the stations on the wall erected by the order of the Emperor Adrian, A.D. 120, to defend the Roman provinces from the incursions of the Caledonians, and which traversed the island from the Solway Firth to the Tyne, terminating at Wallsend, about three miles to the east of Newcastle. The place was named Pons Ælii by the Romans, from a bridge built over the river by the same emperor, and called by his family name. Round this bridge the first nucleus of Newcastle was formed. About the year 208 A.D., the Roman wall originally constructed by Adrian was rebuilt by Septimius Severus, after a repulse he suffered from the Caledonians. From the fact that cinders are frequently found among the remains of Roman stations in Northumberland, it would seem that the use of coal was not unknown to the Romans, although the abundance of timber probably restricted its use to neighbourhoods where it was obtained at or near the surface. After the departure of the Romans from the island, the Anglo-Saxons expelled the Britons from this part of the country, and founded the kingdom of Bernicia. In the immediate vicinity of Pons Ælii the Saxon kings had an occasional residence, called *Ad Muram*, and after the conversion of the Saxons to Christianity the deserted Roman camp was occupied by a colony of monks, from whom it derived the name *Moncaster*, or *Monkchester*. At that period it was the resort of numerous pilgrims, who came to the holy well of Jesus Mount, now Jesmond, about one mile to the north-east. Owing to the incursions of the Danes, the monks were compelled to abandon the place, and it fell into the possession of the Scots.

No satisfactory evidence that coal was either an article of commerce or of domestic use during the Saxon period has been discovered. Shortly after the conquest of England by William of Normandy, the Scots were driven from their settlement on the Tyne by Robert, the eldest son of the Conqueror, who in 1080, during the lifetime of his father, hastily built a castle there on his return from a hostile excursion into Scotland. At that time the town received the designation it now bears. This castle was rebuilt by William Rufus, who also surrounded the town with walls, and conferred peculiar privileges on its inhabitants. The benefits conferred on the town by William II. are commemorated in the following rude lines in Hardynge's "Chronicle:"—

> "He builded the New Castle upon Tyne,
> The Scottis to gainstand: and to defend
> And dwell therein the people to incline,
> The town to build and wall, as did append,
> He gave them ground, and gold full great to spend,
> To build it well and wall it all about;
> And franchised them to pay a free-rent out."

The present castle, however, which is the best example of Norman military architecture in England, was erected by Henry II., between the years 1172 and 1177. A charter is said to have been granted to the town by King John, but the earliest charter extant is that of Henry III., dated 1234, in which, "upon their supplication," the inhabitants are granted the privilege "to dig coals and stones in the common soil without the walls, and to convert them to their own profit, in aid of their free-farm rate of £100 per annum." In the reign of Edward I. Newcastle was captured and burned by the Scots, it having been used by that monarch, and by his successors Edward II. and Edward III., as a rendezvous for the great armies with which they attempted to conquer Scotland. Portions of the walls constructed after this disaster still remain. During the reign of the last-mentioned king, Newcastle successfully resisted an attack made on it by the Scots under David Bruce, and in 1299 the walls on the eastern side were rebuilt. At this early period Newcastle was one of the most important commercial ports in the kingdom, and was noted as a nursery for seamen, and as a resort for merchants and tradesmen of all classes.

The introduction of sea-coal as household fuel encountered an intense and prolonged opposition. It was believed that the smoke from coal was injurious to health, and so strong was this prejudice, that in the reign of the first Edward a man was hanged for having burned it within the walls of London. In accordance with a petition presented to Parliament, the king issued a proclamation, in 1316, prohibiting its use in the metropolis, and as this did not prove effectual, recourse was had to severer measures. Fines were imposed on a first conviction for burning coal, and the penalty for a second offence involved the destruction of the furnaces, etc. But coal would seem to have made gradual progress in spite of all that could be done to suppress its use. In his "Agriculture and Prices in England," Mr. Roger says:—"The appearance at so distant a place as Dover, in 1279, the earliest entry that has come under my observation, suggests that the coasting traffic in this article must have been familiar. It was purchased for the use of the castle, and must, of course, have been burned in a fireplace with chimney. It may be added that among the various traders given in the taxing-bill of Colchester, 'Rot. Parl.,' vol. i., sea-coal dealers are mentioned at the close of the thirteenth century." In 1280 Newcastle had a considerable trade in coal, and soon afterwards it was introduced into London, although at first it was burned only by smiths, brewers, soap-boilers, dyers, etc. The exportation of coal from Newcastle to foreign countries is believed to have commenced about the year 1325. In 1346 the port supplied, on the requisition of Edward III., 17 ships and 314 mariners for the siege of Calais, a larger force than was furnished by any port north of the Thames,

Yarmouth alone excepted. Eleven years later this monarch granted to the inhabitants of Newcastle the entire possession of the Castle Moor and the Castle Field adjoining, "for the purposes of there digging of coals, stone, and slate." Towards the close of the fourteenth, and during the earlier years of the fifteenth centuries, there flourished in Newcastle one of the most eminent merchants of his time, Roger Thornton, "the richest merchant that ever was dwelling in Newcastle," who was three times mayor, and three times member of Parliament, and did much to develop the trade and further the interests of the town. It prospered and increased steadily all through the fifteenth century, and under the Tudors in the sixteenth century the chief trade of the town consisted in the exportation to the Continent of "canvas, sheepskins, lambsfelts, lead, grindstones, coals, and rough-tanned leather." The manufacture of glass was first introduced into England in the reign of Queen Elizabeth, by a body of immigrants from Germany, who established themselves in the neighbourhood of Newcastle.

In the reign of Charles I. Newcastle suffered two severe afflictions. It was visited by the plague in 1636, which carried off 5,000 of the inhabitants; and in 1640 it was surprised and captured by the Scottish army under General Leslie. During this king's reign the use of coal became universal in London. Newcastle espoused the cause of Charles I. against the Commonwealth, and was garrisoned by the Royalists during the Civil War; but at a late period it again fell, after a prolonged siege, into the hands of the Scotch, then in alliance with the Parliament. The author of "Chorographia; or, a Survey of Newcastle-upon-Tyne," writing in the time of the Commonwealth, says:—"Many thousands are engaged in this trade of coals; many live by working of them in pits, and many live by conveying them in wagons and wains to the river Tyne." Some idea of the magnitude of the Newcastle coal-trade at the beginning of the eighteenth century may be formed from the report made by the Master of the Newcastle Trinity House to Parliament, which states that 600 ships, each carrying 80 Newcastle chaldrons of coal, and navigated by a total of 4,500 men and boys, were required for the supply of other ports with that article.

The progress of the coal-trade, and with it the prosperity of Newcastle, were for a long period impeded by the creation of monopolies, and the imposition of oppressive regulations and exactions. From a very early period the Corporation of London had undertaken the task of weighing and measuring the coal brought to the metropolis, and had charged eightpence per ton for their trouble. The power to make this charge was confirmed to the City by charter in 1613. In the reign of Charles I., two monopolies, still more directly affecting the interests of Newcastle, were granted. Sir Thomas Temple and his partners were, in 1637, assigned the exclusive right of selling all the coal exported from Newcastle for twenty years from that date; and in the following year a company of monopolists was empowered to buy all the coal produce of Newcastle, Sunderland, and Berwick, and to sell it in London for any price not exceeding the very high rate of seventeen shillings per chaldron in summer, and nineteen shillings in winter, one shilling per chaldron being the king's share of the profits. These monopolies, along with hundreds of others equally grievous, were abolished by the Long Parliament. Duties for City improvements and other civil purposes have, however, been charged upon coal imported into London from the time of Charles II. to our own day. These rates were first imposed after the Great Fire of 1666, to assist in the rebuilding of the churches and public edifices that had been destroyed. The duties of all descriptions that had been previously laid upon coal brought into London were commuted in 1836 for a rate of 1s. 1d. per ton, which in 1851 produced a gross revenue to the City of £187,991. Eightpence per ton of this rate would have lapsed in 1862 but for the Act of 1861, which continued it in its entirety till 1872, and for the Acts 26 and 27 Vict., c. 46, by which a duty to the extent of one shilling was further continued to 1882, two-thirds being mortgaged for the Thames Embankment and one-third for the Holborn Viaduct; and 31 Vict., c. 17, which again further extended the time of its imposition to 1889, a third of the rate being under this Act applied to the freeing of certain suburban bridges and tolls. An idea of the importance and growth of the London coal-trade may be gathered from the following statistics:—At the Restoration it is calculated that about 200,000 chaldrons were annually imported into the metropolis, and in 1670 the quantity amounted to 270,000 chaldrons. At the Revolution 300,000 chaldrons were brought to London, and in 1750 the quantity was about 500,000 chaldrons, and fifty years later 900,000. In 1866 there was brought into London by sea, rail, canal, and road, no less than 6,020,182 tons of coal, yielding in duty £270,000. The quantity of coal exported from Newcastle in 1801 was 452,092 chaldrons sent coastwise, and 50,401 over sea; in 1811, 634,371 sent coastwise, and 18,054 over sea; in 1821, 692,321 sent coastwise, and 48,097 over sea; and in 1832 the number of chaldrons shipped amounted to 748,348. It must be stated that the Newcastle chaldron, by which the above quantities are estimated, is nearly equal to two chaldrons London measure. The aggregate capital employed by the coal-owners on the Tyne at the present time amounts to about £4,500,000, exclusive of the craft on the river, and the total capital employed in the coal-trade may be moderately estimated at from twenty to twenty-five millions sterling. It is calculated that upwards of 60,000 persons are directly employed in the coal-fields connected with Newcastle.

The export of lead from Newcastle, taken from the mines of Northumberland and Durham, is of great antiquity, and in the earliest records that have been preserved these mines are described as silver mines. Large quantities of lead are annually brought from the Alston Moor and Wearland mines to Newcastle for shipment, and for manufacture into sheets, shot, and red and white lead, and silver is to some extent extracted from the lead ore. Only a small quantity of iron ore was smelted on the Tyne previous to the discovery of the Cleveland ironstone, but since that time this industry has increased enormously, and about 60,000 tons of iron and 3,000 tons of steel are now annually produced there. Copper to the value of about £100,000 is also annually obtained from the copper pyrites used at the great chemical works on the Tyne. The quantity of coke yearly manufactured amounts to some 2,500,000 tons. The locomotive and engineering establishments in Newcastle and the vicinity are among the largest and the most celebrated in the kingdom, Sir William Armstrong's ordnance works at Elswick, a western suburb, being perhaps the most famous. During the past year the operative engineers of this town succeeded, after a long and determined strike, in obtaining a reduction of the hours of labour to nine hours per diem—an event that is likely to exercise a powerful and beneficial influence on the condition of the working classes generally throughout the country. Iron ship-building is carried on, as well as the building of wooden and composite vessels, upon an extensive scale on the Tyne, iron vessels reaching an aggregate of 51,236 tons having been launched in 1863. The chemical manufactures of Newcastle and the neighbourhood have grown to extraordinary dimensions since 1816. It is calculated that upwards of 100,000 tons of salt are annually decomposed in the district, for the production of crystals of soda and other mineral alkalis, while bleaching powder, vitriol, copperas, coal pitch, spirits of tar, aquafortis, glue, vinegar, soap, etc., are manufactured in large quantities. The production of window and flint glass has considerably declined during the last few years, but enormous quantities of bottles are still made at Newcastle and in its immediate neighbourhood, while impressed glass is largely made, and plate-glass to a certain extent. Earthenware also forms an important branch of industry in the town, and glass-staining has been carried to a high degree of perfection.

FARMING AND FARMING ECONOMY.—XIII.

By Professor Wrightson, Royal Agricultural College, Cirencester.

CATTLE.

INTRODUCTORY—PLACE IN ANIMAL KINGDOM—ORIGIN OF EUROPEAN CATTLE.

A correct and intelligent knowledge of the British races of cattle can scarcely be attained without some insight into the position which they occupy in the animal kingdom, and their relations to allied domestic cattle found in other parts of the world. The study of the origin and development of a race of domesticated animals has many elements of interest. Sprung from a wild stock at a remote period of time, they

have lost many of their natural instincts and characters, and assumed a form which can only be preserved under highly artificial conditions. They have been moulded by art, and adapted to the requirements of man, until it is difficult to realise what the form and character of the wild progenitor really was. Our cattle only exist in the domesticated condition, and although feral or escaped cattle abound as wild animals in many parts of the world, true native and perfectly wild cattle do not occur.

It is true that in Chillingham and other parks "wild cattle" are preserved, probably the direct descendants of an aboriginal forest breed. These have, however, been for many generations confined within narrow bounds, and exposed to more or less unnatural and modifying conditions. "The (Chillingham) cattle," writes Darwin, "in their instincts and habits are truly wild. They are white, with the inside of the ears reddish-brown, eyes rimmed with black, muzzles brown, hoofs black, and horns white, tipped with black." At Chartley, the seat of Earl Ferrers, a similar breed exists, and there black calves are occasionally dropped. These cattle represent *Bos primigenius*, well known as a formidable wild animal in Cæsar's time, now semi-wild, and much degenerated in size. We propose to return to this interesting subject, but in the meantime it will be well to glance at the general position of the large family of oxen (Bovidæ) in the animal kingdom, and in doing so we shall also detect the links connecting sheep with cattle in a distinct relationship.

The Bovidæ, or Oxen, are a family of the Ruminantia, a remarkably well-defined, natural order of the herbivorous Mammalia. The general characteristics of this order may be stated as follows:—All are exclusively herbivorous, and, with the exception of camels and llamas, are destitute of incisor teeth in the upper jaw; the toes, two in number, are enveloped in distinct hoofs, and many of the species have two supplementary hoofs in addition; all chew the cud, and are furnished with three or four stomachs. With the exception of the camels and musk deer, all are horned.

The order is divided into families as follows, according to the nature of the horn. (1.) The Camels and Musk Deer, without horns. (2.) The Cervidæ, or Deer, with deciduous horns. (3.) The Giraffe, constituting the family of Camelopardidæ, and characterised by possessing two frontal horns in both sexes, conical and truncated, short, covered with hairy skin, and persistent (Van der Hoeven). (4.) The Antelopes, or Antelopidæ, the first of the hollow-horned ruminants (Cavicornia of Van der Hoeven), distinguished by the persistence of their horns, which are composed of a hollow or bony core covered with a horny sheath. This family is further divided into true Antelopes, remarkable for their grace and lightness of form and agility; the Bush Antelopes, with shorter limbs and more compact form; the Capriform, or goat-like antelopes, represented in Europe by the Chamois goat; the Boviform, or ox-like antelopes, which present various degrees of likeness to oxen. (5.) The Bovidæ, or Oxen, distinguished from all the antelopes by their bulky form and great strength. It is also interesting to note at this point the position of sheep and goats, the Capridæ, which are, like oxen, connected with the antelopes by an intermediate sub-family, the Capriform Antelopes.

The Bovidæ, or Oxen, are thus described by Martin:—"In both sexes the head is armed with horns (we of course except the polled domestic breeds of cattle), and these horns consist of an external layer of corneous fibres, compacted together, and sheathing a cancellous, bony core, continued laterally from a bold occipito-frontal ridge. . . . The progressive increase of the horns is marked by successive ridges or rings at the base. . . . Their form is heavy and massive, their stature generally large; the limbs are low and strong; the haunches wide; the shoulders thick; the head large; the forehead or chaffron expanded; the muzzle (rhinarium), with certain exceptions, broad, naked, and moist; the tongue rough, with hard horny papillæ directed backwards; the neck thick, deep, compressed laterally, carried horizontally, and furnished with a pendant dewlap; the spinous processes of the anterior dorsal vertebræ (withers) are very long and stout." All the ox tribe are gregarious in their habits, and, with the exception of Australia, occur in every quarter of the globe.

This family has been divided as follows into four groups:—Cattle and Buffaloes, having thirteen pairs of ribs. Bisons and the Yak, having fourteen pairs of ribs. Besides these there is also the Musk Ox, or Ovibos (*Bos moschatus*), an animal which constitutes the genus Ovibos of Blainville and Desmar. This animal has a hairy muzzle, and short tail concealed under long hair; the horns approach each other at the base and then proceed outwards and downwards, the points turning up again nearly as in the gnu (Van der Hoeven).

In MM. Moll and Gayot's excellent work on cattle the points of difference between these groups is ably discussed. Taking them in the above order, cattle are distinguished by horny papillæ upon the tongue, by circular rings at the bases of the horns, and by the teats being arranged in the form of a square. This group includes—(1.) The common ox (*Bos taurus domesticus*) and the variety already mentioned; park or forest cattle (*B. sylvestris*) found in Britain in a semi-wild condition as above; the Zebu, or humped cattle of India (*B. Indicus*); and the white buttocked cattle (*Bœuf à fesses blanches*), (*B. bentiger*) which occupy Java and Borneo in a wild state. (2.) The Gour (*B. gaurus*) and the Gayal (*B. gavæus*), both remarkable for the development of the bony spinal processes which give rise to the withers.

The Buffalo (*B. bubalus*) is distinguished by a smooth tongue, horns triangular at the base, and teats set in the form of a trapezium. The buffalo is indigenous to Asia, and is found over a wide area. He has been largely used as an animal of draught; is completely black in hair, skin, hoofs, and horns; possesses short, thick limbs, and a massive body; forehead arched; muzzle large; horns directed outwards and backwards, and finally turning upwards towards the point; hair scattered thinly over the body, but forming tufts on the forehead, knees, and fetlocks; the dewlap is but little developed. He is useful as an animal of draught, especially in humid and fenny countries, where ordinary cattle would not thrive; as, for instance, in the Pontine Marshes. The flesh is inferior to ox-beef, and is sold at a low price in Italy. The milk is excellent. He is very fond of bathing, a partiality which is often inconvenient, as he has been known on sighting a river to rush towards it, laden with perishable goods, and plunge into its midst, there to enjoy the delights of the bath, and to sleep for hours, totally immersed with the exception of his nose.

The Bonassus, or Bison. This group comprises the European bison or auroch, and the American bison, sometimes called buffalo. The auroch is the only member of the ox tribe found wild in Europe. He is, however, exceedingly rare, and is only found in the forests of Moldavia, and in the governments of Grodno and the Caucasus, in the Russian Empire.

The bison differs from the auroch in having fifteen pairs of ribs. In other respects both the European and American species resemble each other. Both are disproportionately larger in the anterior than the posterior portions of the body, due to the great development of the spinal processes of the dorsal vertebræ, which support large masses of flesh (the bison hump) on either side. This ungainliness of form is further exaggerated by a thick coating of hair on the neck and shoulders, which is composed of two qualities. The first, long, coarse, stiff, and harsh to the touch; and underneath this a soft, fine wool, reputed finer than that of the merino sheep. The colour of the bison is blackish brown, turning in the adult male to almost black. These powerful animals have, according to M. Rafinesque, been employed in agricultural work, especially in Kentucky, and the same authority states that they cross freely with ordinary cattle, and that the hybrids are fertile among themselves, and with the two parent species.

The yak has only recently appeared in Europe. He in some respects resembles the zebu. The hump, however, of the zebu consists of fat, while the elevation of the withers in the yak is due to the elongation of the vertebral spines previously mentioned. The yak has a very short neck; horns rising vertically from his head; limbs short, light, and terminated by small hoofs. In general outline the yak more nearly approaches the horse than the ox, and he is well adapted both to draw and carry weights. He is covered with a long fleece, which, like that of the bison, is divided into two portions: an under-growth of exceedingly firm wool, which in Thibet is mixed with the soft hair of the Cashmere goat, in the fabrication of those valuable tissues for which the country is famed. The yak is invaluable in North China, Thibet, and the slopes of the Himalayan Mountains, where he figures as an animal of draught and of burden, a source of milk, of flesh, and of wool. The Imperial Acclimatisation Society introduced this useful

animal into the Jardin des Plantes, at Paris, in the hope that he might become useful in mountainous districts in Europe.

Having considered with, we hope, sufficient brevity the various members of the Bovidæ domesticated by man, we must now devote ourselves to the study of common cattle (*B. taurus domesticus*). Professor Lowe enumerates nineteen breeds of British cattle. Desmarest describes fifteen French races, excluding sub-varieties and imported breeds, and MM. Moll and Gayot figure fifty-five European varieties in their "La Connaissance General du Bœuf." The origin of these closely allied, yet evidently well marked, tribes has been traced by Nillson and Rütimeyer. Following the latter authority, we may mention *Bos primigenius*, the ancestor of some of the larger Continental races, as the Friesland and Hungarian cattle, the Pembroke in Britain, and which, no doubt, now exists in a degenerate form as the wild or semi-wild ox of Chillingham Park. Besides *Bos primigenius*, there are two other extinct species of the genus, from which our European cattle are supposed to have been descended. The first of these, *B. longifrons* or *brachyceros*, was of small size and short-legged. The Highland and some of the Welsh breeds are supposed by Professor Owen to have been descended from this species. Remains of *Bos longifrons* have been found associated with those of the elephant and rhinoceros. The last species, *B. frontosus*, existed in the same late geological period, and is believed by Nillson to have been the progenitor of the mountain cattle of Norway. This species is distinguished by a bony protuberance on the skull, between the horns. We see, therefore, that at least three distinct species of ox have been domesticated in Europe. The uniform colour of the Chillingham cattle has always been one of their best marked peculiarities. In general, the colour may be described as white, with reddish-brown inside the ears. This uniformity of colour is to be observed in several domesticated foreign breeds, and it has been ascertained that cattle which have run wild in the Ladrone and Falkland Islands have assumed a similar light or white colour, with black ears and occasionally black heads. Numerous instances might be given to show the tendency of escaped cattle to become white, with coloured ears, while in other cases a uniform dark brownish-red hue has been assumed. This general tendency has been considered to indicate the colour of at least one of the original wild prototypes of our cattle.

GREAT MANUFACTURES OF LITTLE THINGS.—VIII.

LOCKS *(continued from Page 229)*.

BY CHARLES HIBBS.

THE great convenience of the warded lock for ordinary purposes induced many attempts to provide it with additional features of security. We shall not pretend to notice these in chronological order, our object not being to write a history of the lock manufacture, but rather to illustrate the growth of correct principles in construction. Among other meritorious inventions, one was patented by a Wolverhampton maker, which effectually prevented the possibility of opening the lock with a skeleton key, or making a false key by taking an impression of the wards. The bitt of the key was made telescopic, and would only enter the key-hole when pushed up to its shortest length, while it would only act upon the bolt when drawn out to its longest. In the first part of its revolution it passed over a ward which gradually thickened, and so, by widening the slot, elongated the bitt sufficiently to reach the bolt, after which a fixed piece of metal, so placed that the end of the bitt rubbed against it in its rotation, acted upon it like an inclined plane, and pushed it back into its former shape.

But the inherent defects of the system were incurable. The most obvious was that the obstacles to surreptitious unlocking lay all in the small compass that was represented by the size of the bitt of the key. However ingeniously the position of the wards might be varied, or even their functions changed, as in the last example, it was not possible to produce more than a limited quantity of locks of any given size, the keys of which should materially differ from each other. The maker would soon exhaust all the variations capable of being put into so small a space, and would therefore be compelled to reproduce some, or all of them, to an indefinite extent. This was, of course, more especially the case with regard to the commoner sorts, of which perhaps tens of thousands might be made with their ward arrangements all alike. What security could be felt by the owner of a lock, however complex, if he knew that there must necessarily be others exactly like it in existence somewhere, and that any bunch of keys might happen to contain one that would unlock it? There was another radical defect in the principle, inasmuch as the *impedimenta* all lay in the way of the passage of the *key*, and there was nothing, except the downward pressure of the back spring, to hinder the passage of the bolt. Any one who could gain access to the end of the bolt could shoot it back with a moderate push. In these two essential parts of the principle lurked a fatal element of insecurity; nor was it overcome until the adoption of the tumbler system, which marked a new era in lock-making.

In this system, while the exterior shape of the lock and key was unaltered, and the action of the bitt upon the talon of the bolt remained precisely the same, the wards, the back spring, and the notches on the under side of the bolt, were all taken away. In place of them two square notches were cut on the upper side, and a tumbler, or latch, furnished with a stud that fitted them easily, was hinged at one end immediately over the bolt. This latch was of sheet metal, wide enough to hang like a curtain in front of the bolt, covering about half its surface, the stud being fastened at right angles to its upper edge. When the bolt was *half* shot, this stud was resting upon its top surface, being pressed thereon by a light spring, but when in the locking or unlocking position, the stud fell into one or other of the notches. The bolt was therefore held firmly in its place until the tumbler could be lifted and the obstruction cleared. This was effected by the bitt of the key being stepped to correspond with the depth of the overhanging tumbler, so that when it was turned round to reach the talon of the bolt, it at the same time raised the tumbler to a height sufficient to free the stud from the notch. This simple application of the principle, which we have described first for the sake of clearness, would not of itself afford much security, it being easy to contrive a false key which should effect the required movement; but the difficulty was greatly enhanced by having two or more tumblers, each hinged on a common pivot, but working with its separate stud into a separate pair of notches. The depths were also varied, so that the under edges of the tumblers, technically called their "bellies," hung at different heights, and required corresponding steps to be cut upon the bitt of the key. So far a great advance was made, but still the plan was seriously defective. The tumblers might be lifted to *any* height, and a false key need not be made with such extreme nicety as just to lift the studs out of the notches, and no more, but might be stepped at a rude guess, and, so that it lifted the tumblers high enough, would effect its object equally with the true key. To meet this, an ingenious arrangement was devised. The studs of the tumblers no longer rested on the top of the bolt, but lay in a slot cut out of its middle part, the notches being cut downwards from the slot. Had such been the whole of the arrangement, the studs could not have been lifted higher than the upper wall of the slot. But here a new element was introduced. Corresponding notches were cut *upwards*, opposite to the lower ones, so that if the tumbler were overlifted, the stud entered the upper notch, and equally prevented the passage of the bolt. The slot in the bolt thus resembled rudely the letter H, the upper and lower notches being sufficiently wide to receive the several studs lying side by side. This was a great improvement. If the workmanship were moderately accurate, no false key that was not an exact duplicate of the true one could possibly open the lock. If its steps were too low, they would not lift the studs out of the lower notches, while, if they were too high, they would certainly elevate the studs into the upper notches, and leave the bolt as fast as ever.

Although this lock was not susceptible of being picked, as the warded lock was, by a skeleton key, it was still not altogether proof against the nefarious attempts to make a false key by means of an impression taken of the interior. The bellies of the tumblers hung, as we have explained, at irregular depths, and any means by which an accurate measurement could be taken of their position would indicate exactly the number and depth of the steps to be made upon the key. A blank key, smoked, would show which of the tumblers was first touched, and this at once indicated the place where the lowest

step was to be filed away; and by repeating this process until, by patient trial and filing, the shape of the false key became the exact converse of the lower edge of the hanging row of tumblers, a perfect duplicate of the true key might be made. This fraudulent expedient, too, might be materially facilitated by catching a sight of the tumblers in position through the keyhole, by means of a small mirror, thus enabling the operator to get on with his work to a certain extent before he began to take his smoked impressions, which would be only needed for the finishing strokes. It was speedily felt to be a desideratum that the bellies of the tumblers should lie all upon a plane, so as to afford no indication to the picker as to the height they required to be lifted. This was effectually done by the simple and beautiful expedient of placing the stud upon the bolt, and the slot, or gating, in the tumbler. It was not now the stud which fell into the notch, but the notch which fell upon the stud. The gating—that being the technical term—bore still the rude semblance of the letter H, but according as the legs of the letter were made longer or shorter, the tumbler fell through a greater or a lesser space. Only when the tumblers, or, as they were now sometimes called, the levers, were lifted simultaneously to the position in which the horizontal slots, or cross bars of the H, came together and formed one slot, could the stud, which projected through them all, pass from the locking to the unlocking position, or *vice versâ*. At either of those positions each of the levers fell through a different space, and of course required to be lifted accordingly by steps upon the key, although the bellies of the levers, when down, formed one unbroken surface. It will be clear that if either of the tumblers were overlifted, as would probably be the case with a false key, the lower notch would catch the stud with the same result as when the gating was in the bolt.

We must now proceed to explain the *rationale* of the immense additional security afforded by these locks, in respect of the almost infinite variety with which they can be produced; and we cannot do so better than in Mr. Chubb's own words, taken from his admirable essay. He says:—"The number of changes which may be effected on the keys of a three-inch drawer lock is $1 \times 2 \times 3 \times 4 \times 5 \times 6 = 720$, the number of combinations which may be made on the six steps of unequal lengths (on a six-tumbler lock) without altering the length of either step. The height of the shortest step is, however, capable of being reduced 20 times, and each time of being reduced the 720 combinations may be repeated; therefore, $720 \times 20 = 14{,}400$ changes. The same process, after reducing the shortest step as much as possible, may be gone through with each of the other five steps; therefore, $14{,}400 \times 6 = 86{,}400$, which is the number of changes that can be produced on the six steps. If, however, the seventh step, which throws the bolt, be taken into account, the reduction of it only ten times would give $86{,}400 \times 10 = 864{,}000$, as the number of changes on locks with the keys all of one size (that is, with one key of definite size in all save the lengths of the steps). Moreover, the drill-pins of the locks and the pipes of the keys may be easily made of three different sizes; and the number of changes will then be $864{,}000 \times 3 = 2{,}592{,}000$ as the whole series of changes which may be gone through with this key. In smaller keys, the steps of which are capable of being reduced only 10 times, and the bolt-step 10 times, the number of combinations that may be made will be $720 \times 10 \times 6 \times 5 \times 3 = 648{,}000$. On the other hand, in larger keys, the steps of which can be reduced 30 times, and the bolt-step 20 times, the total number of combinations will be $720 \times 30 \times 6 \times 20 \times 3 = 7{,}776{,}000$." Another lock-maker, Mr. Parsons, showed by a curious table that a lock with 26 levers would admit of 403,291,461,126,665,635,584,000,000 different combinations!

The reader will now see that the plain Chubb key, which has so very unpretending an appearance, as compared with one of the old-fashioned pattern, filled with mazy wards, is in reality a much greater emblem of safety. We must inform him that means are taken by all makers of repute to ensure that the permutating principle shall be carried out as a reality, and not as a sham. The difference between one lock and another is not a matter of haphazard. The keys are, as a rule, made first, and the tumblers adjusted to correspond, that being the method which is found in practice to work the best. The steps are cut by a machine, with which is connected a dividing plate, having notches in its circumference graduating in depth from the highest to the lowest of the steps that are capable of being cut on that particular sized key which the machine is constructed to operate upon. We have seen that even on a small key, not only may the relative positions of the steps be changed, but that each of them may be reduced in height twenty times; there may therefore be a great number of notches on the periphery of the dividing plate, and yet the depths of all will differ in some slight degree. On the surface of the plate, against each notch, a number is engraved, and the operator, working upon an infallible arithmetical system, is thus enabled, by reading off these numbers, to adjust the machine to a succession of combinations, none of which can be repeated until the whole series is exhausted. The notches, it will readily be apprehended, govern the action of the cutting tools, and regulate exactly the height of the steps that are being made upon the key.

These locks were long considered to be impregnable, but we have now to recount the history of their defeat by the invincible American. The first stroke at our fancied security was made by him at the Crystal Palace in 1851, when he declared to a party of scientific men that none of the locks made in this country were proof against a properly directed assault. To prove his statement, he picked one of Chubb's patent detector locks in their presence in a few minutes. Shortly afterwards he made a sort of public challenge to the Messrs. Chubb, by notifying them that he would attempt, on the following day, to pick one of their locks which was on the door of a strong room in the City, and inviting them to be present. They did not avail themselves of the invitation, and the trial came off in the presence of eleven gentlemen of unblemished honour and integrity, who certified that Mr. Hobbs fairly picked the lock in twenty-five minutes, and locked it again in seven minutes with the same instruments. The event was much commented upon in the public press, and thus began the great lock controversy, which we must not follow for want of space.

Mr. Hobbs's dictum was as follows: "Whenever the parts of a lock which come in contact with the key are affected by any pressure applied to the bolt, or to that portion of the lock by which the bolt is withdrawn, in such a manner as to indicate the points of resistance to the withdrawal of the bolt, such a lock can be picked." This indicates the method which has been called the tentative or mechanical method, to which we have already introduced the reader in the description contained in a former article of the manner of picking the letter lock. The principle consists simply in applying pressure to the bolt in the direction tending to unlock it (if it is locked), and then feeling the tumblers very gently, one by one, until the one is discovered which is being pressed most hardly by the stud. It is scarcely within the power of human skill to make the lock so nicely as that the stud shall press equally upon all, and consequently one will be found to be fast and the others loose. The bound tumbler being lifted up very gently, a slight, very slight *give* of the bolt will tell when the unlocking slot has come into position. One of the loose tumblers will now become tight, and must be treated in the same manner, and so on, until by turns all have been got into the required position, when the lock will come open. It need scarcely be said that this is a most delicate operation with a well-made lock, and that a suitable instrument has to be used. That with which Mr. Hobbs worked was simple and ingenious. The reader understands that the only part of the bitt which acts upon the bolt is its final and longest step, the office of the other steps being merely to lift the tumblers and remove the obstructions to the bolt's passage. Mr. Hobbs then made a false key, with a single thin projection, corresponding to the thickness and height of the final step only of the true key. Its proper length of course the key-hole would give him. With this he could reach the talon of the bolt, and by turning it round, as in the act of unlocking, could get the stud to press in the direction he wanted. The false key had no bow, or cross-piece at the top, for the hand to grasp in order to turn it, but its plain stem was filed to a square at the end, to receive the eye of a lever which answered the same purpose, and which, being extended to a considerable length, admitted of a weight being hung upon it to maintain the pressure at a constant degree of tension. Thus one part of the object (the tightening of the stud against the levers) was accomplished. For the purpose of feeling and lifting the levers, a second key, also furnished with a narrow bitt, corresponding to a single step of the true key, and the

stem of which was a tube throughout, was slipped on to the stem of the other key before the lever was affixed. This second key was furnished with cross-pieces which served the purpose of a bow, and could be turned round easily upon the stem of the first. The *modus operandi* is now clear. The second key was pushed forward until its bitt entered the key-hole, and with it the levers were felt and lifted cautiously, and the lock picked.

The lock of the Messrs. Chubb, which Mr. Hobbs publicly picked with the instrument described above, was furnished with their patent detector spring, which we have not yet described. It was fixed immediately over the levers, near the hinged ends, and its action was so contrived that if any one of the tumblers were overlifted ever so little, so that the stud entered the lower slot, the detector spring would seize it, and hold it there firmly, so that the bolt could not be moved either way until the spring was released. The true key would not undo the lock while the detector was on, but it would release the detector on being turned the reverse way. This was a very useful contrivance, as showing when the lock had been tampered with, and stood terribly in the way of a clumsy manipulator who was trying to pick the lock by the tentative process. We may be sure that Mr. Hobbs conducted his operations with such delicacy and precision, that he stood in no fear of the detector; he would be sure *not* to overlift the tumblers; but independently of that, his sagacity soon discovered how the detector might really be made to help him. If the position of the detector could be ascertained from the outside, which might be done by drilling, and if a piece of metal could be so inserted as to hold the detector down, the tumblers could not be overlifted, and the picking of the lock became an easy matter.

Another and more effectual defence against tentative picking was the introduction of false notches. The picker, on lifting cautiously a tight lever, felt it suddenly become relieved, and concluded that the transverse slot had been entered; when, in truth, the stud had only fallen into a slight recess, cut out of the side of the upright slot. This puzzled the picklock amazingly, as he never could make sure when he was right; and although the lock was not absolutely impregnable to him, it was practically so, owing to the time it would take to pick it.

But Mr. Hobbs himself introduced a neat little invention which met the danger in a truly scientific manner. Instead of making his stud a fixture, as in other locks—*i.e.*, riveted to the bolt, and moving rigidly along with it—he fixed it upon a small movable platform, which was let into the substance of the bolt, and turned upon a central pin. When the lock was acted upon with the true key, the stud passed freely enough from one slot into another, and did not move from its position; but when stress was brought to bear upon it, as in pressure applied for the purpose of tentative picking, the stud moved slowly round with its platform, which carried with it a dog which hooked into another part of the works, and pinned the bolt in its place.

The highest application of the tumbler principle is, perhaps, to be found in the parautoptic lock, so called from a Greek word signifying *concealed from view*, patented by Messrs. Day and Newell, of New York, and introduced to this country by Mr. Hobbs. It would be impossible to convey any idea of it by a merely written description; we must be content, therefore, to simply state its capabilities. It has the power of re-adjusting itself to any combination that its owner pleases, and to as many as he pleases. The bitt of the key, with its steps, is formed of a series of movable pieces, which the owner can re-arrange, or substitute others for, at pleasure. When once locked, which may be done with any combination, only the same combination will unlock it, and thus it may be set to a different combination each time. An impression in wax of the true key would, therefore, be of no use to the burglar, as the true key might alter its features from day to day—an advantage which was not possessed by any other tumbler lock. The machinery of the lock was necessarily complicated, and the price high, but that, where absolute safety was the object, was of no consequence.

We have now brought down our survey of lock construction to the point when another new principle comes under our consideration—that of the Bramah. We have not been governed by dates in the order of introducing the inventions here described, but have simply endeavoured to place them in such order as would assist them to illustrate each other, and convey clear ideas to the reader. The same method will be pursued in a concluding paper.

TECHNICAL DRAWING.—LXV.

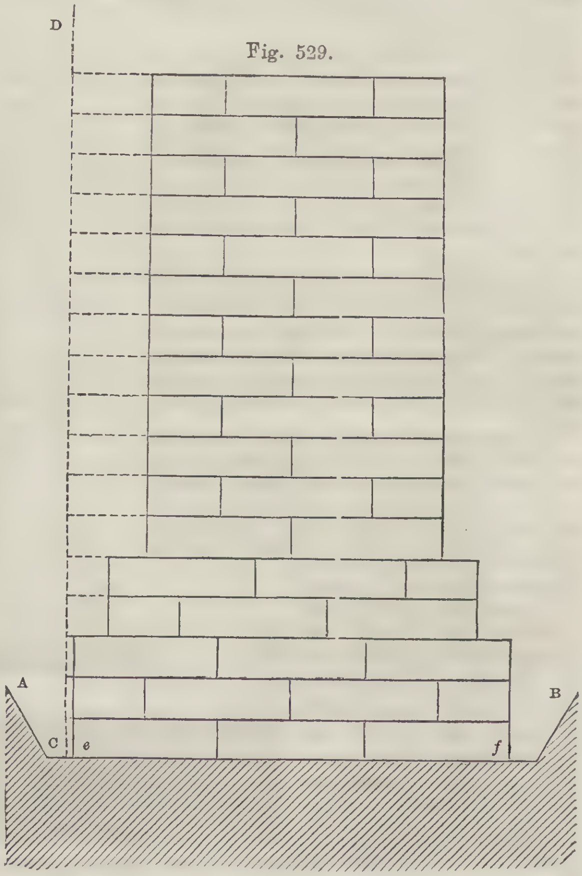
DRAWING FOR BRICKLAYERS.

FOOTINGS OF BRICK WALLS.

THE base of a brick wall is technically called the "footing,"* and it should always exceed the thickness of the body of the wall. The custom is to diminish the base of the wall from the bottom upwards by small steps or offsets of a quarter of a brick on each side, thus making half a brick in all saved upon each projecting course. Sometimes smaller offsets have been used, but none greater should be employed, excepting in walls of one brick thickness.

The offsets are sometimes laid out in every successive course, which in brickwork does not exceed three inches in height for each step, until the proposed diminution is obtained. Sometimes they are laid out in every second or third course, according to circumstances.

Fig. 529.



The example (Fig. 529) represents a section of a wall of two bricks in thickness, having a base of three bricks thick, which has been diminished in the manner described in the opening paragraph of this lesson.

The offsets at the base of a building are usually covered with earth, by the filling in of the original trench excavated for the foundation; but sometimes there may be offsets in a higher level, in which case there is seldom more than one externally, which is usually at a moderate distance from the ground. The others are internal.

The propriety of giving to the walls of buildings a footing such as has been described, arises from the well-known circumstance that the stability of bodies depends in a great measure upon the magnitude of their base. To add to the security of very extensive walls serving as enclosures, they are usually built not only with footings, but also with buttresses at moderate

* See lessons on "Building Construction," Vol. I., page 172.

intervals apart, as may be observed in the walls of dockyards, etc. In common buildings, the several walls serve as buttresses to one another; still, footings are absolutely necessary in bad soil, and are so useful, and add so much to the stability of the structure, that they cannot with propriety be dispensed with under any circumstances, although in some cases their projection may be diminished.

The method of drawing the example given in the preceding page is so very simple that only very few instructions will be required.

Having drawn the trench, A B, draw any perpendicular, as C D, set off on it the heights of the bricks, and draw horizontal lines from these points for the various courses of brickwork. By this plan all measuring and fraying of the paper by alterations is avoided. It will be seen that the first footings are carried up through three courses. Therefore, having marked the width of the base—viz., three bricks—draw perpendiculars at each side, *e f*, thus completing the rectangle, which forms, as it were, the first block of the footings.

The first and third courses of this block are laid alike—viz., three bricks placed so that their length passes through the entire thickness of the footing; the second course consists of two whole bricks in the interior, and one half brick in each side. These are not, however, *half* bricks, but the *ends* of whole bricks laid at right angles to the other two courses—that is, having their length parallel to the surface of the wall.

The next footing is to be drawn in the same manner, the containing rectangle being kept at a quarter of a brick within the lower block, thus leaving the present footing two and a-half bricks. These are laid so that the half (or rather the end) brick is on the one side of the wall in the first course, and on the other in the second.

The wall itself is two bricks thick, and is laid so that the courses consist alternately of two whole bricks, and one whole and two end bricks.

The student is here reminded that it is most important that brick walls should be kept perfectly vertical, for it will be evident that if a wall at the bottom is in the slightest degree "out," the evil (like every other) will go on increasing; the top will gradually extend beyond the foundation and fall. But this is not all; the wall must be kept "plumb," which term does not necessarily mean upright, but a plane surface. Thus a wall may be slanting, as a bank or side of a tower, which tapers towards the top. But in whatever position it may be, it must be kept plumb, and the plumb-rule may not only be used for this purpose, but to keep the joints over each other. This is generally termed "keeping the perpends." Now as this is so important a point in practice, it is of course necessary to be observed in drawing a wall, and therefore the joints which fall above each other should be drawn whilst the set-square is placed for any one of them, for the same line will be required in continuation in each of the alternate spaces or courses.

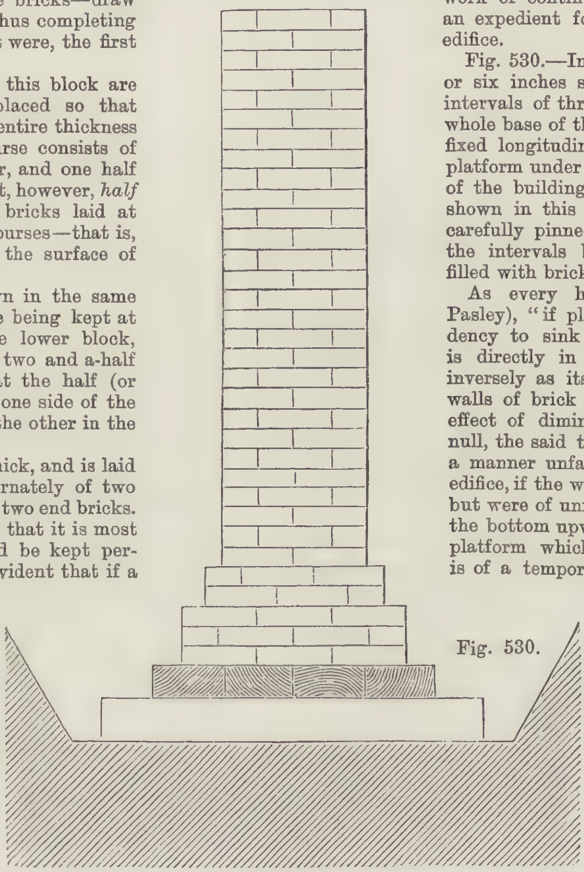


Fig. 530.

FOUNDATIONS OF BUILDINGS IN UNFAVOURABLE SOIL—PILED FOUNDATIONS.

It has been before observed that the soil upon which a building of any importance is to be erected should always be well examined before the work is commenced, which may be done by striking it to ascertain if it sounds hollow, and then by boring it in various parts with an earth-borer. Small shafts, cut at certain intervals, may also answer the purpose of discovering the nature and depth of several strata when the ground is not of uniform consistency.

When the soil is partly good and partly bad, the latter may be cut deeper until good soil is obtained, if it can be found at moderate depth, and thus the footings may be built as in irregular ground—not on one continued level, but in steps or terraces.

When the soil is all of the same quality, but looser in some parts than in others, ramming it well in the loose parts has been considered a very useful and, sometimes, a sufficient precaution; and this method of treating the soil is particularly recommended by some of the French engineers of the greatest eminence.

Even in buildings erected of bricks it has been common to commence the foundation with flat stones, placing the largest as regularly as possible, filling in the intervals with smaller ones, and ramming them down.

When the soil is of a middling quality, not absolutely good, nor yet altogether unsound and treacherous, a grating or network of continued woodwork is often used as an expedient for ensuring the stability of an edifice.

Fig. 530.—In this case, sleepers of about five or six inches square are laid transversely, at intervals of three or four feet apart, under the whole base of the intended wall. Over these are fixed longitudinal planks forming a continued platform under the whole foundation of the walls of the building, as represented in the section shown in this example. The planks must be carefully pinned down upon the sleepers, and the intervals between the latter are usually filled with bricks or stones—not with earth.

As every heavy body (says Sir Charles Pasley), "if placed upon soft soil, has a tendency to sink more or less, which tendency is directly in proportion to its weight, but inversely as its base, the footing given to the walls of brick buildings has in such soil the effect of diminishing, or altogether rendering null, the said tendency, which might operate in a manner unfavourable to the stability of the edifice, if the walls had no such increase of base, but were of uniform thickness throughout, from the bottom upwards. In respect to the wooden platform which has been described, its use is of a temporary nature, as it merely serves to prevent the brickwork, if it sinks at all, from sinking unequally whilst the mortar is yet soft, or the work green, as it is technically termed. After a certain number of years, when the mortar and bricks shall have become completely consolidated into one compact mass, they are no longer liable to separate, even if the woodwork underneath could be removed."

It will perhaps be scarcely necessary to remark that the base of every brick wall of the same height and thickness, or, in other words, of the same weight, should be greater in direct proportion to the softness of the soil on which it is built; also that the projecting parts of the footing of a wall should have a certain depth to give them solidity, otherwise the greater weight upon the central part of the base might fracture the bottom of the wall, and thereby render the footing useless; for this reason it is desirable that the offsets, when there are several, should not follow in every succeeding course, but at greater intervals apart, as already mentioned. Moreover, it is advisable in erecting a building in middling soil upon a wooden platform, such as has been described, either to make all the walls of equal thickness, and consequently of equal weight throughout; or, if that arrangement would not be convenient, to give the thicker wall the greater base in direct proportion to its weight.

In this example the wooden platform is to be drawn first, and the work is then to be proceeded with as in the former study. For illustrations of platforms laid on network of timber the student is referred to pages 47 and 56, Vol. I., of THE TECHNICAL EDUCATOR.

SILK CULTURE.—V.

By Alexander Wallace, M.D.

WILD RACES OF SILKWORMS — THE BOMBYX YAMA-MAÏ — DISEASES OF THE WORM—ITS CULTURAL TREATMENT—THE QUALITY OF ITS SILK.

Thus far have we briefly set forth the culture of the mulberry silkworm, touching but scantily on many points which, did time and space allow, might well demand explanation in detail. We must omit almost entirely to mention those vast tracts in our colonies which, most admirably fitted by Nature to mulberry silk culture, lie waiting the time for their resources to be developed; also the special kinds of mulberry-trees, and the special races of silkworms which may there be most profitably introduced; and to supply suitable instructions for colonial sericulture, where, favoured by climatic salubrity, but devoid of artificial help, the colonist often with the rudest possible appliances brings his labour to a successful termination almost in the open air. We must pass over likewise what has been already done in Egypt, California, Chili, Turkestan, Australia, nay, even in England itself, where much might be cited in furtherance of the views held by practical sericulturists of repute abroad, viz., M. Guérin Mèneville and M. Taurigna, etc., that England is especially fitted, on account of its cool climate, for the production of healthy grain. We must omit likewise at present all reference to silk-reeling, an industry which, in the opinion of many, might easily be followed in England, not merely to the benefit of the women and children employed therein, who would thus find another opening for work afforded them—no small boon in many agricultural towns—but to the advantage also of the weaver and manufacturer, who thus might obtain at home the exact quality of silk required for their machinery, and the colonist as well, who might thus find a home market for his produce, instead of sending it, as at present, to Marseilles. Omitting these and other points of great interest, in the hope of being permitted at some future time to touch upon them, we must hurry on to dilate somewhat on the other silkworm races mentioned in our first paper, generally known as wild races, in opposition to the domesticated *Bombyx mori*, since all these found wild in their native habitats have never yet been entirely subjugated by man.

First and foremost among these, probably in point of beauty, but certainly in point of value, is the Japanese oak-feeding *Bombyx Yama-Maï*, illustrated on page 177.

What we know of the past history of this valuable race is as follows:—For many years the Japanese had cultivated an oak-feeding silkworm as well as the mulberry worm, and according to some writers the profits arising from this species exclusively belonged to the royal family; according to others, its silken produce was employed to make the rich vestments of the imperial family. In either case this valuable species was so highly esteemed that the punishment of death was by law inflicted on any one who exported the eggs. This, then, explains the reason why for so many years this species was unknown to our naturalists and its silk to our merchants. It was not till the beginning of the year 1861 that, during the presence of the French fleet in the Japanese waters, the attention of M. Duchesne de Bellecourt, French Consul-General and Chargé d'Affaires at Japan, having been directed to the beauty of the silken fabrics produced from the cocoons of the *Bombyx Yama-Maï*, he was enabled to obtain some eggs, which were transmitted to the Imperial Government of France, and finally entrusted to the hands of the Imperial Society of Acclimatisation. Now, fortunately, there is no difficulty in procuring eggs of this species in Japan, except that sometimes wooden eggs are fabricated to deceive unwary customers. The eggs first sent over

Fig. 6.—CATERPILLAR, MOTH, COCOON, AND CHRYSALIS OF BOMBYX CECROPIA.

to Europe were carefully tended in the museum at the Jardin des Plantes at Paris. Unfortunately, nothing was known of the habit of the insect, not even its food-plant; when, therefore, the first eggs hatched out, about the 15th of March, 1861, the young worms refused all the leaves presented to them, and perished. But in the beginning of April an oak (*Quercus cuspidata*) placed under glass having put out some leaves, these were eaten by the young worms, and hope was now entertained of rearing them. The President of the Society of Acclimatisation immediately obtained from Toulon and Hyères, in the south of France, young oak-leaves, with which the baby worms were fed from the 9th of April till the time when the oaks at Paris had sufficient foliage. These worms, about forty in all, grew well up to their fourth moult, but being in the serpent-house, the high temperature and close atmosphere proved injurious to them; at least it was probably from that cause that in their fifth stage all the worms (five only excepted) died off in a few days of the same sickness, a black liquid oozing through the pores of the skin. The remaining five made imperfect cocoons, but no moth hatched out. Happily a few eggs of the same batch had been sent to the learned entomologist, M. Guérin Mèneville, that he might name the species; of the few worms hatched out of those eggs one only was born sufficiently late to obtain oak-leaves. It was sent to M. Année, at Passy, where it throve under glass near a door which was always open. It spun a very handsome cocoon, whence a female moth emerged. This attempt, insufficient, unfortunately, to propagate the race, yet sufficed for M. Guérin Mèneville to give a name to the new insect, permitted a study of its habits, of its beauty as a larva, of the size, form, and colour of the cocoon, of the suppleness, brilliancy, and elasticity of the silken fibre, and, lastly, of the physiological and scientific character of the moth. The chance of a second experiment under such circumstances was greatly to be desired; therefore, M. Eugène Simon, the Agricultural Commissioner of the French Government in China and Japan, received a special mission to search out and send over eggs of the *Yama-Maï*. But the Japanese law, entailing death on any one detected in exporting the eggs, was for some time an insurmountable difficulty, and M. Simon was obliged to leave Japan with his mission unexecuted. But happily he had made the acquaintance of a *savant* devoted to the cause, M. Pompe van Meedervoort, medical officer in the Dutch navy, and Director of the Imperial School of Medicine at Nagasaki, who, seeing the importance of such a result, was able most fortunately to attain it. To M. Pompe van Meedervoort Europe owes the possession of this valuable species, the *Bombyx Yama-Maï*. Early in January, 1863, this *savant* returned to Holland with a parcel of eggs. The greater part of these were sent, according to a promise made to M. Simon, to the French Government, and the Government handed the eggs to the Imperial Society of Acclimatisation, and the Society to M. Guérin Mèneville for distribution among the members, etc.; some were retained by M. Pompe van Meedervoort for his friends and his country; and the remainder was given to M. Guérin Mèneville, through the kindness of a Dr. Blecker, for distribution among those naturalists and sericulturists who were not members of the Imperial Society of Acclimatisation. Subjoined is the translation of a notice published by M. Pompe van Meedervoort, relative to the introduction of the *Yama-Maï* into Europe :—

"In 1862 I had the honour to make the acquaintance of M. Eugène Simon. He informed me of the great value of the *Bombyx Yama-Maï*, and together we made every effort, but in vain, to procure eggs of this species; we were told it was absolutely impossible to obtain them. M. Simon being obliged to return, I made him a promise before he left to continue my efforts, and, in case of success, to offer the eggs to the French Government. But the more I tried, the more I saw how difficult, if not impossible, was the attempt. I applied in vain to the Japanese merchants, the silk-growers, to many native naturalists with whom I was on friendly terms, lastly to the government, but all in vain. The reply was, 'The penalty of death is inflicted on any one who may export these eggs.' Another idea then possessed me—to apply to one of my pupils. As the Principal of the Imperial School of Medicine at Nagasaki, I was surrounded with students from the different provinces of Japan, and amongst others from the provinces of Echizen and Vigo, or Hiogo, where alone the *Yama-Maï* silkworms are reared. One of these youths, who had on several occasions given me proofs of his extraordinary devotion, was selected by me for the purpose; to him I explained the whole affair, and proposed that he should go to Vigo at my expense, in order to collect and send me as many eggs as possible. This brave young man, whose name I have promised solemnly never to divulge, started on the morrow, and after an absence of fifteen days secretly sent me the eggs, which he had collected with much difficulty and danger to himself. He told me that no one suspected the object of his journey; that was in October, 1862. My mission to Japan was finished November 1st, 1862. I started for Europe by the English mail packet, and undertook the charge of carrying these eggs to Europe. This was by no means an easy matter on board a steam-ship in the tropics. If the eggs were kept in the cabin a great risk of their premature hatching was incurred, for the temperature there in the month of November is above 95° F., and in the Red Sea 105° and more. I followed the advice of M. Simon, and placed the eggs in the ice-box on board ship, though often but little ice was therein. To this precaution is due in a great measure their safe arrival in Europe in good condition. I arrived at the Hague early in January, 1863, and at once sent out the eggs; the greater part was sent to the French Government and to the Imperial Society of Acclimatisation, according to promise I had made to my friend M. Simon."

From this beginning the new species spread over Europe. Since 1865 several trials have been made in England to rear the species, but as yet unsuccessfully. The same want of good fortune has attended many trials in France, Holland, and other countries; but several gentlemen have attained success even on a large scale. Thus M. Guérin Mèneville, at the Imperial farm at Vincennes, M. Chavannes, Professor of Zoology at the Academy of Lausanne, M. Personnat, at Laval, France, have succeeded in rearing thousands of cocoons. In 1869 the Baron de Bretton, in his woods in Moravia, raised more than 27,000 cocoons, and pursues the culture with considerable success. In 1871, in France and Germany, many thousands of cocoons were reared.

The great drawback to the cultivation of the *Yama-Maï* silkworm in this country is the prevalence of disease. I have had eggs, both sent from Japan and laid in this country, of the healthiest possible aspect; the young larvæ when born seem perfectly healthy, and thrive for a time; yet year after year I have seen the whole brood swept off in a most mysterious and hitherto unexplained manner; and my experience is similar to that of others, both here and on the Continent. From my experience I am led to think the worm is liable to three forms of disease.

First. In early life, in the first or second age, a small percentage of worms are apt to turn yellow, and be affected with diarrhœa; they become soft and die. This form of disease has been described by French writers on silkworms as the jaundice. I believe it is due entirely to want of vitality, as I have noticed that the smaller, later born, and weakly worms are chiefly affected thereby.

Second. In mid-age another malady, caused I believe entirely by too high a temperature, attacks the worms. The first indications are that the vivid beautiful green tint becomes dull and opaque, the skin tightens at the flexures of the segments, a whitish tint is now observed in patches; sometimes, but rarely, some minute dusky specks are visible at the flexures; the larvæ are flaccid, and eat but little. If muscular movement be made, as on the approach of a visitor, the skin cracks, a pale turbid green fluid issues, the worm shrinks, shrivels, and decomposes rapidly.

A third form attacks those nearly full grown or about to spin. Minute dusky specks are visible on the whole body; these rapidly increase and coalesce into brown blotches; the beautiful deep green colour turns into a muddy green-yellow, diarrhœa ensues; the larvæ cease to eat, the claspers retain their grasp; but all muscular power being lost, the body hangs an inert sack, full of decomposing fluids, which burst out at the most convenient spot. In a few brief hours nothing remains of the fine handsome larvæ but dry brown skins.

My own opinion is that shade, moisture, and a cool, even temperature, with very free ventilation, are necessary to the welfare of this creature. In its early life, in May, a temperature of 50° to 55°, or 60°, is desirable, to be increased during June to 65° to 75°; but I think a higher temperature endangers the

safety of the worm; and this I believe to be the chief reason why it has been reared successfully on the Continent for several seasons, and then suddenly and entirely failed.

It is evident that the third form of disease is connected with the secretion of silk in the interior of the larvæ. We find in many cases that the worms pass the spinning-time and make no effort, others spin a little silk and then die, others when examined have no silk within them, others spin a weak cocoon and then die: either, therefore, some necessary element is deficient, or some disturbing cause prevents the formation of the silk. To this point it will be necessary for future observers to pay especial attention.

I will now mention a few points of interest connected with this silkworm. First, it differs from the *Ailanthus* silkworm, *Bombyx Cynthia*, and resembles the mulberry worm *Bombyx mori*, in passing the winter in the egg state, so that the year commences with the egg state, whereas in *Bombyx Cynthia* the perfect insect first makes its appearance in the early summer, after passing the winter in the cocoon stage. A curious circumstance connected with the egg etate of this insect has been observed by M. Guérin Mèneville, that the young larva is fully developed a month after deposition of the egg, and that he lies during the winter perdu within the shell, in a dormant condition, until a vernal temperature and moisture awake him to the active duties of life.

Immediately after birth the young worm, which is handsomely clothed in a yellow jacket slashed with dark velvet lines, is said to expand in volume in consequence of the air inspired, but probably also because the tubercles and spines, which were previously flattened down inside the egg, are now erect and prominent. The statement that the worm seems to grow even before it has eaten is quite correct.

The larva undergoes the same number of moults as the mulberry worm, but assumes quite a different aspect, being adorned with a beautiful vivid green tint, with blue tubercles and some silver spots on each side.

It is erratic at first, but soon settles down to its food, especially if able to obtain drink; for this peculiar larva, quite unlike the mulberry worm, requires a considerable supply of fluid. It is desirable in in-door culture to moisten the leaves twice a day. The worms put down their heads to the drops of water, eagerly imbibe them, and afterwards repose in the attitude so common to all larvæ of *Bombycidæ*, the head, fore-legs, and fore part of the body tucked in and contracted, but elevated in the air in a curve, the hind claspers firmly attached to the twig.

This larva cannot be educated on trays like the mulberry worm, but requires to rest on the twigs of the oak-boughs on which it feeds.

One great climatic difference exists between this country and Japan, viz., the rainy season, which, as we are told, generally commences about the 5th of May. I have been informed by those who have resided in Japan that about that time it rains regularly, without intermission, heavily for several weeks; this coincides with one account given by the Japanese of its culture, "that during the rain the boughs keep quite fresh." It would therefore seem that at least rainy seasons are favourable to the *Yama-Maï* larvæ, and this point is the only one which seems to me to throw any doubt on the probable success of the cultivation of the worm in Europe. Ireland would, therefore, seem to be a country specially favourable; for the same reason the north-west coast of England and Scotland, as perhaps also the south-west coast, would be specially favourable; whereas the eastern counties are probably the worst.

The cocoons of *Bombyx Yama-Maï* are of a green tint, are spun up in the oak leaves, and weigh 7 to 8 grammes each; whereas the cocoons of *Bombyx mori* weigh 2½ to 3 grammes each. The silken material is in the same proportion, viz., 70 to 80 centigrammes; that of the mulberry 25 to 35 centigrammes.

To estimate the resultant silk in weight from a given number of cocoons, it is customary to allow 12 lb. of cocoons to make 1 lb. of silk, allowing for waste, etc. The *Yama-Maï* cocoon will have a slight advantage in this over the mulberry cocoon, owing to its greater size and less waste. It is wound as easily as that of the mulberry cocoons, from end to end in a continuous thread, when placed in boiling water. There are two qualities of silk, the exterior layers of the cocoons being stouter and of a greenish-yellow tint, and the interior of a fine texture and white colour; hence the winding is divided into two operations, so as to preserve the two qualities distinct. Regarding the quality of the silk, M. Gelot pronounced the following opinion at the International Exhibition of Insects at Paris, 1865:—

"The silk of *Bombyx Yama-Maï* seems to me to occupy, after that of the mulberry worm, the highest rank. It is, perhaps, a trifle less fine, but is quite as brilliant as that silk. I believe in many cases it might be employed instead of it; and that if we succeed in acclimatising its production on a large scale, it might make up for our deficiency in the production of mulberry silk. The clear green tint which it naturally possesses is no obstacle to the various shades of dye, for it disappears with washing and becomes white. The rapid development of this valuable branch of industry cannot be too highly encouraged." Elsewhere we read: "Several bales of *Yama-Maï* silk have been purchased at Yokohama, Japan, at 550 piastres the picul (60 kilogrammes). As the piastre is equal to 6 francs, these raw silks fetch at the place of production 55 francs the kilogramme. At the same time and place were sold bales of ordinary silk at 600 to 612 piastres per picul, or 60 to 61 francs per kilogramme, about 25s. per lb."

It will be sufficiently evident, from what has already been stated, that the possession and acclimatisation of a very valuable race of silkworms in Europe is at the present time *un fait accompli;* and that although up to this time we have not succeeded in England in rearing this worm, yet we have good grounds for expectation that as a greater knowledge of its habits and of the precautions necessary to a successful cultivation are diffused, we shall find many ready to take up this new culture in Great Britain and Ireland.

CIVIL ENGINEERING.—XVII.

BY E. G. BARTHOLOMEW, C.E., M.S.E.

LIGHTHOUSES.

THE necessity for enabling ships to avoid dangers from rocks, and to safely enter harbours during the night, must have been obvious to the very first men who undertook a voyage during which land was lost sight of: we may, therefore, reasonably infer that lighthouses or light-giving beacons were coeval with navigation. Moreover, it is obvious that the position of these beacons must have been well known, and would have occupied fixed positions.

We have very early and authentic accounts of structures erected by the ancients with the object stated, of most magnificent designs and dimensions. Indeed, in all the engineering works of the ancients we behold the marvellous combination of beauty, strength, and utility, which as regards the first qualification is sadly wanting in modern structures. The Pharos which stood in the centre of the breakwater guarding the entrance to the port of Ostia may justly claim a few words of notice. Its description reads almost like a fable. It consisted of four distinct storeys, of which the lower three were decorated with orders of architecture, the bottom being the Doric, the second the Ionic, and the third the Corinthian. The fourth or upper storey was surmounted by a fire, which was always lighted at the approach of night, and which, from the height of the structure, could be seen at a great distance. The building was equally convenient as a residence for the officers and men who had charge of the port. Immediately in front of this Pharos stood a colossal statue of the Emperor Claudius.

A still grander, although less architectural, beacon was erected at Alexandria upon the island of Pharos in the reign of Ptolemy. This structure was built upon a rock at the eastern extremity of the island. It was 450 feet in height, and it is stated that the fire which was kept burning at night upon its summit could be seen at a distance of 100 miles; this, however, is doubtful. The Pharos was formed of several storeys, decreasing in dimensions towards the top. The ground floor was hexagonal; the second and third storeys were of the same form; the fourth was square, with a round tower at each angle; and the fifth circular, which was continued to the top or lantern, to which a winding staircase conducted. This immense structure was built entirely of stone.

Descending to more modern periods, we may refer with some degree of pride to the many excellent lighthouses erected upon different points of our own coasts at various times, commencing

about the year 1676. The whole of the beacons and "signs for the sea," as these structures were called, situated upon the English coast, were placed under the entire control of the corporation of the Trinity House by Queen Elizabeth; those in Scotland under the Commissioners for Northern Lighthouses, and those in Ireland under the superintendence of the Ballast Board. These three bodies collectively have under their supervision upwards of 200 lighthouses and floating lights.

One of the earliest erected by the Trinity Board was at Lowestoft, on the eastern coast. It is a circular tower of brick, 40 feet high and 20 feet in diameter. Its upper storey was originally glazed all round, and the light was obtained by a coal fire. This arrangement, however, was altered by the Trinity House in 1778, and a more modern and effective lantern was substituted.

The character and mode of construction of a lighthouse will differ essentially according to the position it has to occupy. It may form an efficient beacon if standing upon a projecting headland, and in no way exposed to the violence of the sea; in such a case not more than ordinary precautions need be adopted in its construction. Very different, however, will be the case when the lighthouse has to stand upon some bare isolated rock, removed many miles from any shore, and exposed to the full fury of wind and wave. Then all the skill of the engineer has to be brought into play, and every mechanical device has to be enlisted to enable the friendly beacon to retain its hold against huge mountains of water hurled at it and over it by the tempest's violence.

One of the earliest of modern lighthouses, and one of the most magnificent structures of the kind in the world, is situated at Cordouan, upon a rock at the mouth of the Garonne, the credit of it being due to Louis de Foix, a French engineer. It was commenced in 1584, and occupied twenty-six years in erection. The tower is 169 feet high from its foundations. The island rock upon which it stands is dry at low water, but entirely covered by the tide at high water. The base of the structure is a circle of 135 feet in diameter, and consists of a mass of masonry, solid, with the exception of the approach steps and the fresh-water cistern, and is carried to a height of 20 feet, terminating in a level platform, upon which the tower stands. This solid base is bounded by sloping sides, reducing the diameter of the platform to 125 feet. It is surrounded by a massive wall for protection against the violence of the surf, 12 feet 6 inches thick at the base and 11 feet at the top, and 12 feet high. The tower itself is 50 feet in diameter at the base, and consists of four storeys. These are highly decorated externally. The lowest is of the Doric order, the second of the Ionic, the third of the Corinthian, and the highest or lantern of the Composite. The original lantern was destroyed in 1727, and a new one of iron substituted. This was effected by M. Betri, who contrived a sort of iron cage or lantern formed of four pillars which supported a cupola, finished with a ball and vane. The lantern was open to admit of the free escape of the smoke from the burners. The circular ceiling was formed into a hollow funnel, the top of which was bent three feet downwards, and being covered with polished tin plates, it served as a reflecting surface for throwing the rays of light to a greater distance. This rude form of reflector became the original for the introduction of a more perfect contrivance which was introduced by M. Borda about the year 1780. His arrangement consisted of an argand lamp which was placed in front of a parabolic mirror. The mirror was formed of a sheet of copper plated with silver and burnished, having a focal length of about four inches, and a diameter of 21 inches. The form of the perfect parabola causes the rays thrown upon its surface from a point of light placed in its focus to issue in parallel lines, so that the area of the reflected beam will not exceed the area of the mirror, and hence it becomes necessary to place the burner a short distance out of the focus, whereby the rays become diverted and spread over a greater space. As a work of art, the lighthouse at Cordouan occupies a foremost position: we shall now have occasion to call attention to some other structures of the kind which, as works of engineering skill, will compare with any either of ancient or modern date.

There exists in the English Channel, in the route of thousands of ships passing and re-passing every year, a group of rocks of a stone called in Cornwall "moorstone," being either gneiss or granite. It lies nearly due south of the promontory called the Ramhead, from which—the nearest point of land—it is about ten miles distant. This group, called the "Eddystone," from the set of the tides and the violence of the eddies and currents which exist there, has always proved a source of extreme danger to shipping, being nearly submerged at high water; and it is a fact that previous to the erection of a beacon upon them, many wrecks occurred upon the rocks surrounding the Channel Islands, owing to the fear entertained by sailors of the Eddystone, which induced them to choose a more southerly course to avoid them. It is, therefore, not surprising that a very early attempt was made to fix a structure upon these rocks which should be capable of resisting the fearful violence of the storms which, coming from the west and south-west, hurled their full force upon this dangerous reef.

The first attempt to erect a lighthouse here was made in 1696 by Winstanley, who worked under the powers invested in the Corporation of the Trinity House by Queen Elizabeth. Winstanley appears to have been an amateur engineer, although certainly a man of considerable genius and capacity, and the fact that he attempted a lodgment at all upon the Eddystone, proves him to have been possessed of great courage and strength of purpose.

Winstanley's lighthouse occupied from three to four years in building. Owing to the exposed position of the rocks, and the almost continual surf which breaks over them, great difficulty and interruption was experienced in fixing the lower portion of the work. The plan adopted was to bore holes in the rock in certain positions, and to fix iron rods therein to form the main-stay for the masonry which was subsequently built around them. The whole of one summer was occupied in boring twelve holes, each 3½ inches in diameter, in a circle about 13 feet across, and securely fixing the iron rods in them. During the second summer a solid mass of masonry 14 feet in diameter, and 12 feet high from the upper surface of the sloping ledge of rock, and 17 feet high from the lower part, was built up around the twelve iron rods. During the third year the upper works were completed. The building as it then stood was 80 feet from the foundation to the vane. It is probable that the upper part of this building, which contained several storeys, was constructed of timber.

Winstanley ventured to remain in the completed lighthouse with several workmen for a considerable period during the summer of 1698, but a severe storm arose which dashed water into the building and did considerable mischief. This, however, was repaired, and a light exhibited for the first time in November of the same year. During the following year it was deemed necessary to strengthen the work; and whilst the diameter of the base was increased to 24 feet, the masonry was carried up solid to a height of nearly 20 feet. This building—which, from the print published by the architect, seems rather to have resembled a Chinese pagoda than a lighthouse—withstood the force of wind and weather for four years, and there is a well-known statement that Winstanley was so satisfied with the stability of his structure, that he expressed a desire to be in it during the fiercest storm that ever blew. He had his desire, for in November, 1703, a terrific tempest arose whilst he was at the rock superintending some repairs, and when the morning of the 27th of that month broke, nothing remained of the lighthouse or of the unfortunate inmates. The rock had been swept bare.

Winstanley's attempt had, however, proved the possibility of planting a structure upon the Eddystone capable of withstanding ordinary weather, and it was hoped that, by adopting greater precautions, a permanent building might be fixed there.

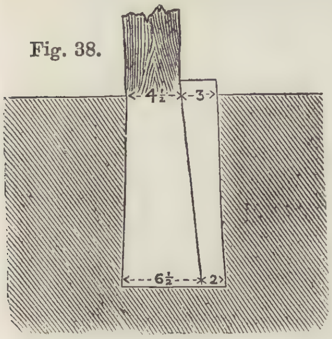
John Rudyerd, a London silk mercer, was in 1706 employed to re-construct the lighthouse. The extreme necessity for such a building was not long in becoming evident, for very shortly after the first structure had been swept away, a splendid ship, the *Winchelsea*, was wrecked upon the dangerous reef, and almost all on board perished.

Rudyerd was not an engineer, at least not by education; this profession did not exist as such in his time, but he formed one amongst other bold, self-taught men who have existed in almost all ages, and whose genius is only brought to the front when some necessity for its development arises.

The second building was, like the first, erected under the auspices of the Trinity House. Rudyerd was, however, not employed directly by the Brethren, but by a Captain Lovet, who under the authority of an Act of Parliament was permitted to take a lease of the intended lighthouse, with its tolls and perquisites, for ninety-nine years. Rudyerd seems carefully to have

studied his subject before commencing work. He adopted the circle as the form for the plan of his building, and carried up the structure as a cone, thus selecting the form which offered the least resistance to the force of the elements from whatever quarter they burst upon it. Smeaton has left us in his narrative some interesting facts connected with Rudyerd's engineering arrangements. From him we learn the following:—A number of holes were bored or "jumped" in the rock, the formation of the holes being peculiar. The object of the designer was to cut wedge-shaped holes, the widest end of the wedge being downwards, and to insert iron bolts into these holes, keying them at the bottom so as to spread them out after their insertion, whereby it became impossible to withdraw them. This arrangement was, in fact, none other than the well-known engineering contrivance called a "lewis." The method adopted was to bore two holes $2\frac{1}{4}$ inches in diameter in a sloping direction, that is to say, they were $7\frac{1}{2}$ inches apart at the surface of the rock, and $8\frac{1}{2}$ inches at the bottom, the depth being about 16 inches. A third hole was bored between these vertically, and the rock between them was then cut away by suitably-shaped tools. By this means a hole of a dovetailed shape was obtained $2\frac{1}{2}$ inches wide, $7\frac{1}{2}$ inches broad at top, $8\frac{1}{2}$ inches wide at the bottom, and 16 inches deep. The iron branches inserted into these holes were specially forged for their positions. They were $4\frac{1}{2}$ inches broad at the surface of the rock, and $6\frac{1}{2}$ inches broad at the bottom, so that a space was left upon one side after they were introduced into the hole of 3 inches at top and 2 inches at bottom. Fig. 38 will explain the arrangement, and will show how secure the irons must have been when so fixed. To make assurance doubly sure, however, a quantity of melted tallow was poured into each hole, and the iron and key heated to a blue heat were then inserted, and the key driven home; then, whilst the iron remained warm, a quantity of red-hot pewter was poured in, which being heavier than the tallow, drove it out. So firm and substantial was the entire arrangement, that when, many years afterwards, the irons were cut out, the iron, pewter, and tallow were found unaffected by the sea-water, which appeared never to have penetrated the holes.

Fig. 38.



After the irons were fixed, a layer of squared oak timber was laid upon the lowest level of the rock included in the plan, and of sufficient thickness to reach to the next higher level. Over this was placed another layer transversely, and over this others, every alternate layer being laid across the one next below it. In this manner a solid mass of oak was piled up, the top of which was two courses higher than the highest part of the rock, and the whole mass was securely tree-nailed together. In the centre of this timber was placed an upright mast securely fixed to the rock by strong irons, and carried up 33 feet, or more than half-way up the intended height of the building. Altogether there were thirty-six irons inserted into the rock, and in each of these seven holes, seven-eighths of an inch in diameter, were bored, through each of which a jagged bolt was passed, by which the several layers of timber were held together.

The basement of the tower consisted of two courses of solid oak, and upon these were laid five courses of Cornish moorstone, each one foot thick, the stone being held together by iron cramps without mortar or cement. The outer courses were further secured against the chance of their being lifted by the action of the sea by upright stones. Upon this 120 tons of moorstone were laid, and then two courses of timber, protected at their exposed extremities by horizontal timbers, scarfed together and bolted to the interior timbers. Up to this point the building was entirely solid. Upon this basement a well-hole was commenced to be left around the vertical mast 6 feet 9 inches square to contain the stairs, and at a point 8 feet above the highest part of the rock the step for the doorway was left. The building consisted of alternate layers of moorstone and timber up to the top of the central mast, and then a flooring of 3-inch oak plank was laid over the whole. The upper portion of the building comprised four rooms, one over the other, formed of upright timbers based upon and headed by a circle of timber to which their extremities were secured. The upright timbers were very securely connected together by tree-nails and bolts. The floor of the lantern was formed of 3-inch oak plank, and around this was the balcony.

The dimensions of the finished structure were as follows:—22 feet 8 inches diameter at bottom; 14 feet 3 inches diameter at top; the height from the circular base to the top 61 feet. The upright timbers which covered the entire exterior of the building varied in length from 10 to 20 feet, united at their extremities by scarfing and overlapping, care being taken that no two scarfs adjoined each other. The uprights were seventy-one in number, made of timber 9 inches thick at the base of the building, and 12 inches broad at the same part, but gradually diminishing towards the top in breadth and thickness. The outside seams between these uprights were caulked with oakum and pitched. The entire weight of stone employed in the building was estimated at 270 tons, and undoubtedly served as ballast in steadying the building. The doors and the shutters to the windows were composed of double plank crossed, and shut close in a rabbet to prevent the ingress of water.

That such a building should have withstood the tempest for fifty-five years is a proof of its strength, and, indeed, its career might have been much longer had it escaped destruction by fire, a calamity which happened to it in December, 1755. There can be no doubt that one of the chief errors in the construction of Rudyerd's lighthouse was the great quantity of timber employed in it, and its employment in such vital position as it occupied in the building.

The magnificent structure which was to follow will be described in our next chapter.

PHOTOGRAPHY.—IX.

By J. C. Leake.

DRY-PLATE PROCESSES: FOTHERGILL'S—COLLODIO-BROMIDE.

The collodio-albumen process described in our last article, while it may be considered as one of the most certain and reliable, is yet somewhat too complicated to become a favourite with those operators who have been used to the simple and rapid preparation of the ordinary wet collodion plates. In this article we therefore propose to describe the processes known as Fothergill's, as well as that which has received the title of collodio-bromide; both of which are more easily manipulated, and perhaps more sensitive than the collodio-albumen, although more delicate and not quite so certain in their action. The Fothergill process is one which will be found exceedingly useful to the photographer who may be constantly employing the ordinary wet collodion process, inasmuch as any good bromo-iodised collodion and the ordinary nitrate-of-silver bath will answer for the preparation of the plates, thus avoiding both the outlay and the trouble of keeping two separate sets of chemicals. The collodion for this process should not be too freshly iodised, as in practice it has been found that an old sample not only produces better results, but that the film adheres more closely to the glass during the various washings which the plate has to undergo. A sample containing a full amount of bromide should be selected, as tending to produce greater softness, as well as helping to secure cleanliness during the development. The only solution required beyond those employed in the wet collodion process will be one of diluted albumen, prepared as follows:—Pure albumen (from fresh eggs), four ounces; distilled water, four ounces; strong ammonia, twelve minims. Mix and thoroughly beat up, as described for the collodio-albumen process. This solution must be filtered before use. After exciting the plate in the usual manner, wash carefully in filtered rain-water, or, better still, in that which has been distilled, so as to remove the whole of the free nitrate of silver. Now immerse the plate in a bath, or flood it with the following solution:—Nitrate of silver, two grains; distilled water, one ounce. If this solution be poured over the plate, allow it to remain on some minutes. The albumen solution should then be poured over the film two or three times, and the plate washed very carefully with a moderate quantity of filtered rain-water. This final washing is of the utmost importance, as upon the proper performance of this much of the success of

the operation will depend. The object is to leave a sufficient trace of the albumen upon the surface of the plate, and consequently a measured quantity of water is used for this purpose, in order to ensure this result. It is difficult to state the exact quantity which should be employed for this purpose, as it seems to vary with the quality of collodion and other circumstances; but as an example, it will mostly be found that one pint will be sufficient for a plate of eight inches by six. After this washing, the back of the plates should be wiped dry with blotting-paper; and they may then be dried in a warm and dry box, of course most carefully preserved from light or dust. The average exposure will be from twice to three times that required for wet plates; and although these plates may be kept for some time both before and after exposure, by far the best results will be obtained by exposing as soon as possible after preparation, and developing within a short time after exposure. Nothing like the same latitude can be allowed in this as in the collodio-albumen process, and it could not be considered safe to keep these plates more than a fortnight before and a few days after the exposure to light in the camera. The plate after removal from the camera should be flooded with distilled water, to which has been added a small proportion of alcohol, and when the film has been thoroughly wetted the developer may be applied. For the process above described, the following will be a proper developing solution:—Pyrogallic acid, two grains; distilled water, one ounce; a few drops of alcohol may be added if required. In a few minutes the picture will begin to appear (if it should be unusually slow in development, a trace of nitrate of silver may be added to the solution), but it will be exceedingly thin. When all the details are developed wash off the solution, and proceed to intensify with the solution composed of pyrogallic and citric acids, as recommended for the ordinary wet collodion process; to which must be added nitrate-of-silver solution as required.

As we have before remarked, the intensity of negatives by dry processes must not be estimated so much by the actual density as by the colour of the deposit, and hence over-development must be most carefully avoided. In this, as in the collodio-albumen process, the hyposulphite-of-soda solution will be the proper fixing agent.

A somewhat important modification of this process has recently been introduced with considerable success by Dr. Ryley. In this the plate, after having been sensitised and thoroughly washed as before described, is coated with the following albumen solution:—Albumen, two ounces; water, four ounces; ammonia, one drachm. This solution to be well mixed as above described, and filtered before use. Allow this to thoroughly soak into the film, thoroughly wash the plate with distilled water, and dry. When perfectly dry moisten with distilled water, and cover with the following solution:—Gallic acid, four grains; distilled water, two ounces. Filter before use. Allow this solution to thoroughly soak into the film, and dry without washing off the gallic acid. Plates thus prepared will retain their sensitiveness for five or six months, and they are particularly clean and free from stains and markings. It is necessary, however, to be particularly careful to remove the whole of the nitrate of silver after the sensitising process. The development may be conducted precisely as in the ordinary Fothergill process before mentioned.

The next process of which we shall have to treat is one which will tax the care and manipulative skill of the operator to a considerable extent, and which should therefore not be attempted until he has acquired considerable experience in other and less delicate and complicated work. The process to which we refer is termed by its inventors, Messrs. Sayce and Bolton, the collodio-bromide; and one of its chief peculiarities is that it dispenses with the nitrate-of-silver bath common to all other methods of preparing a sensitive surface by means of a collodion film, the collodion in this case itself containing the sensitive salt. The collodion suitable for this process is composed as follows:—Pyroxyline (gun-cotton), six grains; ether and alcohol, of each, half an ounce; bromide of cadmium, six grains; bromide of ammonium, two grains. Dissolve the salts in the alcohol, mix with the ether, and add the pyroxyline, until dissolved. This collodion may be mixed in any quantity, as it will keep an indefinite time, but it should be allowed to stand at least a week before use. In order to render this collodion sensitive, nitrate of silver must be added to it in the proportion of from eleven to thirteen grains to the ounce of fluid; the smaller quantity being the safest, and the larger producing the most sensitive film. The nitrate of silver must be ground to the utmost degree of fineness in a glass mortar, and be added by degrees to the collodion in the proportions above given, with constant agitation, in order to ensure perfect combination. Of course this mixing must be effected in non-actinic light, as the compound is exceedingly sensitive to light; in fact, it must be treated precisely as a sensitised wet collodion film in this respect, the smallest ray of light being sufficient to spoil it. After resting a few hours the sensitive mixture will be ready for use. The plate may now be coated exactly as in the wet collodion process; although it may be at times advisable to coat the edges of the glass for about a quarter of an inch over their surface with a solution of india-rubber in benzole, in order to prevent the slipping of the film. When coated allow the collodion to become thoroughly set (much more so than in the ordinary wet process, when a bath is employed), and wash in a dish of water until the greasiness upon the surface disappears, and the water flows freely over the film. The plate will now be ready for the final immersion in a solution prepared as follows:—Dissolve in four ounces of hot water twelve grains of gallic acid, forty grains of tannin, and twenty grains of grape-sugar; and when cold one drachm of alcohol. This solution may be used almost indefinitely. Into this solution immerse the coated plate, and allow it to remain three or four minutes; upon removal drain thoroughly, and dry as in the ordinary process, when it will be ready for exposure in the camera. The time usually recommended for exposure is three times that required for a wet plate, but the writer has found that plates prepared with a full quantity of silver will not, under favourable conditions, require more than twice the exposure necessary for ordinary collodion work; and it should be remembered that the powerful developing agent proper for use with these plates will often enable the operator to bring out an image even when the exposure has been slightly shortened. The proper developing agent for collodio-bromide plates is one of comparatively recent introduction, and is known as the alkaline pyro-developer.

In the preparation of this developer it is advisable to make up stock solutions in three separate bottles, as follow:—No. 1 should consist of pyrogallic acid, one and a-half drachms; absolute alcohol, one ounce. No. 2, carbonate of ammonia, one and a-half drachms; water, one ounce. No. 3, bromide of potassium, ten grains; water, one ounce. When required for use, mix solution No. 1, ten minims; solution No. 3, five minims; water, one ounce; and pour them over the wetted plate. After remaining upon the surface about half a minute, pour this solution back into the developing-glass, and add four or five drops of the carbonate-of-ammonia solution, and apply the mixture to the plate again. In all probability the developing will commence almost instantly, and should it appear too rapid the action must be checked by the addition of a few drops more of the bromide solution. Should the development be tardy from under-exposure or other causes, more of the pyrogallic solution must be employed, leaving the bromide out altogether. With careful and judicious treatment, the development will not take much longer than is required for wet plates, but it is better to work slowly than to hurry the process in the least degree. It sometimes happens that plates develop well, but with little intensity. In this case it is better to wash off the alkaline developer, and complete the intensification with ordinary pyrogallic acid and silver, as in the wet process. It must here be explained that in the compound developer given above the chief reducing agent is the pyrogallic acid, the action of which is considerably intensified by the addition of the carbonate of ammonia. The bromide of potassium is simply a restraining agent, employed to keep the other chemicals in something like order; in fact, it plays the same part as acetic or citric acids in the ordinary processes, and the addition of too much of it will not only restrain the action of the pyrogallic acid, but altogether destroy it, and prevent any development from taking place. When sufficient density has been obtained, the plate may be fixed in the usual way; but it has been advised that cyanide of potassium be used instead of the hyposulphite of soda, on account of the latter causing an increased tendency on the part of the film to leave the glass upon which it is supported.

In concluding this part of our subject, we may here recapitulate some of the most important points which must be observed if the highest success be desired in dry-plate work. In the first place, the glass plates used must be of good quality, and most perfectly cleaned; in the wet process this is important, but much more so in the dry. In the former case the film in its sensitive condition is only in contact with the glass for a comparatively short period, while in the latter it may be for days or weeks. This, of course, gives full scope for any deleterious action which may be set up, and the result is dirty and spoiled plates, many failures, and much disappointment. Besides being quite clean, however, the plates should be perfectly dry, or there will be a greater tendency to splitting and tearing up of the film during the washings which it will have to undergo. When coating the plate, allow the collodion to become well set before immersion in the nitrate bath, or the same tendency will be manifested. Be sure to keep the nitrate bath up to its full strength, and always test it with a wet plate to ascertain that it is in good working order before preparing a batch of dry plates. Allow full exposure in the camera, as a little over-exposure can be remedied, but under-exposure never. Before proceeding to develop a plate, varnish the film about a quarter of an inch round the margin; this will prevent the water getting under it and breaking it up. Wash well after fixing, or the hyposulphite will destroy the negative; above all things, be careful in the water used for washing plates before exposure, as many failures may be traced to the employment of that which is impure. It is for this reason that we have advised the use of distilled water in many cases when ordinary water is usually recommended. Finally, the utmost care and cleanliness must be observed, especially in the dishes and vessels employed for washing the sensitive plates.

SEATS OF INDUSTRY.—XXVI.

NEWCASTLE-UPON-TYNE (*continued*).

BY WILLIAM WATT WEBSTER.

To continue our account of this town, within the past few years the making of fire-bricks has attained gigantic proportions, about eighty millions being manufactured yearly in the district; and gas retorts and sewage pipes are produced in large quantities, and sent to all parts of the world. Grindstones from the Newcastle quarries are made at the rate of about 100,000 per annum, and Portland and other cements are manufactured to the extent of some 11,000 tons. There are several large paper works of high reputation, and several large tanneries in the vicinity of Newcastle. Between five and six hundred dozen hats and caps are weekly produced in the hat factories of the town, which employ an aggregate of about 500 persons; and coach-building has in recent years become an important trade. Besides those we have enumerated, a large variety of minor industries are actively prosecuted in and about Newcastle. The trade of the port consists chiefly of coal, and articles for the manufacture of which coal is largely required. Including North Shields and South Shields, which may be considered sub-ports of Newcastle, more vessels are owned on the Tyne than belong to any single port in Great Britain, Liverpool and London excepted.

Newcastle is situated on the north bank of the Tyne, and is 9½ miles from its mouth, 54 miles east of Carlisle, 244 miles from London by road, and 275 by the Great Northern Railway. It stands partly on an elevated terrace, and partly on ground that slopes towards the river. The pits from which the coal is obtained lie within about two miles of the Tyne, and extend from within two miles of its mouth for sixteen or eighteen miles up the river. There are upwards of fifty large collieries at work within eight miles of the town. During the past fifty or sixty years very extensive improvements have been made in the streets and houses of Newcastle, and it is now one of the handsomest towns in England. Formerly a large proportion of the houses were constructed of timber, with the upper storeys projecting over the lower, and quaint gables and dormer windows, and at a later date they were built of brick; but all the modern streets are lined with houses of stone, which is found in abundance in the neighbourhood. It was principally through the exertions and public spirit of an enterprising citizen, named Richard Grainger, that this change was effected; but an extensive conflagration that took place in 1854 also indirectly contributed to the improvement of the town. Many of the streets, squares, and public edifices possess great architectural beauty, and the town is excellently lighted and paved. The water-supply, which is abundant and of good quality, is derived from streams and small rivers to the north-west of the town. The railway viaduct, or High Level Bridge of Newcastle, is one of the engineering triumphs of Robert Stephenson. This gigantic work is 1,337 feet in length, and its height above the water-mark is 112 feet. It consists of four river and two land arches of cast iron, supported on piers of masonry; and below the railway there is a carriage road for ordinary traffic 35 feet wide. The entire structure cost £491,153, and was opened by Queen Victoria in 1849. All the railways entering the town stop at a large station near its centre, and nearly seventy trains arrive and depart daily. The market for the sale of butchers' meat and vegetables, constructed by Robert Grainger, is 310 feet in length, has an area of 9,050 yards, is lined with 243 shops, besides stalls, and is entered by 14 doors. It is one of the most spacious and convenient public markets in the kingdom. A bi-weekly corn, and a weekly hay, produce, and cattle market are held in Newcastle, and both are of considerable commercial importance. During the year 1862, 54,936 fat cattle, 286,110 sheep and lambs, and 34,544 swine were sold in the cattle market. The Newcastle News Room is one of the finest in Great Britain; and the theatre, situated in Grey Street, the handsomest thoroughfare in the town, is an elegant building, designed after the Pantheon at Rome. There are thirteen churches and chapels connected with the Established Church in Newcastle, and about twenty-eight places of worship belonging to other denominations. The most ancient and interesting ecclesiastical edifices are the church of St. Nicholas—originally founded in 1091 by Osmond, Bishop of Salisbury, and placed under the jurisdiction of the Bishop of Carlisle—which was burned in 1210, the present structure having been finished in 1359; and St. Andrew's Church, said to have been built by David, King of Scotland, partly Norman in style, with a large but low embattled tower. Among the educational and literary institutions of the town, the most noteworthy are the Free Grammar School; the School of Medicine and Surgery, the lectures at which qualify for the diploma of the London College of Surgeons and the licence of the Apothecaries' Company; and the Literary and Philosophical Society, established in 1693, which occupies a handsome Doric building, and possesses a museum and a library. The principal monuments in Newcastle are a column, surmounted by a statue of Earl Grey, erected in commemoration of the passing of the Reform Bill of 1832; and a bronze statue of George Stephenson.

During the present century the population of Newcastle has increased at nearly the same rate as other English towns. In 1801 there were in the borough 28,366 inhabitants; in 1811 the number declined to 27,587; in 1821 it rose to 35,181; in 1831 it was 42,760; in 1841, 69,430; in 1851, 87,784; in 1861, 109,108; and in 1871, 128,164. Although in a different county, and under a separate jurisdiction, Gateshead, on the opposite bank of the Tyne, must be considered as a suburb of Newcastle. The population of Gateshead ought, therefore, to be added to that of Newcastle, and in 1851 there were in Gateshead 25,568 inhabitants, making a total population for Newcastle, plus Gateshead, in that year of 113,352. In 1861 the population of Gateshead was 33,587, which, with the population of Newcastle, makes a total of 142,695; and in 1871 it was 48,592, giving in the same way an aggregate population of 176,756. The electoral limits of Newcastle were enlarged under the Boundary Act so as to include, with the old borough, the townships of Jesmond, Heaton, Byker, Elswick, and Westgate. Newcastle was divided by the Municipal Act into 7 wards, and is governed by a mayor, 13 other aldermen, and 42 councillors, and has a commission of the peace under a recorder. The town has the privileges of a county, and it is represented in the House of Commons by two members. Among the eminent natives of Newcastle are numbered Duns Scotus; Mark Akenside, the poet; Hutton, the mathematician; Lord Eldon, the celebrated Lord Chancellor; his hardly less celebrated brother, Lord Stowell; and Admiral Collingwood. Intimately connected with the town, though not born there, were Thomas Bewick, the famous wood engraver; Robert Morrison, the Chinese scholar; and George and Robert Stephenson, the engineers.

SANITARY ENGINEERING—XIX.

CLOSETS AND TRAPS.

In our last paper we gave some detailed information as to the saving of water by means of flushing cisterns, and also alluded to the necessity of providing ventilation for systems of pipes. We now approach a branch of the subject which, although it may not be considered pleasant by the general reader, is perhaps, considered from a strictly sanitary point of view, superior in importance to any that have preceded it, as we now come in contact for the first time with a matter which has recently occupied no small share of public attention—namely, sewage gases; and before entering upon the mechanical details, it may be as well to show to a certain extent the nature of the dangers to be apprehended and the difficulties to be overcome.

Sanitary engineering, as far as this particular branch of it is concerned, may be dated as commencing within a century. Previous to that date the old cesspool system was almost alone in operation, and although probably, or indeed certainly, the various complaints arising from imperfect hygiene were as widely spread and as deadly in their effects, public scientific attention had not been awakened, and the information now at our command was not available. And here let us note that it is by no means the most offensive gases that are the most deadly. As an extreme instance, we may quote a case which occurred in the western part of London some years ago, when on entering a large section of a public sewer which had been hermetically closed for some time and out of use, and through which no current either of water or air had passed, some of the party were actually and instantly stifled by the deadly vapour. Others who escaped with difficulty described the only warning of danger they received as something like a faint smell of rotten cheese.

Again, in another form, in a house recently erected in the north of London, three successive families who occupied it lost almost immediately several of their members by typhoid fever, although there was no such distinct intimation of the presence of defective drainage arrangements at any time as would be sufficient to attract attention. This we may take for granted, as otherwise the house would not have been entered by fresh tenants at comparatively short intervals of time without some investigation being made. Ultimately the case was taken up by the local sanitary authorities, when it was discovered that beneath the surface of the basement was a bed of partially decayed vegetable and sewage matter, from which this sewer poison arose, though its presence was not so patent as to be detected by any ordinary occupant. Quoting from a pamphlet by Dr. Alfred Carpenter on this subject, he says:—"It was not until the general introduction into towns of closets and pipe-sewers that the injury produced by the gas was sufficiently isolated to be positively identified. The result of the introduction of closets within the walls of our houses casts a reflection which is not altogether deserved, and which need not necessarily be borne. This mischief has arisen from a neglect of a natural law—viz., not providing for exits as well as for entrance, sewers not being, like soda-water bottles, sufficiently impermeable as to allow of being charged with gas under pressure."

In succeeding practical illustrations we shall more than once have occasion to refer to this axiom, as we may term it. In the early sanitary works which were carried out under the authority of the Public Health Act of 1848, the consequences of sewer gas not being foreseen, were not provided against. No provisions were made to prevent its ascent into the house or exit into the open air before it could reach the inside of the dwelling. "As a factor in the production of typhoid fever its power is now well known; many other disorders of the system have been directly traced to its influence, diarrhœa, dyspepsia in all its forms, various forms of asthma, and headaches constant and intermittent."

The same author also quotes a very telling case of ill-considered trapping. When the Warehousemen and Clerks' Schools at Russell Hill were first opened the children were in the enjoyment of good health, but in the autumn of 1867 typhoid fever made its appearance. It seems that a smell at first slight, but afterwards intense, had been perceived in the laundry. The place of exit was trapped, and the smell prevented at that place from the sewage gas until it reached the interior of the building. The consequence was that it was conveyed from the cesspool by the pipe-sewers into the lower part of the building, and then into the other rooms. The arrangements for general ventilation being deficient, and many of the rooms heated by hot water, so that there were no open fires, an accumulation of sewer gas frequently took place during the night, and the children entering the rooms before breakfast were exposed to its influence under the most unfavourable circumstances, the result being that 40 per cent. suffered from forms of typhoid fever, which was, however, fortunately of a mild type.

Instances might be multiplied almost indefinitely showing the deleterious effects of sewer gas. The last two we have quoted show how in positions where such a result might be considered quite unexpected, its evils were experienced, and we must leave untouched the vast question connected with the crowded dwellings of the poorer classes, where in many parts of London and our larger provincial towns, sanitary arrangements, though much improved of late years, are still lamentably defective.

Having thus briefly indicated the direction in which precautions have to be taken, we now proceed to the mechanical part of the question, merely premising that each example selected is only one of a class. The number of appliances patented within the last twenty years may probably be reckoned by hundreds, some entirely novel, some merely adaptations; and we commence with the general statement that in all closets treated in the present paper the water-lute or hydraulic seal is the principle adopted. With earth-closets and other methods of sewage disposal, in which different methods are employed, we propose to deal at length in future articles. The general principle of the water-lute is that a body of water shall always be maintained at the topmost part of any system of sewage delivery, so that no free air-passage for gas is left open. The simplest form for illustration of the principle is the old-fashioned brick trap with a dipstone, as in Fig. 14, applied in an ordinary drain.

We give this illustration at this point to show the simplest possible arrangement for the passage of sewage and water and the exclusion of air in the course of an ordinary drain, assisted by flushing, and the necessary currents to which drains should always be laid. It will be seen that the "dipstone" has its lower edge always in the water, thus stopping all passage of air; but there is this remark to be made, that a "*double trap*," as it is technically called, is invariably a source of failure and discomfort. Supposing by some blunder two of these traps constructed in one drain within a few feet of each other, the gas contained in the intermediate portion of the drain immediately becomes "water-bound," and instead of passing away through the second trap, this acts as a check upon the air or gas, whichever may happen to fill the space, and although the sewage or water may run off, the gas confined between the two traps, instead of passing off through the *second*, will bubble up through the *first*, unless (and here we may refer to our last paper on the ventilation of pipes) an *exit* to the external air is provided, either in the shape of an air-pipe or by some other means. We give this illustration in the plainest form, as it embodies the one leading principle of all closets or traps where water is used, however complicated in their appliances or expensive in their fittings—to provide an efficient hydraulic lute or water-seal, and avoid all chance of "*back* pressure," whether arising from double-trapping or tidal influences, a most important point for consideration in low-lying districts, such as Bermondsey, or waterside localities, such as Scarborough.

The plain general principle thus stated, we arrive at the first portion of the subject proper of our paper, "Closets," and proceed to give a few illustrations of the appliances now in general use, with a few words of explanation as to each. The great improvements in what may be called sanitary pottery have placed us very far in advance of the last generation in this respect. Our first (Fig. 15) is a plain cottage trap, dependent upon simple flushing, without any mechanical contrivances. This is made of plain earthenware.

Our next illustrations (Figs. 16, 17) show the action of one of the most recent improvements in earthenware. It will be seen that the valve, closet, and trap are manufactured in one piece of earthenware. The manufacturer is Mr. George Jennings, of Lambeth.

We now pass to various descriptions of closets where the basin only is in china and earthenware, and other portions of fittings in metal. Fig. 18 is what is ordinarily described as a *pan* closet. Within the receiver A (Fig. 18) is contained the hinged pan B (Fig. 19), and the water-line, when shut, is indicated as before.

SHOWING WATER-LINE FOR VERTICAL PIPE.

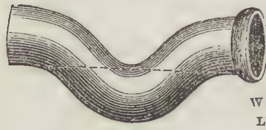

Fig. 23.

SHOWING WATER-LINE FOR HORIZONTAL PIPE.

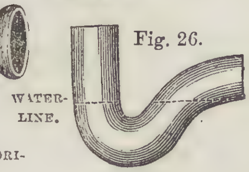

Fig. 26.

Valve closets are differently constructed. Here (Fig. 21) the water-line is maintained by a valve at the bottom of the basin, carefully ground in or maintained in its place, or hermetically sealed by a lever and spring. The valve is at A, B is the lever, and C is the spring. In this case the additional security of what is technically called a D-trap is shown at D; this is made of lead, and its internal construction and water-line are shown in the outline sketch in Fig. 20.

Fig. 22 shows a closet known as Underhay's Patent, which provides a bellows arrangement for the gradual delivery of the water, indicated at A. These closets are often provided with elastic or india-rubber valves, and there are many mechanical details of construction introduced, upon which a volume might be written; but with this last instance we dismiss the question of closets, and proceed to that of traps, of which we shall also give some sketches, showing two or three of the most important improvements recently introduced.

We have now passed the points of construction at which

water-supply and ventilation only are to be dealt with, and have arrived at that period in our papers on "Sanitary Engineering" at which it is to be taken for granted that all air to be dealt with is *foul*, that is to say, charged in a greater or less degree with sewage gases; and the *raison d'être* of *traps*, is to provide a vessel through which, in whatever form it may be constructed, sewage elements may pass if contained in a volume of water, without allowing any air to return by the passage. And here arises a question as to the comparative *size* of pipes and drains. When the subject was, as we may say, in its infancy and little understood, the idea was started that by having the minimum size both of pipe and drain, sewage elements could be forced downwards with their attendant gases, and the whole bodily discharged into the ultimate receptacle, whatever that might be; and at that time it was not uncommon to hear of conveying the whole drainage of a household through a 3-inch pipe. The error in the first place was in the theory, as these gases can never be forced downwards, the effect of any pressure slightly exceeding that of the ordinary atmosphere being sufficient to return them through all the ordinary traps and water-lutes, and to raise them to the surface in bubbles; and in the second place, mechanical, as the accompaniments of ordinary kitchen washings, sewage being left out of the question, were sufficient, by their gradual accumulation of solid matter, grease, or otherwise, to create an absolute stoppage. We quote from a well-known publication :—" In the 'Menzies' system it is supposed that by having pipes only of sufficient size to carry the sewage matter, gases will have no room to form, or be forced downwards. Unfortunately the facts are otherwise. For the pipes often choke at Aldershot, where this system is in operation, and the *matter* (*sic*) bubbles up, entailing a cost of several hundred pounds annually to open and repair them, in effecting which it is impossible to avoid danger from letting loose some of the gas."

A pipe of ample size, well flushed and thoroughly ventilated, has been proved by experience to be the only efficient medium for removing sewage. Into the detail, construction, and manufacture of the various descriptions of pipes we do not here enter, as under another heading in the series of THE TECHNICAL EDUCATOR these questions will be dealt with at length. We content ourselves with giving a few sketches (Figs. 23, 24, 25), showing the various methods of trapping stoneware drains, marking the water-line in each case. It will be seen that in every case the only protection is the water-lute or hydraulic seal to prevent the passage of foul air.

The D-trap, of which an outline sketch is given in Fig. 20, and which in a slightly modified form is also called a P-trap, was for many years the only form of trap available in plumbers' work. Where size is required, it is made of pieces of lead soldered together, into which the inlet and outlet pipes are secured by similar means. A new form of trap has, however, been introduced within the last few years by Messrs. Beard and Dent, and is the subject of a patent. The trap can be cast in one piece of lead to any size, as may be seen in the sketch, and presents many advantages. There is much less room for the accumulation of sediment, offensive or otherwise, and the absence of joints is a great safeguard against leakage or failure from any similar cause. We subjoin two sketches (Figs. 26, 27) showing the form of trap and the water-line. It will be seen that though the material is different, the principle is identical.

The difficulty overcome, and therefore the secret discovered and made the subject of the patent, was the removal of what is technically called in casting the "core," *i.e.*, the inside of the mould; an ingenious mathematical combination of pieces which we can only compare to a puzzle, and which no diagram could make intelligible, attains the desired effect. The same firm have applied these traps to closets, with various improved valves, india-rubber and otherwise; but having already given some general ideas of that subject, we have no space for further detail.

The last modern improvement is the introduction of ventilating traps, which, while they intercept the passage upwards of foul air from the drains, provide also for its dispersion to the external air *outside* the walls of the house.

We give a section of one, Mansergh's patent (Fig. 28), applied to a sink only, but it will be readily seen how it is also applicable to the *release* of foul air from any system of drainage. Another recently introduced is the invention of Mr. Cottam, an Associate of the Institution of Civil Engineers. It consists of what may be called a twofold trap (Fig. 29), with an exit to the open air in the centre, provided with a body of charcoal as a disinfectant to the gas involved. In giving this we are to a certain extent touching upon the subject of subsequent papers—the disinfection of sewage gases; but as perhaps the most novel effluvium interceptor, as it is termed, which has been introduced, we conclude at this point the subject of closets and traps, one of the most important (as will appear from the cases cited at the commencement of this paper) of all that fall within the province of the engineer.

BUILDERS' QUANTITIES AND MEASUREMENTS.—X.

BY E. WYNDHAM TARN, M.A.

JOINERY AND IRONMONGERY (*continued*).

IN the last lesson we explained at length the methods adopted in measuring the various works which are executed by the joiner in the erection and finishing of buildings. We now proceed to show by examples how those rules are to be put into practice by the measuring surveyor, either in taking out quantities from plans, or in measuring work actually executed. In practice it is advisable to enter the works on each floor separately in the dimension book, so that they can more readily be referred to afterwards, if any question should arise as to the correctness of the measurements. The measurer is also less likely to miss any part of the work by completing each floor before he proceeds to the next. The staircases may be left to the last, unless they differ at each flight, when they may be taken at the same time as the work on the floor to which they belong is measured.

TWO-PAIR FLOOR.

15 0 12 6	187 6	2 cut w. batten folding floor.

No. 2 c. i. brackets and screws.

MINING AND QUARRYING.—XXII.

BY GEORGE GLADSTONE, F.C.S.

BRASS.

CONSTITUENTS — MODERN PROCESS OF MANUFACTURE — ANCIENT PROCESS — YELLOW METAL — PROPERTIES OF BRASS — LACQUERING — ACTION OF ACIDS.

BRASS is an alloy of copper and zinc, in various relative proportions, but the ordinary composition is about 70 per cent. of the former to 30 of the latter. If more zinc be added, the alloy will lose in tenacity; and all the compounds in which there is an absolute excess of zinc are so brittle as to be practically valueless. The ordinary commercial article will often be found to contain some small quantity of lead and tin, but these are generally accidental impurities, often arising from the melting down of old metal to which some solder may be adhering.

The simplest plan of making brass consists in the direct combination of the two metals when brought to a molten state; but even in this some precautions are necessary in order to produce a satisfactory result. The process may either be conducted on the hearth of a reverberatory furnace or in crucibles placed in a kiln. The principal objection to the former is the risk of great loss in the weight of the product from the readiness with which the zinc oxidises and becomes volatilised.

The crucibles used are made of refractory clay; in these a certain quantity of pure copper is placed, and heated up to just the melting-point, when small pieces of metallic zinc are gradually dropped in and allowed to mingle with the other until a suitable proportion has been arrived at. This point will, of course, be determined according to the kind of brass wanted; but in any case the quantity of zinc used will have to be somewhat in excess of that desired to remain in the alloy, as, under the most careful management, 24 lb. of copper and 12 lb. of zinc will only produce $34\frac{7}{8}$ lb. of brass, having the per-centage composition of 68·8 of copper and 31·2 of zinc, showing that the loss is exclusively in the latter metal. Under the repeated re-meltings to which it may be subject in after use, the brass will continue to suffer some further loss in weight, and the relative proportion of copper will be found to be still on the increase.

As soon as the contents of the crucible have properly combined, the metal may at once be poured into sand moulds to make castings; but if it is intended merely to produce ingots of brass, for subsequent rolling or re-melting, closed iron moulds are used, which are gently heated prior to the alloy being poured in. The interior surface of the moulds is previously oiled, and dusted over with a little charcoal powder, to prevent the metals from adhering together.

The original process, but which is now rapidly going out of use, on account of being more tedious and expensive, though it is supposed by some to yield an article possessing superior properties, consisted in exposing the copper in crucibles to the action of a mixture of calamine or blende with charcoal. Calamine and blende are the two ores of zinc of most common occurrence in nature, and by this process of cementation the metal is separated from the carbonate and sulphide with which it is associated in the ore, and unites immediately with the copper without ever existing in a free state.

The arrangement of the furnace used in this manufacture is shown in Figs. 1 and 2, the latter being the horizontal plan at the level, A B, of one of the bed-plates of the kilns, C, D. The air is admitted through E, the open chamber below, and it thence passes up through the perforations (shown in Fig. 2) in the bed-plate, the current being increased by a flue which passes from F F into the chimney G, and which can be regulated by means of a damper as needs may require. On the bed-plate the crucibles H, H, etc., are so placed as not to interfere with the air-holes, and the space between them is loosely filled with coke, care being taken not to choke the draught. Each crucible will hold about 100 lb. of finished metal, but the weight of the ingredients which constitute the charge will be about 140 lb. The proportions of course vary according to the kind of brass to be produced, but the weight of calamine is usually in excess of that of the metallic copper, and the quantity of charcoal about one-fifth of the latter. The copper is always used in a granulated state, so as to present as large a surface as possible to the action of the other ingredients; and the calamine or blende is first calcined and finely powdered. If a brass is wanted which shall contain a large proportion of zinc, old brass is often used in part substitution of the copper. The crucibles are covered over, and the lids luted closely down, and they are kept up for some hours at a white heat; but the contents are not allowed to rise to a temperature at which the copper would melt, because in that case the liquid copper would all collect together at the bottom of the crucible, and only the upper surface would be exposed to the action of the zinc ores. After a time some white fumes of volatilised zinc will be found to escape from the stacks in the luting, which indicate that the process of conversion has so far progressed that the temperature may now be gradually reduced. The crucibles are then removed from the kiln, and opened; the dross is skimmed off the surface, and the contents then poured at once into the moulds.

Brass, under the name of yellow metal, is very largely used for the sheathing of ships, in lieu of copper; and as these sheets have to be manufactured upon a very great scale, it is not found to be practically convenient to make it by either of the processes already described. The most approved propor-

tions for this alloy are two-fifths of zinc to three-fifths of copper, and any variation from this should rather be towards an increase of the former than of the latter metal. It does not withstand the action of the sea-water nearly so long as pure copper, but the difference in the first cost is so great as to make it the more economical for the sheathing of ships; and the gentle action to which it is constantly subject from the sea-water always maintains a bright clean surface. It is usually made in reverberatory furnaces, the copper being first reduced to a molten state; and then the zinc is gradually added. A considerable amount of oxidation necessarily takes place in this kind of furnace, and under the most careful management the loss of zinc from this cause will be so uncertain as to render it necessary to test the metal before running it out into the moulds; in practice, moreover, it is rare that the pure metals alone are used, for the old metal which is stripped from the ships' bottoms at each re-sheathing (which occurs usually about every three years) is taken back by the manufacturer and re-melted, so that further elements of uncertainty are introduced into the operation. It is usual, therefore, to draw a proof of the alloy from the furnace, just as in the refining of copper, and test the sample ingot by passing it through the rolls, and then breaking it to see the character of the fracture. This is repeated till a satisfactory specimen is obtained, when it is at once run out into iron moulds, as we have already described. The ingots are rolled out into sheets while hot, then annealed, and finally cleaned by immersion in weak sulphuric acid, and a scouring with sand and water.

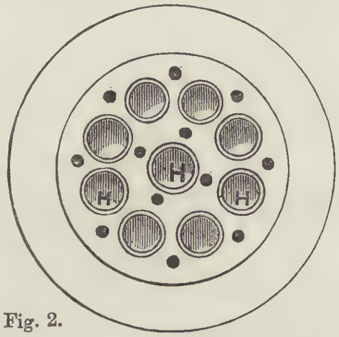

Fig. 2.

The physical properties of brass bear a strong general resemblance to those of copper; but it possesses certain advantages over the pure metal. The first of these is an economical one, the price of zinc being so very much lower than the other, that after allowing for the expense of manufacture, the cost of the product is very much lower than that of copper. The alloy is harder than either of its constituents, and is of greater density than their mean; but it melts at a lower temperature than copper, and produces very good and sharp castings, all which circumstances combine to render it a most suitable material for small engineering work. Moreover, it is less affected by atmospheric influences than copper, and by a very simple process which will be referred to presently, a most brilliant surface can be given to it which will effectually prevent it from tarnishing.

Hence it is applied to an almost infinity of uses, domestic, engineering, and scientific. It is constantly to be met with in locks, hinges, handles, buckles, and bolts; in ornaments for the table or mantelpiece; in chandeliers and gas-burners; in weights and scales; in the finer parts of nearly all steam-engines and other machines; in clocks; in mathematical and optical instruments, etc.

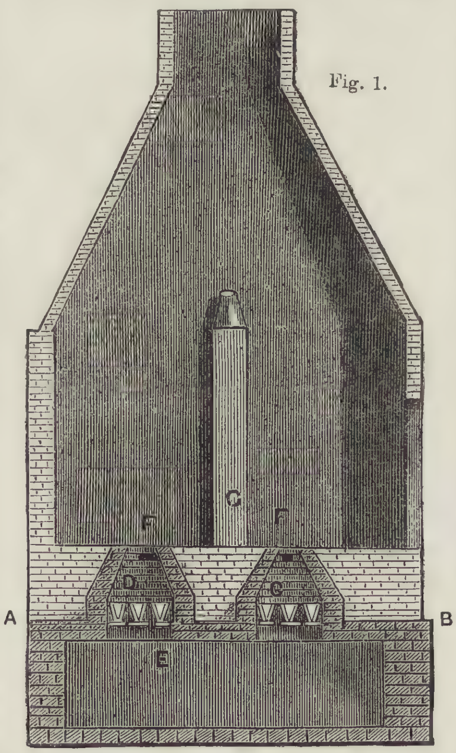

Fig. 1.

Brass is also highly tenacious, so that it can be rolled or beaten out into very thin sheets, and drawn into very fine wire. It can, indeed, be beaten out into leaf, quite as thin if not thinner than that of gold, for which it is often used as a substitute.

All these different qualities are of course more or less affected by the relative proportions of the respective ingredients; the table at the end of this article will serve to show roughly which are the most appropriate combinations for the various purposes that may be required. It should be borne in mind that the two metals will combine in any proportion; and the general character of any intermediate combination may be very fairly judged of by comparing the two given in the table between which it would take its place. As more zinc is added the alloy becomes still more brittle, it loses its fine colour, which then passes into a grey, and has no special quality to recommend it.

A slight admixture of lead, not exceeding about $2\frac{1}{2}$ per cent., is rather an advantage if the brass is intended to be worked upon the lathe, and a similar quantity of tin will not injuriously affect it when employed in making castings, while it is even advantageous if the brass is to be used by the engraver; but a much less proportion of either of these metals, or of antimony, will destroy its value for wire-drawing. For this last purpose the alloy cannot be too pure. A little antimony will in like manner affect the rolling of it into thin sheets by rendering the metal brittle.

Brass resembles copper in its behaviour under the hammer, and needs annealing from time to time in order to restore its malleability. During these repeated heatings the surface becomes tarnished by the formation of oxide, from which it is subsequently purified by dipping it into weak acid, and then washing it with water.

On prolonged exposure to the action of the atmosphere it gradually acquires a dirty black colour, but this can be effectually prevented by coating the surface when quite pure and bright with a thin film of lacquer. This is made by dissolving shellac in alcohol, and applying the solution to the surface by means of a fine brush. Both the articles to be lacquered, and the lacquer itself, should be thoroughly warm; and then, on drying, the thin film of lac will be found to be quite transparent, and to have so smooth and bright a surface as to resemble the most highly-polished metal. The lacquer adheres with such pertinacity to the surface that it can only be scraped off with difficulty, and the brass may afterwards be bent to and fro as much as one pleases without its being separated. By discolouring the surface of the metal, through the agency of acids or otherwise, prior to lacquering, various tints, such as those of bronze, can be produced; or a deeper tint may be given to the lacquer itself by the addition of some of the more highly-coloured resins.

If a dull or frosted surface is desired, which often forms an agreeable contrast to the other in ornamental work, it is produced by a process which is termed "dead dipping." In this case the brass is exposed for some time to a comparatively strong solution of nitric acid until the surface has become thoroughly granulated. It is then washed in pure water to remove all the acid, and next dipped in a cold weak solution of tartrate of potash, after which it is dried by rubbing it with hot sawdust. It is then ready for the application of the lacquer.

The action of acids upon various kinds of brass is not a little remarkable and instructive: for instance, a strong nitric acid will dissolve equal quantities of copper and zinc in an alloy in which the two metals exist in equal proportion, while a weak acid will especially attack the zinc and very slightly affect the copper. Indeed, if the alloy contains an excess of zinc the action of a weak acid will be much greater than if the two metals were treated separately; while if the zinc is only equal to or less than the copper, the alloy is only very slightly acted upon at all. Strong hydrochloric acid will dissolve out nearly

all the zinc from an alloy consisting of equal parts of each metal, leaving the copper almost untouched. A weak hydrochloric acid will dissolve out a portion of the zinc, provided this metal is in excess; but it has no effect whatever upon an alloy of equal parts of the two metals, or of any combination in which the excess is on the side of the copper. Again, with the strongest sulphuric acid, if the zinc is in excess, zinc only is dissolved, and that sparingly; but if the two metals are in equal proportion a greatly increased action takes place, and both metals are equally attacked by the acid. A weaker acid, having the formula $H_2SO_4 + 2H_2O$, scarcely affects any of the alloys containing an excess of copper; and that consisting of equal parts of the two metals is absolutely unaffected by it.

TABLE SHOWING APPROPRIATE COMBINATIONS OF COPPER AND ZINC FOR BRASS.

COPPER.	ZINC.	COLOUR.	OTHER CHARACTERISTICS.
PER CENT.	PER CENT.		
85	15	Yellowish red.	A very hard fibrous metal, with good working qualities.
80	20	Reddish yellow.	Rolls and hammers well. Good for wire-drawing.
75	25	Brass yellow.	Good working qualities. Highly tenacious. Used in machinery.
70	30	Brass yellow.	Common brass. Works well under the hammer.
65	35	Full yellow.	Rolls and hammers well. Good for wire-drawing.
60	40	Yellow.	Used for sheathing ships. Rolls moderately well.
50	50	Golden yellow.	Very fine colour; suitable for ornamental castings, but too brittle for other purposes.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXVII.—THOMAS TELFORD, ENGINEER.

BY JAMES GRANT.

THOMAS TELFORD, one of the most distinguished of our civil engineers, was born in 1757, of humble parents, in the secluded and pastoral valley of Eskdale, as the eastern portion of Dumfriesshire is designated. At the parish school of Westerkirk, he received the education which generally falls to the lot of Scottish children of his class, and was sufficiently well grounded as to make himself master of Latin, French, and German. At the age of fourteen years he left school, and was bound apprentice to a jobbing builder in his native parish, and there he worked for some years as a stonemason. At the expiry of his time he proceeded to Edinburgh, where a new town was then in the course of erection, and studied the principles of architecture, till 1782, when he proceeded to London, where his skill, intelligence, and superior education speedily found him employment under Sir William Chambers, in the building of Somerset House. His merit soon became so conspicuous that he was soon after entrusted with the superintendence of certain works for Government at Portsmouth Dockyard; and in 1787, in his thirtieth year, he was appointed Surveyor of Public Works in Shropshire, a situation which he held till his death.

In 1790 he was employed by the British Fishery Society to inspect and report upon the state of the harbours at their respective stations; and he devised the plan for that extensive establishment at Wick, in the county of Caithness, which is known by the name of Pulteney Town, a modern and thriving suburb of the ancient and royal burgh, and now in every respect, save antiquity, regarded as the town, and Wick as the suburb. Prior to the time of Telford, its site was a large barren heath on the entailed estate of Hempriggs. He designed the harbour, the streets, and a certain number of buildings adapted solely for purposes connected with the herring-fishery, which in the season finds employment for more than a thousand boats, the crews of which are Highlanders, Norsemen, and Dutchmen.

In the years 1803 and 1804 the Parliamentary Commissioners for Making Roads and Building Bridges in the Scottish Highlands appointed Telford their engineer, and under his directions more than 1,100 bridges were built, in some instances where none had existed before, and 860 miles of new road constructed in districts that prior to his day had no other tracks than the old war-paths or drove-roads of the men of Fingal's time and the clansmen of later years.

The new bridge of five arches across the Don (superseding the ancient and well-known "Brig o' Balgownie"), at Aberdeen, was built by Mr. Gibb from a design furnished by Telford. Each arch is of 75 feet span, with 24 feet of rise. Its total expense was £14,000, and though it was in an unfinished state during the tremendous floods of 1829, it escaped on that occasion without injury.

In all these and various other works executed by him in his native country, in England, and in Wales, his wonderful skill enabled him to surmount natural obstacles and difficulties of the greatest magnitude; but the most stupendous undertaking in which he was engaged, and perhaps the most imperishable monument of engineering fame, is the Menai Suspension Bridge over the Menai Strait, one of the most magnificent works in the world.

It was full time that some such means of crossing the strait were constructed, as between the years 1664 and 1842 no less than 180 persons had been drowned at the Ferry of Moel-y-don. So early as 1810 more than one design for a bridge had been designed, and rejected as impracticable; and it was not until the completion of the great Holyhead road by Telford, that he saw the absolute necessity of devising some safe means of crossing. He selected a spot called Ynys-y-moch, where the bold and rocky shores on each side gave opportunities for a lofty roadway, which was carried 100 feet above high-water mark, so as to allow vessels of the largest size to pass underneath. It is difficult for the eye to estimate the colossal proportions of this wonderful bridge in the air, and it is only after attentively observing the vehicles and human figures crossing it, and looking in the distance through the high trellis-work of iron like flies in the web of a spider, or sparrows fluttering in a net, that it is fully appreciated. A sensible vibration is produced by the passage of a vehicle, or even a man and horse; but it has withstood the greatest storms of wind almost without injury. The weight which the chains support is calculated at 489 tons, and that which they are capable of supporting, at 2,016 tons, leaving an available power of 1,520 tons to resist any unusual strain. The total cost of its construction was £120,000. The masonry is of a hard limestone from Penmaen in Anglesea.

Prior to this work, in 1808, Telford was employed by the Swedish Government to survey the ground and lay out an inland navigation through the central part of the kingdom, with the view of forming direct communication by water between the North Sea and the Baltic. Plans for this purpose had been devised, but vainly, in earlier years. In 1516, Bishop Brask proposed to connect Lake Wettern with the Baltic; Gustav I. thought seriously of it. Charles IX. was the first to commence the undertaking by opening a port called Carls-Graf to avoid the upper falls of the Göta River. In the reign of Gustavus Adolphus a commencement was made of the Hjelmar Canal, but it was not completed till 1701. At a later period surveys of a line between the Wettern and the Baltic were taken by Daniel Thunberg, and in 1793 a company was formed for making the Trollhatten Canal by Eric Nordevall; but the real founder of the great Göta Canal was the Baron Baltazar von Platen, who in the year named, 1808, "summoned the famous Scottish engineer, Thomas Telford, and in twenty days the whole line was marked out nearly over the same ground as that contemplated by Daniel Thunberg." The work was chiefly done by the infantry of the Swedish army; and when, in 1813, Telford again visited Sweden, the gigantic undertaking was in full progress, but it was not fully open until 1822.

The genius of Telford was not, however, entirely confined to his profession. In early life he was a contributor of many pieces of considerable poetical merit to "Ruddiman's Weekly Magazine of Edinburgh Amusement," a periodical published then by the Brothers Ruddiman, in Foresters Wynd, which opened off the Lawn-market. These effusions appeared under the signature of "Eskdale Tam;" and he addressed, in rhyme, an epistle to Robert Burns, a portion of which has been inserted by Dr. Currie in his well-known life of the poet. Though he

soon relinquished, as unprofitable, the task of rhyming, he remained a poet all his life.

"The poetry of his mind," it has been said, "was too mighty to dwell in words and metaphors; it displayed itself by laying the sublime and beautiful under contribution to the useful for the service of man. His Caledonian Canal, his London and Holyhead Road, are poems of the most exalted character, divided into numerous cantos, of which the Menai Bridge is the most magnificent one. What grand ideas can words raise in the mind to compare with a glance at that stupendous production of human imagination?"

The most important of Telford's public works was the planning and laying out of the Caledonian Canal, a magnificent line of inland navigation $60\frac{1}{2}$ miles in length, through Glen Mhor na' Albyn, or the Great Glen of Caledonia, which extends due west and north-east from the isle of Lismore, in Loch Linnhe, to the sutors of Cromartie, on the Moray Firth. This great canal was one of a series of improvements which had peculiar reference to the Highlands and the condition of its people at that time, and was pressed upon the Government as a means for checking that emigration which threatened to leave all that part of Scotland a wilderness. It was proposed by Telford that the canal should be wide enough to admit the largest class of Baltic and American traders, or even a fully armed 32-gun frigate, with an uniform depth of 20 feet of water, and with locks measuring 170 feet long by 40 feet wide. His original estimate for this, and cutting the necks of land connecting the chain of locks, was no more than £350,000; but ere the great undertaking was concluded the sum amounted to £1,023,628, £43,500 of which was spent in obviating legal opposition and chicaneries alone.

It would appear that the present traffic on the canal is probably not $2\frac{1}{2}$ per cent. of the whole trade going through the Pentland Firth. The average of tonnage passing through the canal, exclusive of steamboats and local traffic, has been about 20,000 tons per annum. To prevent the delay—sometimes of three or four months—of going round Cape Wrath during westerly winds was one of the principal objects of the canal; but this end is defeated by the circumstance that as it lies in the trough, or hollow, between two lofty ranges of mountains, the wind blows always parallel to the line of the canal, so as necessarily to be a foul wind in one direction; and, consequently, as ships can neither tack nor be tracked by horses, the whole length, which ought not to occupy more than four days, takes at times as many weeks.

Steam-vessels are now, however, placed on the canal, and the whole scenery, from Corpach to Inverness, is so singularly romantic and sublime, that its character is greatly enhanced by the passing and repassing of large vessels gliding over the bosom of these vast lakes under the shadow of lofty mountains and forests of birch and fir, thus fulfilling the prediction made by a Highland seer, four centuries ago, "that vessels with white sails would be seen traversing the lonely Glen of the Lakes."

It was opened from sea to sea, according to Telford's plans, after twenty years of labour, on the 23rd of October, 1822.

Telford was a Fellow of the Royal Societies of London and Edinburgh; and from its commencement, in 1818, was annually elected President of the Institution of Civil Engineers. His gradual rise to the summit of his profession is to be ascribed, not more to his genius, his consummate ability and persevering industry, than to his plain, honest, straightforward dealing, and the integrity and candour which marked his character throughout life. He died unmarried, at his house in Abingdon Street, Westminster, on the 2nd of September, 1834, and was buried in Westminster Abbey.

TECHNICAL DRAWING.—LXVI.

DRAWING FOR BRICKLAYERS.

When the soil on which a building is to be erected is very soft or swampy for a considerable depth below the surface, which is the worst kind of foundation that can occur, it has been usual to secure the base of the walls by a wooden grating or platform of the nature described in the last lesson, but supported upon strong piles of a length sufficient to penetrate into harder soil, and acquire a fixture there, and which are driven until they will go no deeper. Such piles are usually shod with iron, and are driven at intervals of three or four feet apart. There ought to be at least two rows of piles under the foundation of every wall, as in the example shown in Fig. 531, so that every pair of piles support a transverse sleeper.

Less than two rows of piles would not give sufficient stability to the wall even of a common building. More than two rows, or three at the utmost, can only be required for the foundation of very substantial masses of masonry, such as revetments, wharf walls, etc.

The principle of the stability derived from a piled foundation is thus described by Sir Charles Pasley:—"By the laws of mechanics the force of percussion greatly exceeds that of simple pressure by dead weight; and in the pile-engines used in this country the ram (sometimes called the 'monkey')—that is, the weight by which the pile is driven—falls upon the head of it

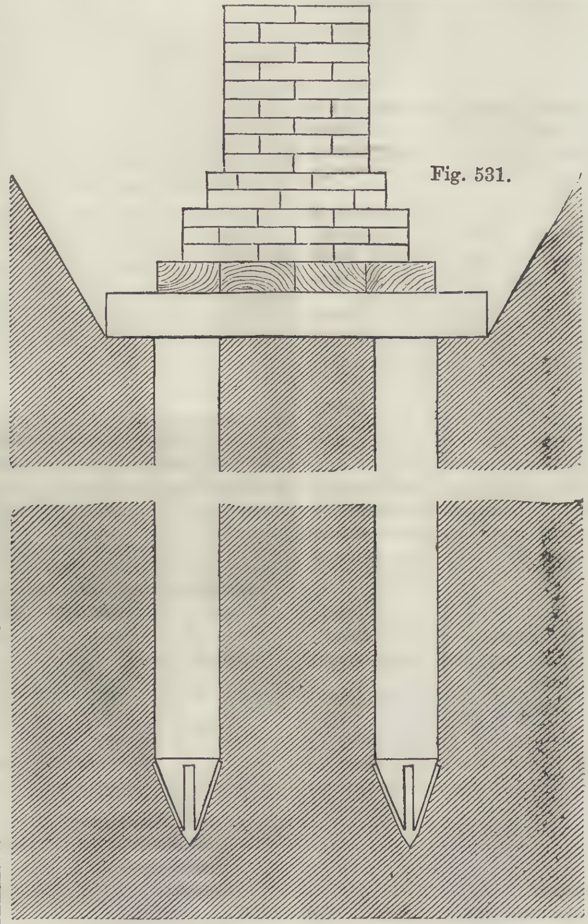

Fig. 531.

from a considerable height, which greatly increases the effect as compared with the old system of pile-driving still used abroad, in which the ram is not raised more than four or five feet. Now the momentum of ten or twelve hundredweight, a common weight for the ram of a pile-engine, falling from the height of fifteen or twenty to thirty feet, produces a greater effect than the dead weight of any common mass of building; hence, if a pile be driven by such an engine until it can go no further, there can be little risk of the foundation giving way afterwards in consequence of the mere pressure of the walls."

Foundations built on piles are, however, liable to failure, first, from the piles losing their original position in consequence of the soft ground offering too little resistance against a lateral movement, so that the walls built on them may have a tendency to fall over. The different forms of wooden and iron piles, the pile-driving machine, and the steam pile-driver are described in lessons in "Building Construction," Technical Educator, Vol. I., page 57.

In order to guard against this evil, the piles for walls are sometimes driven obliquely, so as to diverge at bottom, and those especially for leaning revetments or for the abutments of bridges may be driven in such oblique directions as to oppose the greatest resistance to the unequal pressure, which acts chiefly on one side of the wall.

Secondly, a failure may arise from wooden piles rotting or being corroded by worms in process of time, the former of which evils is almost sure to occur in foundations alternately wet and dry. Fortunately, the kind of soil where piles are most required is that where water is found a little below the surface; and if the woodwork be kept at such a level as always to remain wet, there is little or no risk of its decaying by rot. The perfect state in which trees have been found after the lapse of many centuries is well known. A few years ago, on throwing two arches of Rochester Bridge into one, the piles of the intermediate pier, which must have been there for several centuries, were taken up perfectly sound.

Reverting to the system of wooden platforms in foundations, they are of course liable to decay in process of time under most circumstances.

Now, since the uniform thickness of such platforms cannot exceed a few inches, this kind of failure taking place after the building has become completely consolidated, will not be attended with those injurious consequences which would arise from the decay of a piled foundation. Still, it is desirable to avoid using continuous planking, and to employ a couple of parallel longitudinal timbers for the same purpose, laid at a sufficient interval apart, which, when surrounded by brickwork or masonry, are called *chain timbers.*

These are shown in Fig. 532, in which is shown a section of a portion of one of the walls of the buildings in Lancaster Place, adjoining Waterloo Bridge, London. In this illustration, which will be further described presently, two parallel chain timbers are seen in section. These, which are in thickness about equal to the height of four courses of brickwork, are laid upon transverse sleepers placed parallel to each other at certain intervals.

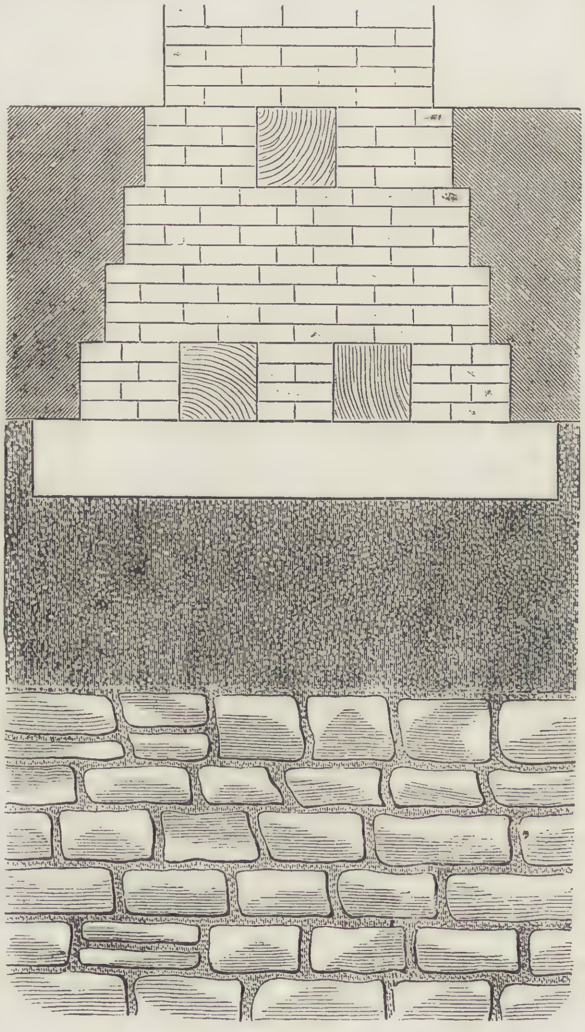

Fig. 532.

In this arrangement it will be evident that in the event of the woodwork decaying, the base of the wall will have a sufficient and solid footing on the natural ground or on the surface which has been prepared for it to rest on; for the intersecting cavities in the brickwork occasioned by the rotting of the timber are too small in themselves, and at too great intervals apart, to injure the stability of the brickwork.

It will be understood that the chain timbers which extend all round the building, and which therefore must be in several pieces, are firmly connected at the ends by scarfing or otherwise, and they are pinned down to the sleepers on which they lie. A third chain timber is also used, not on the same level with the others, in which case it might weaken the wall too much, but in the middle of the thickness of the wall, two or three feet higher up, as, for instance, at the part where the uppermost offset of the footings terminates. This third chain timber is also shown in the example, and it will be evident that the three combined will produce nearly the same favourable effect in the first instance as a continued planking, but without being liable to any of its inconveniences.

The buildings referred to are founded in very bad soil, which proved on examination to have consisted originally of soft mud, but which was intersected in all directions by the remains of the foundations of old houses and wharves. Trenches having been cut to a sufficient depth and width along the proposed line of the new foundations, fragments of the old walls were laid therein as regularly as possible, in the same manner as large flat stones might have been used. These were well sluiced with water, then mixed with grouted gravel,* and rammed down flat; the work being thus continued until the fragments alluded to were expended. Then the rough foundation was continued to the proposed footing of the brickwork with grouted gravel alone, and at that level transverse sleepers were used at intervals of about four feet apart (all under piers, none under the position of doors or windows), upon which were laid two longitudinal chain timbers of the thickness of four courses, completely surrounded by the brick, but immediately under, and flush with what was intended to be the exposed surface of the principal wall of the building after the work should be raised to a certain height; and a few feet higher, opposite to the top of the uppermost offset of the brick footing, a third chain timber of the same scantling was bedded in the middle of the wall. Thus these three chain timbers combined cover a space of not less than 2 feet 3 inches wide, being equal to the thickness of a three-brick wall, and this arrangement is continued throughout the whole extent both of the external and cross or party wall of that row of buildings.

The foundation here described is everywhere 8 feet wide, and of the same average depth. The brick footings have a base of 5½ bricks, which, by four successive offsets on each side at intervals of three courses apart, diminishes at the height of 3 feet to 3½ bricks, which is the thickness of the front and back walls of the lowest storeys of the buildings, which are vaulted and used as stables or stores. Over this the walls of the basement floor, and the inhabited part of those buildings, are 3 bricks thick, which dimension is gradually diminished by successive offsets to 1½ bricks in the uppermost storey of the house.

The height from the top of the brick footing to the coping of the parapets in front and rear is not less than 88 feet, to which, adding the footings and foundation, it appears that there is a mass of brickwork, rough masonry, and grouting nearly 100 feet in height—that is, on the side nearest the river.

* *Grout.* A thin semi-liquid mortar, composed of quick-lime and fine sand and gravel, which is poured into the internal joints of masonry; it is particularly used where the work consists of large stones. The process is called "grouting."

SHIP-BUILDING.—XII.

BY W. H. WHITE,

Fellow of the Royal School of Naval Architecture, and Member of the Institution of Naval Architects.

THE SKINS OF IRON SHIPS.

In our remarks on this subject it will be desirable to follow the same order as was followed in describing the skins of wood and composite ships; the arrangement or disposition of the plates being first considered, and afterwards their fastenings.

The outside surface of a wood ship's bottom is flush, and in some of the early iron vessels the plating was also made flush by means of the plan illustrated (in section) by *a* in Fig. 34. It will be observed that the edges of adjacent strakes of plating are connected by narrow plates or strips, fitted inside them, and riveted to each. The strips being made continuous in a longitudinal sense, it was impossible to fit the plating directly upon the frame angle-irons, and it became necessary to fill in the spaces between the plates and the frames with pieces of iron, termed "liners;" these are shaded across in the section for the sake of distinction from the plating and strips. A flush outer surface was thus obtained, but at considerable cost. The liners, for example, taken together amounted to a considerable weight, and added nothing to the strength of the hull. Then, again, the fact that the edges of the plates were flush-jointed, necessitated more care in fitting them and caulking them, than would have been needed if lap-joints had been used; besides which the amount of riveting required in the edge-fastenings was double that needed for lap-joints. In fact, the plan was wanting in economy of material and workmanship, and it gave place to others very soon; it has, however, been again used in a few ships built recently on the Tyne.

a *b* *c* *d*

Fig. 34.

The section marked *b* in Fig. 34 shows the "clinker" plan of plating, which was formerly much used in iron ship-building, the name being derived from the resemblance of the plan to that followed in planking wood boats and small vessels. Here the upper edge of each strake is fitted directly upon the frame angle-irons, and is overlapped by the lower edge of the adjacent strake. All the edges are therefore lap-jointed, and a considerable saving in weight and cost of workmanship was consequently effected, as compared with the flush-jointed plan. Liners were still required, however, to each strake, and they will be seen to be triangular or tapering in section; thus needing to be specially shaped in order to properly fit the spaces between the plating and the frames; whereas on the other plan the liners were of parallel section, and could be cut from plates.

The next section, *c*, represents the arrangement now used almost universally, in plating iron ships. Alternate strakes are worked directly upon the frame angle-irons, and are termed "inner" or "sunken" strakes. The intermediate strakes overlap the inner strakes at both edges, and are known as "outer" or "raised" strakes. Liners are thus required only to one-half the strakes, and at the same time are of parallel section, so that little care is needed in fitting them; while all the advantages of lap-joints, as respects saving in riveting, weight, etc., are obtained. The fact that this plan has been so generally adopted furnishes sufficient evidence of its superiority to the two preceding plans.

The fourth section, *d*, represents a plan of plating which has not been much used, but possesses some advantages. It is usually known as "Lamb's Patent," but there is reason to believe that it had been suggested previously to the date when this patent was obtained. All the strakes of plating are worked directly upon the frame angle-irons, liners being entirely dispensed with, and their weight saved. The flush edge-joints are then secured by continuous strips, resembling those fitted in section *a*, but worked outside instead of inside the plating. Of course, this arrangement necessitates twice as many rivets being used for edge-fastenings as are required in either the clinker plan, or the in-and-out system; and it also requires the edge-strips to be twice as broad as the laps, thus adding a weight which probably exceeds that saved on the liners. On the other hand, the later plan possesses some advantage in simplicity, and the directness of connection between the plating and the frames; it entirely does away also with the necessity for using liners that do not contribute strength to the hull. Hitherto, however, ship-builders prefer the in-and-out plan, and do not seem inclined to use the other.

Many plans besides the preceding have been proposed, but have not found favour. The use of two thicknesses of plating for the skins of iron ships has been repeatedly patented, some persons preferring to work both thicknesses longitudinally, and others to work them diagonally. The latter proposal, it need hardly be said, is based upon an entire misconception of the efficiency of the skins of iron ships. The use of two thicknesses of plating is confined in most vessels to a few strakes which are situated in critical parts of the structure where exceptional strength is required; and so far as we are aware the only instance of the more extended use of the plan is found in the skin-plating behind the armour of our iron-clads, illustrated in Figs. 24—26, page 224. In these vessels the double thickness is used to give greater resisting power to the target formed by the ship's side, rather than as a means of adding to the strength of the ship considered as a girder.

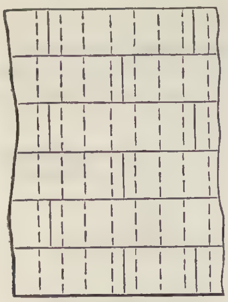

Fig. 35.

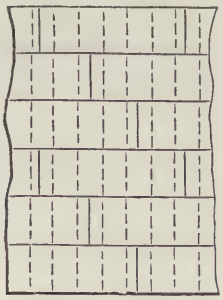

Fig. 36.

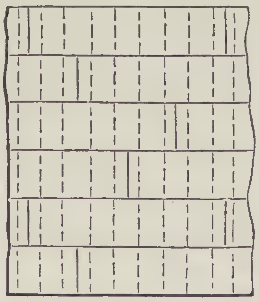

Fig. 37.

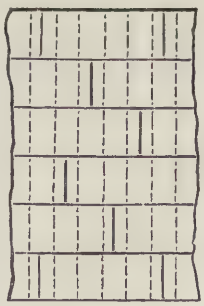

Fig. 38.

Other inventors have proposed to substitute special forms of plating for the plain sheets, or plates, generally employed. "Corrugated" plating has been advocated by some; "trough-shaped" plates by others; and still more singular forms that need not be mentioned. Against all these plans the great objection lies that they would necessitate considerable outlay on the mere *preparation* of the plating, besides causing more difficulty in its combination. In fact, ship-builders have unanimously declared in favour of the plain sheet-iron, which can be rolled with ease, and most efficiently combined; and this preference receives considerable support from the fact that the progress of the iron manufacture now enables much broader and larger plates to be procured than could formerly be

obtained. Twenty years ago the plates commonly used were not more than 2 feet broad and 7 or 8 feet long; and now plates more than twice as broad and twice as long can be rolled without difficulty, and are often used.

Attention will next be directed to the shifts of butts usually adopted for the plating of iron ships, examples of which are given in Figs. 35—38. Before describing these, however, it is proper to remark that the butts of skin-plating are not necessarily sources of weakness, while the butts of an ordinary wood ship's planking are unavoidably so. The plating is, as we have seen, pierced at each frame angle-iron by rows of rivet-holes, and thus weakened sections are produced. If the ship-builder, therefore, can make the sections of the plating at the butts as strong as the unavoidably weakened sections at the frames, he will have done all that is needed, and the butts will not be sources of weakness. This result may be attained by means of well-arranged and well-fastened butt-straps, as we shall show hereafter; and so a closer approximation to uniformity of strength may be made than is possible in the skin of a wood ship. At a section passing through a line of butts in the latter, every fourth (or butted) strake may be regarded as practically ineffective against tensile strains; whereas in an iron skin the butted strakes can be made as efficient as need be against both tensile and compressive strains. Consequently the iron ship-builder has a greater freedom than the wood ship-builder in disposing the butts of the skin; but he must exercise great care if he would fully develop the capabilities of the iron. Not only has he to consider the relative positions of the butts of the various strakes of plating, but also their positions relatively to the longitudinal frames or strengthenings; and a neglect of the latter consideration has in some cases caused serious weakness in ships otherwise well built.

In the sketches illustrating the various shifts of butts, the *dotted* vertical lines represent the stations of the frames, and the *drawn* vertical lines represent the butts of the strakes of plating, of which the horizontal lines show the edges. The first disposition, in Fig. 35, has only *one* passing strake between consecutive butts, and is termed the "brick" arrangement, from its similarity to the method of laying bricks in building walls, etc. It was formerly much used, and was not ill adapted to the short lengths of plating then procurable; it has, however, now given place (to a large extent) to the arrangement shown in Fig. 36, termed the "diagonal" plan, where there are *two* passing strakes between consecutive butts. In this arrangement it will be remarked that the butts of adjacent strakes form "steps," similar to those which wood ship-builders are so careful to avoid in arranging the butts of the outside planking; and it may be remarked that so long as a minimum shift of from three to four feet is secured between adjacent butts, iron ship-builders do not consider it essential to avoid such steps. The third arrangement, in Fig. 37, gives *three* passing strakes between consecutive butts, and is identical in principle with the ordinary shift of butts in the planking of wood ships, illustrated by Fig. 27, page 256. It is not very commonly used, but is well suited to cases where the plates employed are from 14 to 16 feet in length. Fig. 38 shows *four* passing strakes between consecutive butts, and is much used in the construction of merchant vessels. Unlike the plan in Fig. 37, it lends itself readily to the use of plates 9 or 10 feet long, and yet gives as great a minimum shift between adjacent butts.

The ship-builder would be mainly guided in his choice of the shift of butts by the lengths of plates he proposes to use, and in fixing the latter particular would naturally have regard to the relative cost of plates of moderate or of great length. Suppose, for example, a private builder had contracted to build a ship to be classed at Lloyd's. He would meet all the requirements of the Rules by adopting the shift of butts in Fig. 38, and yet not require lengths of plates exceeding 10 feet; whereas with the shift of butts in Fig. 37 he would require plates 14 feet long. Now the shorter plates would also be procurable at the cheaper rate per ton, and it would consequently be to the builder's advantage to use them, although the number of butts in the skin would be made greater in consequence. In another paper we hope to illustrate the close connection that should exist between the shift of butts and the character of the butt-fastenings; but for the present it must suffice to mention the obvious truth, that by increasing the number of passing strakes between consecutive butts a decreased amount of fastening will give the strength required to the butts.

The term "outside plating" is applied to the whole skin from keel to gunwale. The garboard strakes, coming next the keel, are usually thicker than the remainder of the plating; and the "sheer-strakes," coming in wake of the upper-deck beams, are also thicker by $\frac{1}{16}$ or $\frac{1}{8}$ of an inch than the plating on the sides, down to the turn of the bilge. The plating from this point in to the garboards is sometimes distinguished as "bottom plating," and is generally about $\frac{1}{16}$ of an inch thinner than the garboards. Some builders, however, use plating of uniform thickness over the whole space between the garboards and the sheer-strake. The "bilge-strakes" near the turn of the bilge usually have considerable curvature in a transverse sense, and are so made specially efficient, even when unstiffened by framing, against buckling under longitudinal strains. When additional longitudinal strength is required, one very common way of obtaining it is by doubling the sheer and bilge strakes, by means of another thickness of plating worked upon them, and having the butts carefully strapped and shifted from those of the plating on which the doubling plates are fitted.

The plates used have their maximum breadth and thickness at the midship section. As the girth of transverse sections rapidly diminishes towards the extremities, the breadths of the individual strakes have to be diminished also, and some of the strakes often have to be stopped short of the stem. A similar arrangement has frequently to be adopted with strakes of planking in wood ships, and in both cases the strake abutted is termed a "stealer." Beyond the end of the stealer the two strakes which were adjacent to it on the midship section are broadened, so as to occupy the space that would otherwise be left vacant. In the case of a wood ship this can easily be done, but in an iron ship special devices are needed in order to properly secure and caulk the butt of the stealer. The thicknesses of the plates are also usually diminished towards the extremities by $\frac{1}{16}$ or $\frac{1}{8}$ of an inch; it being considered that the strength required at those parts is much less than that needed amidships. Allusion having already been made to the discussions that have taken place on this question of reduction in the scantlings at the extremities, we need only add that hitherto no definite conclusion has been reached, practical experience and the requirements of local strength having far more weight than purely theoretical considerations.

BUILDERS' QUANTITIES AND MEASUREMENTS.—XI.

BY E. WYNDHAM TARN, M.A.

JOINERY AND IRONMONGERY (*continued*).

We now proceed with the measurement of work done by joiner and ironmonger's fittings which was commenced in the last number.

GROUND FLOOR.

15 0 12 0	180 0	1¼ in. tongued batten floor, with iron tongues.
2) 4 0 0 9	6 0	Add recess.
6 6 2 0	13 0	Add bay window.
3 3 0 9	2 5	Add door.
	201 5	
3 6 1 6	5 3	Ddct. hearth.
	196 2	
7 0	7 0	1¼ in. mitred border.
43 0 1 3	53 9	1¼ in. mouldd. and rebd. skirting in 2 heights.

No. 10 tongued and mitred angles to skirting.

	43 0	43 0	1 in. skirting grounds, plugged.
	6 6 5 6	35 9	Solid oak frames, rebd. and mo., 4″ × 3″, with mullion and transom, mitred and beadd. sill, 2 in. lamb's-tongue casement, circular on plan (measured nett), $\frac{1}{4}$ in. rise.

No. 2 pr. 2 in. brass b. and s. 2 brass casement fastgs.
,, 2 brass hook and eye.

	6 6 5 6	35 9	$1\frac{1}{4}$ in. 2 panl. bd. flush and sqre. shutters, hg. with brass pulleys, pat. lines, lead wts.
	13 0	13 0	Groove for beads.

No. 1 brass thumbscrew and plates.
,, 2 brass sk. flush rings.

	6 6 0 4	2 2	$\frac{3}{4}$ in. mahogy. flap.

No. 1 pr. $1\frac{1}{2}$ in. brass b. and s. 1 brass flush ring.

	5 6 1 6	8 3	$1\frac{1}{4}$ in. 2 pl. mo. window back.
	23 0 0 5	9 7	1 in. framd. and bdd. grounds.
	23 6	23 6	$1\frac{1}{4}$ in. arch. mouldg, $3\frac{1}{2}$ in. wide.
	25 0	25 0	1 in. picture grounds, $3\frac{1}{2}$ w., plugged.
	7 0 3 3	22 9	2 in. deal 4 pl. mo., b. s. door.
	17 6 1 3	21 11	$1\frac{1}{2}$ in. deal framed linings, 2 pl. jambs, 1 pl. soffit, moulded and dble. rebd.
2)	18 3 0 5	15 3	1 in. framed ground.
2)	19 0	38 0	$1\frac{1}{4}$ in. arch. mo., $3\frac{1}{2}$ in. w.

No. 1 pr. 4-in. brass b. and s. 1 6-in. 3 bolt $\frac{5}{8}$-in. mortise lock, and china furniture.
,, 2 pr. china finger plates.

	7 6 3 6	26 3	$2\frac{1}{4}$ in. oak 6 pl. bolection mouldd. b. s. door, lower panels bead flush 1 s.
	3 6 2 0	7 0	2 in. oak ov. fanlight, circular head.
	15 0	15 0	$1\frac{1}{4}$ in. arch. mo., $3\frac{1}{2}$ in. w.
	6 6	6 6	Ditto circular.

No. 1 10-in. draw-back lock. 1 patent latch.
,, 2 escutcheons. 1 pr. 5-in. brass b. and s.
,, 2 10-in. brass barrel bolts. 1 brass rack chain.

	6 6 4 6	29 3	Dl. cased frame, oak dble. sunk, weathd. and throatd. sill, 2 in. ov. sashes, dble. hg. brass pulleys, patent lines, i. wts.
2)	6 6 1 2	15 2	$1\frac{1}{4}$ in. mo. and bd. flush foldg. shutters, panels in 2 heights.
2)	6 6 1 0	13 0	$1\frac{1}{4}$ in. bd. fl. and sqre. back flaps.
	17 6 0 7	10 3	$1\frac{1}{4}$ in. proper boxings.
	13 6 0 9	10 2	1 in. plain back linings, tongued.
	4 3 2 3	9 7	$1\frac{1}{4}$ in. mouldd. 1 pl. window back.
	4 3	4 3	$\frac{3}{4}$ in. capping.
2)	2 3 1 0	4 6	1 in. plain elbows, rebd.

No. 2 elbow caps. 2 soffits to boxings. 1 brass sash fastening. 1 w. i. shutter bar and plates, 3 ft. long. 2 pr. 2 in. b. and s. 2 pr. $1\frac{1}{2}$ in. back-flap hinges and s.

	23 0 0 5	9 7	1 in. framd. grounds.
	23 6	23 6	1 in. arch. mo., $2\frac{1}{4}$ w.
	3 6 3 3	11 5	1 in. mahogy. fram. seat and riser, Fr pold.
	3 6	3 6	Mold. nosings to ditto.
	3 6 1 9	6 2	1 in. mahogy. beadd. flap and frame, Fr. pold.
	7 0	7 0	$\frac{1}{2}$ in. mahogy. sqre. skirtg., 4 in. w., ditto.

No. 1 hole cut and dished. 1 beadd. hand-hole.
,, 2 roundd. corners to skirting. 1 pr. $1\frac{1}{2}$ in. brass b. and s.
,, 1 $\frac{3}{4}$-in. quarter round mahogy. shelf, 9″ × 9″, on chamfd. fillets.

	7 3 2 6	18 2	2 in. dl. clamped dresser top.

No. 2 rounded corners to ditto.

	7 0 0 9	5 3	$1\frac{1}{4}$ in. beadd. front to dresser.
2)	3 0 0 6	3 0	1 in. beadd. drawer fronts.
2)	7 6 0 6	7 6	$\frac{3}{4}$ in. dl. dovetailed sides to drawers.
2)	3 0 2 4	14 0	Ditto tongued bottom.
	9 6	9 6	Runners.
2)	2 4 0 9	3 6	$1\frac{1}{2}$ in. ends to dresser.
	12 0	12 0	Wrot. and framd. legs $2\frac{1}{2}$ in. sqre.
	7 0 2 6	17 6	1 in. pot board.

	12 0 0 4	4 0	1 in. riser.
2)	5 0 0 9	7 6	$1\frac{1}{4}$ in. cut and dimd. standards.
3)	7 0 0 9	15 9	$1\frac{1}{4}$ in. shelf.
	21 0	21 0	Groove.
	7 0	7 0	$\frac{1}{2}$ in. stop.

No. 3 doz. brass hooks. 4 ebony drawer knobs.

9 6 7 0	66 6	$2\frac{1}{2}$ in. mahogy. lamb's-tongue shop sashes.
7 0 2 6	17 6	Ditto circular, quick.
7 0 3 6	24 6	2 in. ditto astragal and hollow folding sash doors, dimd. stiles, lower panels, mo. and bd. flush.

No. 2 pair patent swing centres. 4 brass handles.

18 0	18 0	Mahogy beadd. door frame, 3″ × 3″.
9 6 2 0	19 0	$1\frac{1}{2}$ in. dl. mo. and sqre. stall board.
2 6 2 0	5 0	Ditto circular on plan, quick.
9 6	9 6	Mouldd. edge, 4 in. girt, to stall board.
2 6	2 6	Ditto circr. on plan, ditto.
14 6 3 0	43 6	Cradling to entablature, ploughed and tongued blockings.
14 6 1 6	21 9	1 in. dl. keyed frieze, joints feather tongued, lower edge rebd. for soffit.

„ 4 mitres.

3 0	3 0	Wrot. and chamfd. mahogy. fillet.
11 6 3 0	34 6	1 in. mahogy. framd. front, mod. and sqre.

SOLDIERING.—IV.

BY A STAFF OFFICER.

EQUIPMENT ARMS (*continued*)—ARTILLERY.

In speaking of the "big guns," as they are usually called, I said that we might include among them all pieces larger than those which a man can carry. The large guns are, however, again subdivided into several classes, each implying some distinctive character in the organisation with which it is connected. Thus we have, first of all, the broad distinction between the "field artillery" and the "garrison artillery." The former comprises all those guns which accompany an army in its movements in a campaign and in battle; the latter comprises those which are too large and heavy to be so used. The field artillery is again subdivided into "horse artillery," "field batteries," "position batteries," and "mountain batteries." The horse artillery is intended to act with and support cavalry, with which it has therefore to be trained. The field batteries are the special support of the infantry. They also, however, usually form the main bulk of the artillery as an arm of the service in the field. It is, therefore, an error to lay it down as an axiom or point to start from in discussing their character, that they are *intended* to work with infantry. Every arm of the service is intended to do its part in contributing as much as possible to the efficiency of the whole. We shall, therefore, consider in due time how far their equipment determines for the field batteries what that part is. At present we must be content with noting the reason for the broad distinction between the horse artillery and the field batteries.

We require to have certain guns which *can* move with and support cavalry. As those guns must be able often to be moved at a gallop for great distances, and at all times at the same rate as cavalry ordinarily moves, it is clear that they must not be very heavy. Moreover, with these weapons there is another difficulty in very much increasing the size of the piece; for as the gun is made larger, the ammunition you have to carry with it becomes rapidly much heavier in proportion to the number of rounds. As, therefore, we cannot afford very much to diminish the number, we must on this account also restrict the size of the gun which is specially intended to accompany the cavalry.

But we want also to have with us, in a condition to be used as effectively as possible, the heaviest guns we can get. Moreover, we want to be able to place these just where they will be most effective, and, time being always of value, to place them there as rapidly as possible. Now it is quite possible for a gun to be moved very rapidly about which would yet be altogether too heavy itself, and would require too heavy ammunition, to fulfil the condition of moving with cavalry. This has led to the formation of the "field batteries."

Once more, it is quite possible that though a gun may be too heavy to be moved rapidly about the field and put just in the positions in which it is wanted at every moment, yet that if we once knew where the really decisive point was, a few such very heavy pieces might be moved up thither. Now as very heavy guns produce an immensely greater effect, both physical and moral, than the lighter kinds, it is well worth while to have, for the special purpose of being brought up to the most desirable point at the most decisive moment, a certain number of such guns. This consideration has led to the formation of "batteries of position."

The purpose for which "mountain batteries" have been formed is sufficiently indicated by the name. Obviously a gun must be of very light construction which is intended to be able to accompany the army by any mountain foot-path.

In general, the means by which the several degrees in the need of free movement of the different classes of guns (with the exception of the mountain gun) is met, is by an employment of horses adapted to the work required. So essential to both the horse artillery and the field batteries is rapidity of movement that the horse is almost as much an element in their actual fighting equipment as he is with the cavalry. The extreme importance of good horsemanship for the artillery requires some explanation. A gun cannot be fired whilst it is being transferred from place to place. The gun always travels with its back part or "breech" towards the horses' heads. It has to be "unlimbered," as it is called—that is, unhooked and turned round—before it can be loaded, pointed, and fired. Moreover, as the distance is very

considerable at which artillery always opens fire, that distance can only be guessed very roughly. A trial shot at least, if not more, has to be expended before a sufficiently accurate estimate can be made of the range or distance of the object aimed at. Hence every movement made by artillery from place to place represents a serious loss of power, due less to the distance moved over than to the number of moves. Moreover, if a thoroughly good commanding position has been taken up at first, the artillery gains little by being only *rather* nearer to the enemy. To the infantry every advance is a clear gain, both in the effect with which their fire can be brought to bear, and in their approaching nearer for the final rush. The artillery, on the other hand, if they can fairly see what they are firing at, can modify the distance at which their shot strikes, within such a very wide margin, that it is not worth while for them to move, except over a considerable distance. Nevertheless, very distant artillery fire is never very effective. It is in the comparatively close firing, where the effect of every shot can be seen, that the power of artillery comes out in all its deadliness. Artillery cannot be too close, provided it is just out of effective infantry range, and in a good position.

At the beginning of an action, moreover, the artillery is usually pushed forward into the most advanced positions which have been already secured by small bodies of the infantry. This is done in order that the two points in which it is superior in its fire to the infantry—its long range and weight of projectile—may be made to tell with their full effect on the enemy's position before the infantry moves forward to the attack. But as the artillery fire from these first positions begins to take effect, the enemy's fire slackens and the infantry is able to advance. The infantry thus secures positions from which the artillery can act with far greater effect. It is then that the artillery has to be moved at great risk rapidly and boldly forward. Hence, for the field batteries, which are the portion of the artillery mainly concerned in bringing crushing fire to bear on the enemy's position, the two great necessities are, as they are also for the horse artillery, rapidity and facility of movement:—the one, in order that as short a time as possible may be wasted in the ineffective period of advance, and that the guns may be allowed to remain a long time at the same spot, yet be brought up at the moment when they are wanted to a new one; the other, in order that the positions selected for the guns may be chosen so as to obtain the most effective fire, and that wherever such considerations would suggest that guns ought to go there they may be able to go. Now, these two necessities of rapidity and facility of movement can only be provided for by having the horses in the highest possible condition, and both horses and men trained in the highest possible degree.

Thus the horse, though he does not with the artillery aid as he does in the cavalry in the actual blow by which the power of the weapon is made to tell, is yet so intimately concerned in paving the way for each successful effort of the guns, that he is as essential an element in the fighting power of a battery as he is in that of a squadron.

There are six horses to each gun, and of these the three on the left-hand or near side are ridden postilion fashion by three men, each of whom also drives the horse beside him. Two gunners sit immediately behind the horses on the front of the gun-carriage. This front consists of two boxes, each carrying ammunition, *i.e.*, shell and cartridges; solid shot being never carried by artillery in the field. (For the different classes of shell carried see the papers on "Weapons of War.") Each front of a gun-carriage is thus a small field magazine for the supply of its own gun with ammunition. The whole gun-carriage when put together forms a four-wheeled vehicle. When the gun is unhooked, the front part, or "limber," forms a two-wheeled cart carrying the ammunition-boxes. The gun when unhooked rests partly on the axle-tree arms of the other two wheels, and partly on the point or end of a solid block of wood called the "trail," which supports the bed on which the gun rests. When the gun is thus in action the end of this trail rests on the ground. In order to hook the gun on to its carriage, the end of the trail, which consists of a solid iron eye, fastens into a solid iron hook at the back of the "limber." After the gun has been unhooked it can be moved by hand for considerable distances, if a sufficient number of men are available to work it, and the ground is not very heavy. The trail is lifted by three men, while as many others as are available work the gun forward by pushing at the spokes of the wheels. This explanation applies both to the horse artillery gun and to that of the field batteries. Each, too, has a wagon attendant upon the gun. This wagon consists of a limber exactly similar to that of the gun-carriage, and a "wagon body." The latter is a sort of double limber, having four ammunition-boxes instead of two. The whole wagon forms a four-wheeled carriage. The wagon body hooks on to its limber just in the same way as the gun hooks on to its limber. The limber of the wagon can, as soon as the ammunition in that of the gun is exhausted, move up and take its place whilst the limber of the gun is being re-filled from the body of the wagon.

It is essential that the wagon should be placed as completely out of danger of being struck by one of the enemy's shells as it can possibly be; for there is no object whatever in the wagon being exposed to the same extent to which the gun must often be to the enemy's artillery. The gun has its position selected quite as much with a view to enable it to fire with effect as to be itself safe. The wagon cannot fire at all. It has no means of acting whatever by itself, being simply a magazine of ammunition. Its size is very much greater, and therefore affords a very much more conspicuous mark than the gun when the latter is in action. For the wagon remains with its limber attached to it and all the horses hooked into the limber, while the horses and limber of the gun are taken out and sent to the nearest convenient protection. Above all, if the gun is struck by a shell, it does not at all follow that any irreparable injury is done to it; if the wagon is struck by even a large splinter, that splinter may cause all the large store of ammunition contained in the wagon to explode. Now that store is so great that it is quite sufficient to explode, one after another, all the other wagons, and by the general explosion destroy the limbers and guns also, unless the wagons have been removed to a safe distance. At the battle of Speicheren, during the war of 1870, an entire battery was thus swept completely away. Not another round was fired from it. Almost every man in it was killed. The entire destruction was due to one shell, part of which struck one ammunition wagon and exploded it. He would be a very bold man who would undertake that any battery in which a wagon not far removed to the rear had exploded should ever fire another round. The question, therefore, under the present conditions of all efficient fire, is one vital to the existence of artillery. For the horse artillery it is one easily solved; for the field batteries the solution has not yet been found, or at least applied; and it is at this point that the great distinction between the arrangement of the two appears.

The horse artillery, the purpose of which is essentially different from that of the field batteries, requires an altogether different fighting equipment from that of the latter. As it is to act expressly with cavalry, a number of mounted men belonging to the battery itself ride with it. When the gun is to be unlimbered and brought into action, certain of these men, in addition to the two sitting on the limber of the gun, dismount in order to load, lay, and fire the piece. Others are employed to hold the horses of those who dismount, while some of the horses are held by the drivers of the centre horses. Cavalry actions are always quick, sudden, and short. Therefore, the artillery which accompanies cavalry requires to have with it very few rounds of ammunition. Accordingly, horse artillery never moves for action with its wagons. The wagons keep away at a safe distance, and when it is necessary to replenish the supplies with the guns, they send up their limber after the action is over. Thus there is hardly any danger of a wagon's exploding. If by chance one does explode, few men are injured, and the efficiency of the battery is not impaired. The field batteries, on the other hand, have, with the exception of the officers and a few non-commissioned officers, no mounted men riding with the battery. The men who are to lay, load, and fire, sit either on the limber of the gun or on the limber or body of the wagon. For ordinary times—for marches, that is to say, and even for the latest movements up to the moment of coming within range of the enemy—the plan is entirely satisfactory. Field batteries do not require to move very rapidly at such times, and the wagons can trot at a very good pace—can, in fact, move almost as rapidly as the guns. But when the gun is to move up to a position for action the whole difficulty of the case presents itself. It is far too dan-

gerous to allow the wagon to move forward where the gun is. Yet unless the wagon does accompany the gun, how are the men to get there who are to work the piece? The gun is wanted up in a great hurry. Till it can be moved to a certain position nothing can be done. The gun dashes up at a gallop. The wagon stops at the last point to which it can safely move. Often it is necessarily delayed even at a more distant point; for during that last critical movement when the enemy's position is being approached, no portion of the army can be allowed to encumber the way which is not capable of bringing direct action to bear against the enemy. The wagon, therefore, a mere magazine and transporting carriage for men, has to allow masses of infantry to pass it. The gunners dismount and rush up after the gun. But men cannot race with horses, and the gun has all along had a considerable start over the wagon. The gunners, therefore, from the wagon arrive panting and unfit for work many minutes after the gun has reached its destined position. Those minutes are all precious. It is not possible to fire from the exact spot where the horses are obliged to drop the gun. The very reason for the selection of the position is, that there is a convenient bank a few yards off where cover will be just sufficient for the guns and the view perfect. Yet it is hopeless, with the only three men available, to push the gun by hand over the heavy ground intervening. All waits for the artillery. The infantry cannot advance a step till some relief has been obtained from the deadly fire of the enemy's position. It is a time when every officer in the brigade, from the youngest subaltern of infantry to the brigadier-general himself, has more than enough to do with his own work. All eyes and thoughts are strained in watching the enemy's position. Yet no one but the brigadier and his staff are near enough to the guns at the critical moment. Already the enemy have seen the tall headgear of the drivers showing over the bank. In another moment they will have found the range, and may render it impossible for the guns to open fire at all. Down jump brigadier and staff, abandoning all thoughts and cares, lending hard mechanical aid in pushing forward the guns into position. This is no fancy picture. An account of how it occurred in the Crimea may be read in Mr. Kinglake's description of the bringing up of the 18-pounders at the Alma. The remedy was then pointed out. Yet during the autumn manœuvres of last year (1871), in the attack on the Hog's Back, exactly the same thing occurred again as happened seventeen years before. Brigadier-General Browne and his staff assisted personally in pushing forward the wheels of the guns that were brought into position at the village of Seale. Newspaper correspondents applauded the zeal displayed by the officers. Others may, perhaps, mingle with their applause some regret that such waste of power should be necessary. The price in the labour market of a man who can push a wheel is not quite so great as that of one who possesses the capacity to govern 5,000 men. The moment chosen for placing the brigade commander under the necessity of taking part in the mechanical employment, is precisely the one when his higher powers are of exceptional value.

Experiments are now being made with the intention of ascertaining how the difficulty can best be met. It is to be hoped that a satisfactory solution may be arrived at; for it is useless to disguise the fact that since brigadiers can scarcely be provided to work every gun, till some other means of having men to work them, when they are wanted, have been found, our splendid field artillery can scarcely enter upon a campaign at all without the most serious risk.

Various means have been employed by different armies for avoiding the difficulty. Our own Indian artillery used to have gunners on the three horses at present driven, not ridden, by the drivers. The Prussians have men seated on two boxes on the axle-trees of the gun itself. These, with the three men who can be put on the limber and the non-commissioned officer who rides in charge of the gun, manage the handling of the piece fairly well. Our present experiment consists in providing the men with seats on the axle-tree boxes. Unfortunately, we have forgotten to provide them with any satisfactory support for their feet, and the bars to their seats are so uncomfortable that it is by no means easy to ride in them. The gun-carriages have no springs, and cannot have any; for travelling as they necessarily do over very rough ground, only a strong simple construction can be employed. Hence, as the moving a gun often requires very considerable exertion, and the men ought to be quite fresh and up to hard work when they dismount, it is very necessary that their travelling should be made as little fatiguing to them as possible. When the difficulty has been satisfactorily met, either by some means of this kind, or, which is no doubt the easier and simpler plan, by adding one or two more mounted men to the complement of the battery, the field artillery will be able to assume its own definite position and proper place. At present it is, from the circumstances I have explained, in so precarious a condition that it is indispensable to note the changes that must sooner or later be made in it.

The "position batteries" are drawn over the ground by large teams of strong horses intended simply for slow draught, not for manœuvring purposes. Hitherto we have not had any of them formed and kept ready for work in the way in which our horse artillery and field batteries are. But the guns are made, and occasionally they are horsed for the purpose of some large review or for practice. Obviously the same high training is not necessary for those who are to drive and direct them, in order to enable them to move satisfactorily, as they are required. But for them in proportion high training in the use of their weapon for shooting purposes is indispensable, as it is indeed also for both the horse artillery and field batteries. Of this subject I shall, however, have to speak somewhat more fully by-and-bye. At present it is the distinction in the characteristics of the several artillery weapons, as determining the nature of their organisation and use, on which I wish to fix attention.

The mountain guns are usually carried on the backs of mules; the gun on one mule, the gun-carriage on another. These are dismounted and put together when required for use.

In addition to the other classes of weapons which I have enumerated as belonging to field artillery we now include the mitrailleuse; for it has recently been recommended, by the committee appointed to investigate the question, that this instrument shall be employed like other classes of guns in regular batteries. It has one important distinction from all other classes of artillery, however, and it is therefore here that it is convenient to notice what is, for all other kinds of guns, their specific characteristic. They all depend for their effect upon the great superiority both of the distance to which they can throw their projectiles and of the weight of these projectiles themselves over the distance and weight of infantry fire. But the gunners cannot both attend to the handling of their big gun, and at the same time use any small weapons which will enable them to protect themselves if any body of armed men gets close up to the gun and among them. The big gun cannot be well handled against the multitude of small ones over which it has under these circumstances no advantage from its superior range of fire. The gunners, if alone, are therefore helpless victims to the fire of the assailing infantry. Hence artillery can never be left to protect itself. It always requires an escort to guard it. The whole efficiency of its action turns on its being employed just out of the effective range of infantry fire, or at greater distances than that. Thus, though artillery is alike valuable to the army which is on the offensive, and to the army which is on the defensive, its value to the army on the defensive depends on its power of striking such heavy blows against the assailant that he is not able to commence his operations effectively, rather than on its capacity for actually defending the position against him on which it is itself placed. Now the function of the mitrailleuse is the exact opposite of this. It scatters its storm of bullets most effectively from just beyond the range of ordinary infantry fire up to the ground in front of its own muzzle. Hence its action is essentially defensive—defensive of the very spot on which it is placed. It would be too much to say that mitrailleuse batteries will not require, like artillery, escorts to protect them; for they will require all the attention of the men who work them, who will, therefore, be personally unarmed; and at best these men will not escape when defeated so easily as the infantry can do, without abandoning the weapon.

We need not concern ourselves further for the present with the characteristics of the weapons of the field artillery. The yet heavier pieces which are employed by the men who form what is known as our garrison artillery are of one or two kinds. Either they are too heavy to be moved about at all, when they are kept either in fortresses or in batteries specially designed

for coast defence; or they are such as would be required by an army for the purposes of a siege. In either case the first special characteristic of the weapons which affects the character of the organisation and training of the men who work them is the great size and weight both of the guns themselves and of the projectiles which they throw. From both of these, but more especially from the immense size and weight of the guns, it results that mechanical skill of the highest kind is required to move them without an undue expenditure of labour. Every kind of material appliance has to be used, and the men have to become not only, as it has been well said, "skilled mechanics," but mechanics skilled to *work together* in a way that few mechanics are accustomed to work. But this is not all. From the size of the projectiles it is possible (as those will have seen who have studied the papers of THE TECHNICAL EDUCATOR specially devoted to the arms now used) to render them immensely more effective by elaborate workmanship. The explosive materials used are of the most terribly destructive kind, and their care requires a special training of its own. Hence on all these accounts the care and management of the weapon in all its parts, gun and projectile, requires and properly occupies all the attention of such men as are to be really skilled gunners; more especially since, where such enormous masses are to be thrown by a single piece of ordnance, it is of the utmost importance that they should be accurately thrown into the very place where they are intended to create destruction; and therefore the training of the gunners to shoot well requires much time and care. There is one point which is a common characteristic of all classes of artillery weapons. When a very great effect is to be produced upon any one part of an enemy's position, the purpose is to throw into that part as many projectiles as possible. Hence, as guns throw their shot and shell from a very great distance, it is not at all necessary that the guns whose projectiles are all to hit the same place should be themselves all near together. Hence, since nearly always it is more important to produce a great effect at one point than a little effect at a great many, our great object is to concentrate the fire, but to scatter the guns; for since the scattered guns can concentrate their fire, they will be as effective against the enemy, and will be a smaller mark and less observable by him.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXVIII.—LEONARD EULER, F.R.S.

BY JAMES GRANT.

THIS distinguished mathematician, who became Director of the Royal Academy of Berlin, Member of the Imperial Academy of St. Petersburg, Fellow of the Royal Society of London, and Corresponding Member of the Royal Academy of Sciences at Paris, was the son of humble but respectable parents, Paul Euler and Margaret Brucker, and was born on the 15th of April, 1707, at Basle, in Switzerland. "The years of his infancy," says M. Fuss, "were passed in a rural retreat, where the example of virtuous parents contributed greatly to form him in that amiability of character, and uncommon purity of sentiments and manners, which were manifested during the whole course of his life."

Though the wishes of his father, then pastor of the village of Riechen, were that Leonard Euler should study for the Church, he preferred science, and applied himself with success to mathematics under the celebrated James Bernouilli, who in 1687 had been appointed a professor in the university of Basle, which had long ranked as one of the most famous seminaries in Europe. Euler attended its classes with strict regularity, and as his memory was wonderful, he performed his tasks with rapidity, and all the time he gained was devoted to geometry, which became his principal study. Euler hence became the favourite pupil of Bernouilli (then esteemed one of the first mathematicians in the world), whom his genius and rapid progress inspired with genuine admiration.

In 1723, Euler took his degree as Master of Arts, and on that occasion delivered a Latin discourse in which he drew a skilful comparison between the philosophy of Newton and the Cartesian system. He afterwards applied himself to the study of theology and the Oriental languages, and he became the friend and intimate associate of the two sons of Bernouilli, Nicholas and Daniel, through whom it was that his connection with the Academy of St. Petersburg came to pass. Peter the Great's project of erecting that academy was afterwards executed by Catherine I., and on the two young Bernouillis being invited to the Russian capital in 1725, Euler promised to follow if they could procure for him a suitable appointment; and in the meantime he applied himself to the study of physiology, and attended closely the medical lectures of the most eminent professors at Basle.

While thus engaged, he composed a "Dissertation on the Nature and Propagation of Sound," and an answer to a prize question concerning the *masting of ships*, to which the Academy of Sciences adjudged the *proxime accessit*, or second rank, in 1727. From this discourse and other circumstances, it would appear that the comprehensive mind of Euler had curiously enough been turned to the study of navigation—a study which he afterwards enriched by many valuable discoveries.

The lot of certain civil and academical honours which he deemed his due having been decided against him, he left Basle, not without a certain sense of mortification, joined Daniel Bernouilli at St. Petersburg, and with him became joint professor in the university. He now produced several memoirs and papers, and carried to new degrees of perfection the integral calculus, invented the calculation of functions, reduced analytical operations to a greater simplicity, and thus threw a new light on many parts of mathematical science.

In 1730 he was appointed Professor of Natural Philosophy, and three years after succeeded, in the chair of mathematics, his friend Daniel Bernouilli. In 1735 the Academy proposed a problem which required expedition, and for the solution of which the most eminent mathematicians demanded the space of some months. To the astonishment of the Academy it was solved by Leonard Euler *in three days*, but so laborious had been the task, that it cast him into a dangerous fever and deprived him of his right eye. The Academy of Sciences at Paris, which in 1738 had adjudged the prize to his memoir on "The Nature and Property of Fire," proposed for the year 1740 the subject of "Sea Tides," a problem requiring the most arduous calculations, together with a comprehension of the entire solar system. The discourse of Euler on this subject was deemed an exhaustive masterpiece, and it was thought more honourable for him to share the academical prize with such illustrious rivals as Daniel Bernouilli and Colin Maclaurin of Edinburgh, than to have carried it away from others of less reputation. "Rarely, if ever, did such a brilliant competition adorn the annals of the Academy; and no subject proposed by that learned body was ever treated with such accuracy of investigation or force of genius, as that which here displayed the philosophical powers of those three extraordinary men."

On being invited in 1741 to Berlin, where the Academy was then rising into form under the auspices of Frederick the Great, he enriched the last volume of "The Miscellanies of Berlin" with five memoirs which make the principal figure in that collection. With astonishing rapidity other papers followed on the most important subjects, and these are scattered through the "Memoirs of the Prussian Academy," which, ever since its final establishment in 1744, has published one volume annually. The labours of Euler were the more surprising, when it is borne in mind that he did not discontinue his philosophical contributions to the Academy of St. Petersburg, which granted him a pension in 1742, when he was in his thirty-fifth year; and it was with much difficulty that in 1766 he obtained permission from Frederick to leave Prussia and return to the Russian capital, where he was anxious to pass the rest of his life.

Soon after his return, when he was nobly rewarded by the munificence of Catherine II., he was seized with a violent disorder, which terminated in the total loss of his sight! A cataract had formed in his left eye, which had become seriously impaired by too close application to study, and thus he was deprived of the use of that organ; and it was while in this distressing situation, that the untiring philosopher dictated to his servant (who had been a tailor's apprentice, and was totally ignorant of mathematics) his "Elements of Algebra," a work which, though purely elementary, discovers all the characteristics of an inventive genius. It excited applause and astonishment by the circumstances under which it was composed; and in it alone is to be found a complete theory of the analysis of Diophantes, a mathematician of Alexandria, who flourished

before the Christian era, and an edition of whose works, with notes by M. Fermat, was published at Paris in 1670.

When his " Elements " appeared, the Academy of Sciences at Paris honoured him by naming him one of the foreign members of that learned body, and adjudged the prize to three of his memoirs concerning " The Inequalities in the Motions of the Planets." The two prize questions proposed by the same academy for 1770 and 1772 were designed to obtain from astronomers a more perfect theory of the moon.

Assisted by his eldest son, Euler, though totally blind, and in his sixty-fifth year, was a competitor for those prizes, and gained them both! It was a wonderful effort of genius to be able to arrange all his vast calculations by the power of *memory* alone, and when, by embarrassment in his domestic circumstances, a fire having consumed his library and much of his property, compelling him to quit a house which by long habit was familiar to him, he had to compose "a work which alone was sufficient to render his name immortal."

In the great fire of 1771, in addition to the loss of his library, he nearly lost his life. M. Grimon, a native of Basle, on learning that the flames had reached the house of Euler, boldly pressed through the conflagration, and rushing into the apartment of the blind philosopher, brought him out on his shoulders at the greatest risk. By the courage and ability of Count Orloff, the whole of his MSS. were saved.

In this last memoir he reserved for further consideration several inequalities of the moon's motion, which he had failed to determine in his first theory, on account of the complicated calculations in which the method he then employed had engaged him. With the assistance of his son, he had the courage to review his whole theory, and to pursue his researches until he had constructed the new tables, which, together with his great work on the moon, appeared in 1772. Working in darkness, " the heroic patience and tranquillity of mind he displayed need no description," to quote an eulogy of Euler; "and he derived them not only from the love of science, but from the power of religion. His philosophy was too genuine and too sublime to stop its analysis at mechanical causes; it led him to that divine philosophy of religion which ennobles human nature, and can alone form a habit of true magnanimity and patience in suffering."

About this time the famous Wentzel, by couching the cataract, restored the sight of Euler; but the satisfaction and joy of that restoration were of short continuance. By some negligence on the part of the surgeons, and his own impatience, perhaps, to use an organ the cure of which was not complete, he lost his power of vision a second time, and the relapse was accompanied by tormenting pain. However, with the assistance of his son, and Messrs. Kraft and Lexell, he continued those labours of science with an ardour which neither blindness nor the infirmity of advanced age could damp. His lunar tables were, at the suggestion of Turgot, rewarded by the Board of Longitude in France; and when the more perfect tables of Mayer obtained the great premium of £3,000 offered by the British Parliament, the sum of £300 was awarded to Euler for having furnished the theorems made use of by Mayer in his work.

In 1773, Euler published at St. Petersburg his great work on the construction and management of vessels. A new edition soon after appeared at Paris, and by desire of Louis XVI. it was introduced into the schools of marine, and a reward of 1,000 roubles transmitted to the author, accompanied by a handsomely worded letter written by the celebrated Turgot. Almost at the same time Italian, English, and Russian translations of it appeared, and the Government of Catherine II. presented Euler with a gift of 2,000 roubles. Though blind, in the course of seven years he transmitted no less than *seventy* memoirs to the Academy of St. Petersburg; and about two hundred more, that he had written or dictated, were revised for him by his friend Nicholas Fuss. "Euler's knowledge," says the latter, "was more universal than could well be expected in one who had pursued with such unremitting ardour mathematics and astronomy as his favourite studies. He made a very great progress in medical, botanical, and chemical science. What was still more extraordinary, he was an excellent scholar, possessing what is generally called erudition in a very high degree. He had read with attention and taste the most eminent writers of ancient Rome. The civil and literary history of all ages and nations were familiar to him; and foreigners, who were only acquainted with his works, were astonished to find in the conversation of a man, whose long life seemed solely occupied in mathematical and physical discoveries, such an extensive acquaintance with the most interesting branches of literature. No doubt, in this respect, he was much indebted to his most uncommon memory, which seemed to retain every idea that was conveyed to it from reading or meditation. Hence he could repeat the 'Æneid' of Virgil from beginning to end, and indicate the first and last lines of every page of the edition he used."

Several attacks of vertigo, in the spring of 1783, did not prevent him from calculating the motions of air-balloons, which at that time occupied the attention of philosophers. On the 7th of September he dined with M. Lexell, and spoke of the planet Herschel. Soon after he was amusing himself with one of his grandchildren, when on a sudden his pipe fell from his hand, and he expired of an apoplectic stroke, in his seventy-sixth year.

Euler was twice married, and had three sons and two daughters; the latter predeceased him, but twenty-six out of thirty of his grandchildren were alive at the time of his death, which was deemed a national calamity by the Russians, and the Academy of St. Petersburg decreed him a marble bust at their own expense. A complete list of his works occupies no less than fifty-one pages of Nicholas Fuss's " Elogé," which was published there, in quarto, in 1783; and a collection of the best productions of Euler appeared at Brienne, in eighteen volumes, in 1797.

Euler was a rigid Calvinist, and so long as his sight was spared he assembled the whole of his household every evening and read a chapter of the Bible aloud; he was wont to add a little exhortation or discourse, theology having been from his boyhood one of his favourite studies. His habits were ever sober and temperate; his manners unaffected and pleasing; his temper cheerful and happy.

THE LATHE.—VIII.

By Henry Northcott.

SLIDE-RESTS (*continued*)—MODERN HAND-LATHE.

The slide-rest illustrated at Fig. 25 is of more modern design than those hitherto noticed. This instrument is intended chiefly for operating upon metals, whilst the previous ones were adapted chiefly to act upon more tractable materials, and as a consequence of this difference in the nature of its work the present slide-rest is constructed wholly of iron, and of more massive proportions. In action it is precisely the same as those already described—that is to say, it has a foot-plate, *a*, which is planed underneath, so that it may bed nicely down upon the planed surface of the lathe-bed, and carry the various slides duly level and square. The slot shown along the foot-plate is, of course, for the holding-down bolt to pass through it.

It may be remarked here that the bottom surface of the foot-plate of any slide-rest should not only be planed and rendered smooth, but its area should be large, so that it may steadily support the slides against the pressure resulting from heavy and irregular cuts. If the foot-plate be too narrow, the whole rest becomes very unstable when a heavy cut is being removed from a piece of work, and this unsteadiness becomes especially noticeable when the tool is moved to the end of its slide on either side, as then the tendency of the strain upon the tool is to upset the rest or to depress the cutting tool. Many slide-rests are rendered almost unserviceable from having a foot-plate too narrow to firmly resist the pressure upon the tool.

The slide-rest also has a strong traverse-slide, *b*, with the usual screw and winch-handle, and also a surface-slide, *c*, the top part of which, *d*, is the tool-plate. The tool-holder is somewhat different from those heretofore described, consisting of a flat plate with three screws in it. The plan of this plate is triangular, and the three screws are placed one at each of the three corners of the triangle. The plate has a hole through its centre by which it is supported upon the central spindle, and the fit is a loose one, so that the plate may be swung round upon the central spindle, and placed in any position with regard to it. The tool is placed under two of the screws, and is fixed at any angle that the nature of the work may render

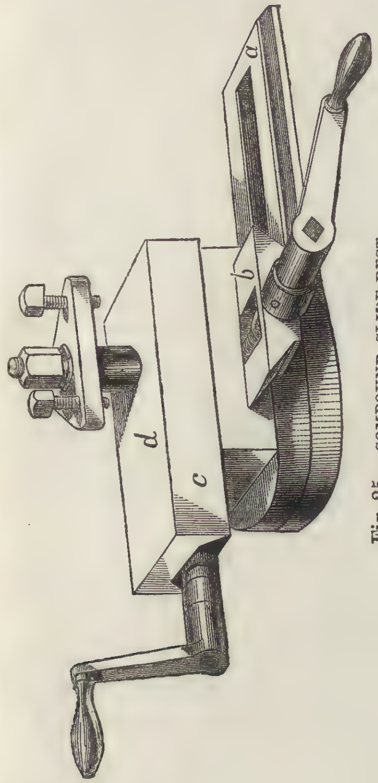

Fig. 25.—COMPOUND SLIDE-REST.

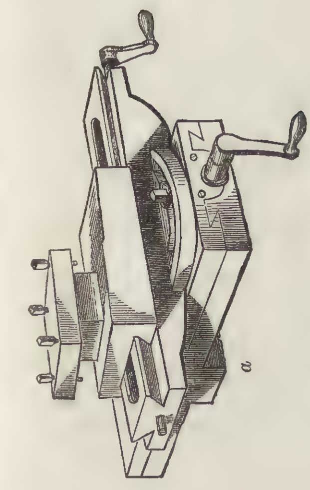

Fig. 26.—COMPOUND SLIDE-REST.

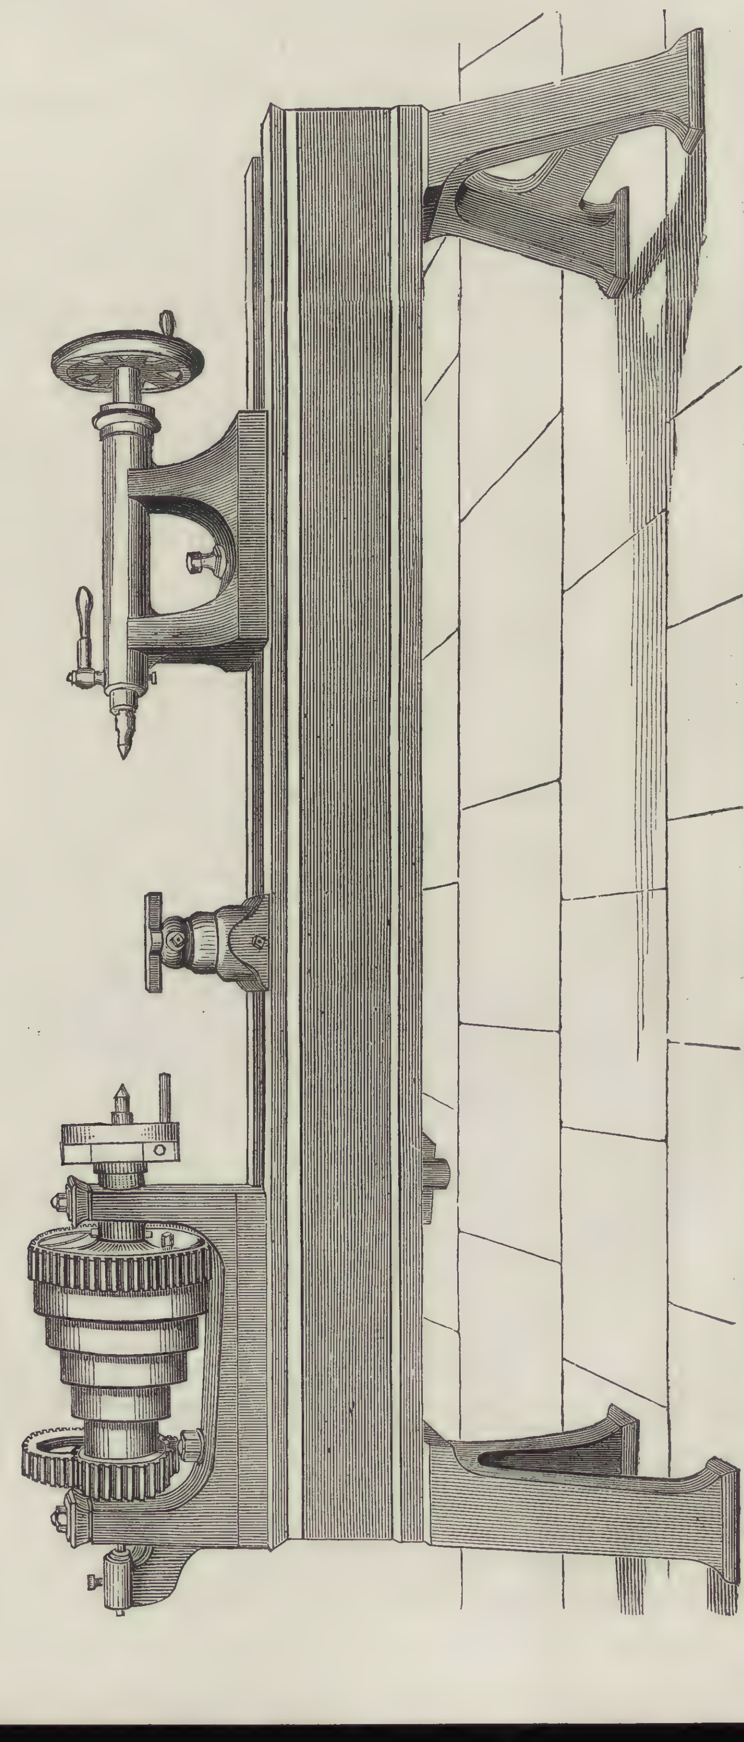

Fig. 27.—HAND-LATHE, CONSISTING OF TWO HEAD-STOCKS, CATCH-PLATE, FACE-PLATE, REST-SOCKET, AND TOP CONE-PULLEY.

necessary by tightening the two screws down upon it. The third screw acts simply as a support to the other corner of the triangular plate, to keep the plate horizontal, and prevent the two screws holding the tool down from throwing any cross strain upon the central bolt. A convenient and efficient tool-holder is quite essential to the satisfactory action of any slide-rest. This one is simple, and its principle is good, but in the example it is not so well carried out as it might be, and more favourable specimens will be met with hereafter. The three screws should in every case be made of steel and hardened throughout, but their points should be left somewhat harder than the thread of the screw, as they come in contact with the hard steel tool, which would otherwise flatten or "upset" the ends of the screws. It is advisable also that the plate should be of a good thickness, especially at the part where the screws go through it, as the continually screwing down so hard and unscrewing these screws soon wears out the thread if the plate be thin.

At Fig. 26 is shown another and more complete example of a compound slide-rest. This one also is constructed wholly of metal, and all the sliding surfaces are planed up, and should be scraped to a true surface. The projecting rib at *a* goes between the two slabs of the lathe-bed to preserve the parallelism of the traverse-slide, and the position of the rest generally. The arrangement of the traverse and surfacing slides is shown very clearly by the sketch. They are constructed in much the same manner as the previous ones, and it will be seen that the upper slide has an angular motion, with a curved slot and screw for the production of tapering and angular work. The tool-holder in this case has four screws, arranged one at each of the corners of a square plate. This plate is not movable, as the last was, around a central pin, but is firmly fixed to form a part of the upper plate. The tool is placed under any two of the four pinching screws, and there is thus a choice of four positions, any one of which may be chosen that the shape of the work may render most convenient. The choice of positions is much more limited than in the last example, and this is no doubt a disadvantage, but the holder is very strong and efficient in all other respects.

At Fig. 27 is shown a strong substantial lathe of modern design, for the execution of tolerably heavy hand-turning in either wood or metals, but chiefly in metals. The massive cast-iron bed is carried by two strong cast-iron standards, which are required to support it steadily. The surfaces where the standards come in contact with the under-side of the bed are planed, and they are bolted together, so that the bed and standards may be as firmly attached to each other as if they were one solid casting. The top surface of the bed also, and the inside edges forming the space between the two sides of the bed, are truly planed up to a smooth surface, so that the screw head-stock may be slid anywhere along the lathe-bed without affecting the position of the line joining the lathe-centres. The driving head-stock is, of course, firmly fastened down upon the lathe-bed, its bearing-surface being planed to fit properly down upon the surface of the bed. The rib projecting from the under-surface of the head-stock, instead of being made to fit nicely between the two slabs of the bed, is sometimes left much narrower, in order that the whole head-stock may be shifted bodily out of the usual line of lathe-centres. This provision, however, is only of use for sliding lathes, or with lathes having slide-rests with fixed slides, as the object of it is that with the tool following its usual course parallel to the proper line of lathe-centres, taper and angular work may be produced instead of ordinary turning. When the head-stock is so constructed two screws are placed through the projecting web, and so as to come across the space between the two planed edges of the lathe-bed, which they accurately fit. By turning these screws in the proper direction the position of the head-stock may be very nicely adjusted to produce any small amount of taper, or it may be adjusted to the slide-rest for producing a flat surface or a parallel shaft. Of course this arrangement is not required for lathes intended solely for hand-tool turning, nor for such as have slide-rests with shifting slides. With the first the shape of the work would be quite unaffected by the position of the lathe-spindle, and with the second the taper can be produced by shifting the slides, and without shifting the head-stock. The cone-pulley of this lathe has five speeds, and is adapted to receive a flat leather belt and to drive from a shaft overhead. The speeds may be still further varied by the double-gearing, in the manner previously explained. The small hand-tool rest shown in place upon the bed may be removed, and a slide-rest substituted, when the nature of the work renders it advisable.

PRACTICAL APPLICATION OF THE FINE ARTS.—XI.

THE ART OF MOSAIC (*continued*).

By P. H. Delamotte, Professor of Drawing, King's College, London.

In the practical application of fine art to mosaic, we must use those canons of art which are universally true, modifying these according to the material in hand. Of course, designs for the decorations of walls will be different from those for floors. The Romans certainly did put much good work and beautiful pictures upon the floors, much as we see handsome carpets now-a-days with bunches of flowers and even landscapes portrayed upon them. Still we suppose that scarcely any one could put his heavy boot upon the Cirencester Ceres or Flora without a pang; if his taste did not feel it, he would deserve a twitch of gout to remind him of what he ought to consider. It would be very inconvenient to be continually jumping about to avoid pressing an unhallowed heel upon some fair production of nature: we cannot, therefore, admit the representation of natural objects upon a floor intended for general traffic. It remains for us to discuss the character of designs that are admissible; and our choice is limited to colour and form.

In form we cannot do better than go back to the simplest patterns and the most classical models. The common Grecian border (Fig. 23, Cirencester), either in its ordinary form or as we have it here, is an unfailing source of pleasure to the eye. Another very common border, very convenient from the possibility of turning or stopping at almost any point, is the twisted cable, as shown in Fig. 22. The Grecian is slightly altered, by being adapted to what might be almost called oblique co-ordinates, and enclosed in a diamond-shaped compartment in the pavement from Threadneedle Street (Fig. 26). In this relic we have, too, another very common design, the endless knot, whilst square compartments are mingled with diamond-shaped ones, rhomboids affording a pleasing variety of oblique, acute, and right angles. In this, too, we have idealised flowers and leaves of two kinds. The endless knot and some of the other ornaments occur again in Fig. 25, from Cirencester, combined with some other very felicitous forms. The arrangement of eight rhomboids around a point in a shape somewhat approaching both a cross and a star, is very happy; and the introduction of regularly curved lines in the terminal border breaks the monotony of so many straight lines with no greater curves than those of the endless knot. In this example the cable is coloured on the inner side of a brownish-orange, whilst the two outer rows of tesseræ are nearly white; the same colours and arrangement hold good of the endless knots. The diamonds are separated by black lines; the interior of all of these are yellow; whilst the line immediately round the interior is black and orange in alternate diamonds, white coming again between this and the black.

In Fig. 20, from Abbots Ann, Hampshire, we have scarcely more than the idealised leaves of the former figure carried out a little further, and more idealised, and more geometrical; and in Fig. 21, within a similar border to some of the former, a more complicated figure is introduced, still, however, mainly founded on the cross and circle.

The next kind of ornament that we meet with is of a somewhat different character. It consists no longer of mere geometrical lines, straight and curved, adapted more or less to pleasing shapes, and sometimes approaching the form of idealised flowers and leaves; but we have now in such patterns as that from Cirencester (Fig. 24), and from Woodmanchester, in Gloucestershire (Fig. 19), the scroll-work of which the main foundation is the imitation of leaves and branches; still, of course, thoroughly idealised. This style of ornamentation can at the present day be carried into far higher perfection than was the case under the Romans, since the experience of so much mediæval and renaissance work, though the latter may be considerably overcrowded and redundant, has contributed greatly to a just taste in such designs. Too much cannot be done in this direction, where the material in hand will admit

of adaptation to this use. This will be the case especially when natural materials or *smalti*, as the small pieces of glass are called, are employed. These *smalti* are fragments of glass broken off larger cakes of six or eight inches long by four or five wide, and of a tolerably uniform depth of nearly half an inch. These broken pieces, of course, are not quite uniform in shape, so that the form can be chosen which is best adapted to the pattern in hand, whilst for flat surfaces the pieces most nearly approaching regular cakes are preferable. But if terra-cotta or other forms of clay manufactured in the shape of small tiles are employed, it will most naturally happen that these fall into regular geometrical patterns. Of course, where the subject is large, and the tiles employed are very small, and both cubical and triangular, a very near approach can be made to either a scroll pattern or an imitation of natural objects; but after all this is rather adapting a somewhat unwieldy material to a purpose alien from the best use of ornament, which consists in applying the material to the most pleasing effect of which it is naturally capable.

When the surface to be covered is a wall or piece of furniture, there is then no reason why a picture should not be imitated. Thus the great churches of Italy have their walls decorated, and these copies of the masterpieces of great painters carry to posterity a very close approximation of the original works unimpaired by the passage of time. We say a very close approximation, because however accurately a great work is copied—and the Italians are certainly great copyists in the best sense of the word—a copy can never convey the whole grace and beauty, and thought of the original, unless the hand and heart of the master be employed upon the copy, when, of course, it becomes no longer a copy.

But even of pictures, some are more suitable to this style of material than others. To a great extent the subjects suitable for fresco painting are also adapted for representation in mosaic. A study of great works in the various churches in Ravenna, of which photographs have been taken, will show the character of work which the early workers in mosaic thought best adapted to their material. Here we have the calm, placid figures represented in a dignified repose, such as one might expect would be consonant with the feelings of the descendants of the Greek sculptors of old. No excited emotions, but a calm dignity of feeling—not absolute rest, but a position of motion temporarily and naturally suspended; these characteristics lend themselves agreeably to the means in the artist's hand.

It is not granted to every one to have the means of studying the best models, nor is it by any means in the power even of those who ardently desire it, to design great works of art; but that is no reason why all who make attempts in any branch of art should not place before themselves the highest attainable model, and strive to the best of the ability they may happen to possess to approach as near perfection as possible in the works they take in hand. The constant exercise of all one's powers must lead to increased facilities and capabilities, and thus the hand, the eye, the taste, and the knowledge become expanded and strengthened, just as under the judicious training of a gymnast the muscles of the body gain both strength and rapidity of motion.

TECHNICAL DRAWING.—LXVII.

DRAWING FOR BRICKLAYERS.

THE MANNER OF LAYING BRICKS—THE TERM "BOND" DEFINED.

In building with bricks, as all the parts are equal and regular, they are laid in horizontal courses from the foundation upwards. The reason is obvious: regular bodies, such as bricks placed on a horizontal base and with vertical sides, have no tendency to move laterally. If, on the contrary, bricks were laid on an oblique base, they would have a tendency to slide downward in one direction. Hence the wall might eventually bulge or crack, or lose its perpendicularity.

If we suppose a wall of only half a brick thick, all the bricks used would of course be laid lengthwise, so as to show their whole length in the face of the wall, in which case they are called "stretchers" ("Building Construction," Vol. I., p. 141).

In laying a second course of bricks, care must be taken to prevent any two vertical joints from coinciding. This would be effected by placing the joints or meeting of the ends of the second course of bricks over the middle of the bricks of the first course. The same arrangement would be attended to in the third and in all the succeeding courses.

Fig. 533 is the plan and Fig. 534 is the elevation of part of a brick building in which the walls are supposed to be half a brick thick—that is, $4\frac{1}{2}$ inches—and built in the manner just described.

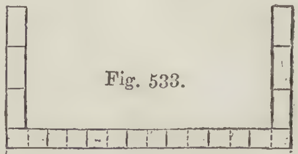

Fig. 533.

This arrangement of never allowing any two vertical joints to coincide is technically termed "breaking joint," and a wall thus built is said to have a proper bond—a term which implies that the parts are properly connected.

It will be observed that all the bricks represented in the elevation are stretchers, showing their whole length in the surface of the wall, excepting one brick at the angles of the wall in each alternate course, *a*, *a*, *a*, *a*, which shows itself in the elevation. A brick thus laid is called a *header*.

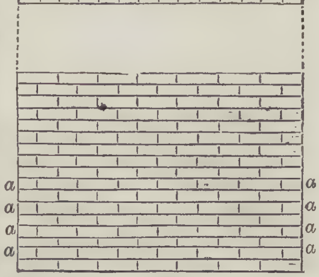

Fig. 534.

By this method of placing a header at the angle of each alternate course, a "bond" is obtained. If the whole were laid in stretchers throughout, as in Fig. 535, all the vertical joints would coincide, and the wall would only consist of upright piles of bricks, the entire weight of each pile resting on one brick below, and there would be no connection between the upright stacks but the mortar in the vertical joints, which would, of course, be insufficient to prevent either one from separating. This has been fully explained in lessons on "Building Construction."

It must be mentioned that the above example is introduced merely as an illustration of the necessity for correct bonding of the bricks; but walls of half a brick thick are not used in any proper building, being far too weak to afford the necessary stability even to the smallest buildings, unless the brickwork be held together by a wooden frame, of which it fills the intervals. This style of building, used for economy, is altogether unsuitable for public buildings, unless of a very temporary character, and is called *brick nogging*, specimens of which are seen in many villages.

Brick nogging is sometimes used for partitions in dwelling-houses.

All proper walls, then, are one-brick thick and upwards, and it is to be observed that in such, bond cannot be obtained without introducing parts smaller than a regular brick near each angle or opening—that is to say, not only at the corners of the walls, but also at each side of every door, window, or recess throughout the whole building.

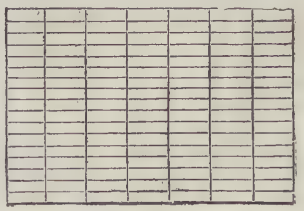

Fig. 535.

For instance, if we suppose a wall to be one brick (that is, about 9 inches) thick, the bricks may evidently be laid either as *headers*, in which case one brick laid across, front to back, occupies the whole thickness of the wall; or as *stretchers*, in which case two bricks laid alongside of each other in the direction of the length of the wall make up the thickness.

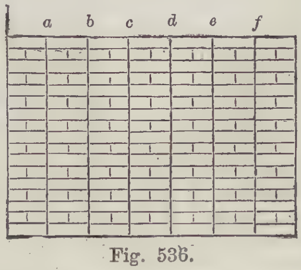

Fig. 536.

Now if we suppose Fig. 536 to represent the elevation of a wall in which the bricks are all of the regular full size, and laid headers and stretchers alternately and in successive courses, it will be evident that one-half of all the vertical joints, *a*, *b*, *c*, *d*, *e*, *f*,

must necessarily agree, because every two headers occupy in the face of the wall precisely the same space as one stretcher, and the effect would be practically the same as that shown in Fig. 535—namely, the wall would be formed of mere stacks one brick wide.

To obviate this inconvenience, which would render the bond very imperfect (since, although the vertical stacks are bonded together by the bricks of which they are formed crossing each other, it has been shown that they are only united by the mortar), small headers, only a quarter of a brick in width, are used near each angle, opening, or break in the wall, as was before mentioned, the utility of which will be evident on comparing Fig. 537, in which this method is represented, with the preceding figure.

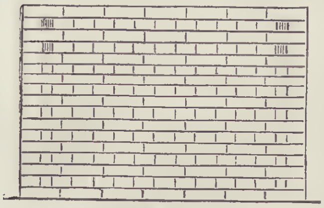

Fig. 537.

In this figure, some of the small headers are shaded, in order that they may be better visible. They are technically termed *closers*, and are further described and illustrated in lessons in "Building Construction."

On examining any brick building the student will at once see that this arrangement is generally followed, and thus a perfect bond is produced throughout the whole wall, it being observed that these narrow bricks appear in alternate courses only, and are the second brick from the angle of their respective courses, the first or corner brick of the same course being always a header.

Broken bricks are generally called brickbats; but the term *bat* is by workmen specially applied to the one half of a brick broken across the middle.

A regular bat, or half-brick broken a second time, produces two pieces, each a quarter of a brick in width and half a brick in length, which combine to form a closer. These pieces singly are called *half-closers.* When a brick is broken transversely into two unequal parts, the larger of the two is called a *three-quarter bat.*

The remarks hitherto made upon the bond of brickwork apply only to the external surface of the wall, as seen in elevation, which may be judged of by the eye. In walls of certain thickness, the internal bond, which cannot be seen or examined after the work is finished, is of equal importance.

Fig. 538 represents the section of a wall two bricks in thickness, in which the courses are supposed to be laid alternately, all headers and all stretchers, so as to correspond with the foregoing elevation, and yet, owing to a faulty arrangement of the bricks used, all the vertical joints in the middle of the wall coincide with each other. It will be evident that such a wall, although it would appear strong and perfectly bonded if the external surfaces only be examined, has no proper bond internally, for one vertical joint prevails from top to bottom, and from one end of the wall to the other; so that such a wall would be liable to split in two by a longitudinal fracture.

By adopting a different arrangement, as in Fig. 539, which represents the section of a wall of the same thickness, the above defect will be completely obviated, for it is evident that all the vertical joints, internal as well as external, are now perfectly broken, and that a sufficient bond is thereby obtained throughout every part of the wall.

Fig. 538.

Fig. 539.

It will hereafter be seen that it is often convenient, if not absolutely necessary for the purpose of obtaining the most perfect bond, to finish one side of a wall, not exactly, although nearly, in the same manner as the other, so that although both elevations may appear alike to an inexperienced observer, the arrangement of the joints of the one will in reality be less regular than the other. In this case the *face of the wall*, which in a building implies the external surface, being that exposed to view, must be finished in the most regular manner, in preference to the *back* or internal surface of the wall, which is eventually (at least in most cases) concealed from view by plastering or papering.

Having thus defined the term "bond" in general terms, and having entered into the subject at some length in lessons on "Building Construction," it is now proposed to give further instruction on this all-important branch of the bricklayer's work. In doing this, it may be necessary to repeat some few paragraphs or illustrations from the lessons on the general subject, with the view of showing their intimate connection with the present course of lessons. The student is urged to make himself thoroughly acquainted with the subject as a whole before proceeding with further detail. It is not, however, sufficient to read, even though that reading be accompanied by drawing: the instruction must be *realised*, and for this purpose a number of wooden bricks should be provided. These can be obtained from any carpenter, and may be of any convenient size,

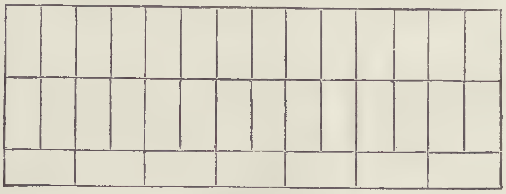

Fig. 540.

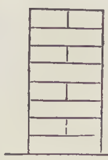
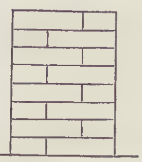
Fig. 542.

Fig. 543.

Fig. 545.

Fig. 546.





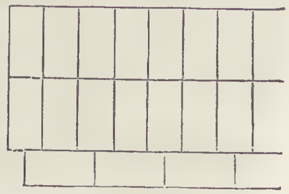


Fig. 544. Fig. 547. Fig. 541.

so long as the true proportions are kept up. About half the real size will be found best adapted for class teaching, whilst for private study quarter size will be sufficient. Amongst these model bricks should be bats (or half-bricks), closers (or bricks cut in half lengthwise), and also a few quarter-bricks.

With these the walls of different kinds and thicknesses, in two or three courses, should be built according to the instructions here given. The drawing will then be intelligently made, whereas it would otherwise degenerate into a mere copy of straight lines.

DRAWING FROM SOLID OBJECTS.

In all the examples hitherto given, *one surface* only has been shown of each of the subjects under consideration.

Now, for absolutely working drawings this is all that is necessary, such drawings being required to show the exact position

of every wall, or of cornice, sill, or step, so that the work may be executed according to the exact measurement of the design.

But if it be required to draw a house or any other object in such a manner that an impression of solidity may be given, further study and practice becomes necessary, and the student is referred for instruction on this head to the series of lessons on "Object Drawing" commencing at page 3, Vol. II. of THE TECHNICAL EDUCATOR.

LINEAR DRAWING BY MEANS OF INSTRUMENTS.

We have in lessons on "Building Construction" given the general distinction between English and Flemish bond, and we

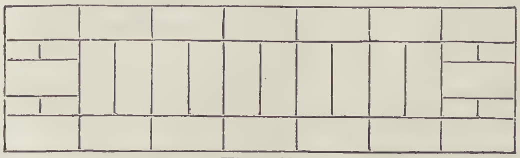

Fig. 548.

Fig. 549.

Fig. 552.

Fig. 553.

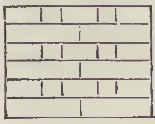

Fig. 550.

Fig. 551.

Fig. 554.

now proceed to the further elucidation of the subject, adopting the system laid down by Sir Charles Pasley, R.E.

COMMON ENGLISH BOND.

In common English bond, alternate courses of headers and stretchers appear on each side of the wall, so that the elevation of it is the same which has already been described in relation to Fig. 537. But with the exception of the stretchers, already mentioned, which appear externally, no others whatever are used, so that the remainder of the wall consists exclusively of headers.

In looking at a wall thus built, those courses where headers appear to the eye, are called *heading courses;* but those in which the stretchers appear, are called *stretching courses*, notwithstanding that the inside of the latter may be filled up with headers.

It is essential in common English bond, that the horizontal joints in each course shall never be broken, but that the bricks shall be so arranged that the whole of the opposite joints shall extend transversely in one and the same right line from one side of the wall to the other—that is to say, the bricks of the same course must always be arranged as in Fig. 540, not as in Fig. 541.

By attending to this rule this style of building will be found

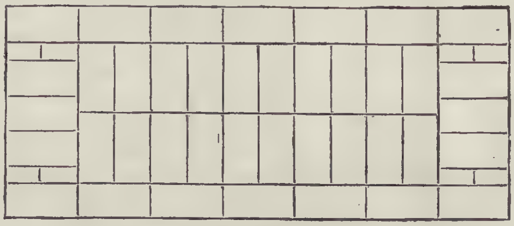

Fig. 555.

extremely simple. In a wall whose thickness is either one brick, two bricks, three bricks, four bricks, or any other dimension involving a whole number, the stretching courses agree on both sides of the wall; but if the thickness be one brick and a half, two bricks and a half, three bricks and a half, or any other dimension involving a half brick, that which is a stretching course on the one side of the wall is a heading course on the other side, and *vice versâ.*

In order to exemplify the common English bond thus described in general terms, we will suppose a portion of a brick wall equal to seven bricks in length, and terminating with both its ends at right angles to the general line of the wall. This portion of brickwork may represent part of a wall contained

Fig. 556.

between the openings of two adjacent windows. It is true (says Sir Charles Pasley) that the sides of windows are not now usually finished in such a simple manner; "it was, however, the method used formerly," and we will therefore suppose them to be so for the sake of illustrating the peculiar kind of brickwork now under discussion.

Fig. 542 represents the plan of the stretching course and Fig. 543 the plan of the heading course of a wall of this description—one brick thick. In the heading course it will be observed that closers are laid next to the extreme header at each end, without which the proper bond could not be obtained.

Fig. 544 is the section or end of the same wall.

Figs. 545 and 546 represent two successive courses of a wall of

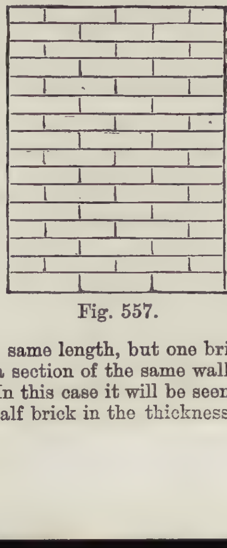

Fig. 557.

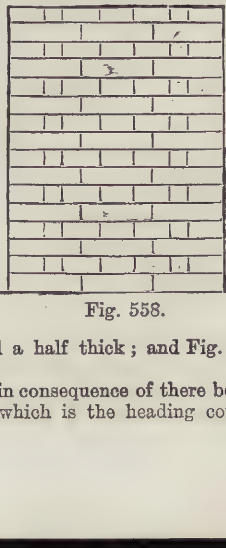

Fig. 558.

the same length, but one brick and a half thick; and Fig. 547 is a section of the same wall.

In this case it will be seen that, in consequence of there being a half brick in the thickness, that which is the heading course

in front is the stretching course in the rear of the wall, and *vice versâ.* At the ends of the wall three-quarter bats are used in alternate courses in order to obtain the proper bond.

In this example, too, it will be observed that the two sides of the wall are not exactly alike, and the same will occur in all walls built according to common English bond, in which half a brick is involved in the thickness of the wall.

Figs. 548 and 549 represent the plans of two successive courses of a similar wall of two bricks thick. On attaining this thickness the ends of the wall present a more considerable surface than in the former examples, and require to have their joints broken by means of a couple of closers in alternate courses, it being necessary to treat the square ends of walls of a certain thickness precisely in the same manner as if they were short portions of the front of a building. Fig. 550 is the section and Fig. 551 the end elevation of the same wall. Figs. 552 and 553 represent the plans of two successive courses of a wall of the same description, but of two and a-half bricks in thickness.

Fig. 554 is the end elevation of the same wall in which a half brick, shown also in Fig. 555, is necessarily used in the centre of each alternate course in order to obtain proper bond.

Figs. 555 and 556 represent in like manner the plan of two successive courses of a wall three bricks thick. Fig. 557 is the transverse section, and Fig. 558 the end elevation.

MUSEUMS: THEIR CONSTRUCTION, ARRANGEMENT, AND MANAGEMENT.

BY SAMUEL HIGHLEY, F.G.S., ETC.

VII.—NATIONAL MUSEUMS.

In my article on Museums at page 358, Vol. II. of The Technical Educator, I have given a theoretical notion or Utopian idealisation of what *the aims* of a national museum should be. I shall now attempt to show how far such ideas may be realised in practice, under conditions which are sure to arise in a great city, that would prove antagonistic to the carrying out in its entirety any such scheme as I have therein suggested.

A review of all the facts connected with such a question are well worthy of the careful consideration of naturalists at the present moment, when through the exigencies of space at the British Museum, it has been determined, notwithstanding the grave objections, hereinafter stated, that have been raised by influential persons to separate the natural history collections from the antiquarian departments and the library of the British Museum, and remove them to a new museum now being erected on a plot of ground on the Gore Estate, on the site of the International Exhibition of 1862.

It behoves all who have any influence to see that the new National Museum of Natural History shall not be cramped in its future development for want of sufficient space; that the architectural arrangements and internal fittings meet the requirements of the day; and that its entire organisation shall be established on a true and proper basis for "arranging, preserving, and exhibiting in a fitting manner a natural history collection worthy of the country as well as of its capital, and intended not only for the special advantage of students and scientific men, but generally for the rational amusement and instruction of all classes;"* even whether it should not also embrace the aims of the Museum d'Histoire Naturelle in the Jardin des Plantes at Paris, as defined by the Directory of 1793, viz., "the advancement and teaching of the natural history sciences in all their branches and in their application to the arts and manufactures."

In commencing this inquiry, it is advisable to consider the objections that have been raised to the severance of the scientific from the antiquarian, artistic, and bibliothecal collections. Foreigners regard our British Museum unique as to its aims in collecting under one roof all attainable specimens illustrative of literature, science, and art, so that it may be "regarded as a consulting encyclopædia, a repertory for reference to all these departments of human knowledge."† But, nevertheless, while protesting against any breaking up of the present harmonious system, nor failing to notice that while our Parliament year by year, votes supplies for the purchase of additional specimens, it injudiciously does not allow of their proper display, by begrudging money for an extension of the galleries of a museum palpably over-crowded, many of our own countrymen expressed their objections not only on this head, but on the inconvenience that would be experienced if the natural history collections were separated from the scientific books in the Museum library. Others conceived that the natural history collections would be little visited if removed from their present central position to South Kensington, and on this score the severance would prove of especial inconvenience to working naturalists. So strong was this feeling on the question of dismemberment, that the late Sir Roderick Murchison, one of the trustees of the British Museum, declared before the committee that though he had bequeathed to the British Museum the colossal vase of Siberian avanturine granite presented to him by the Emperor of Russia, under the impression that it was the proper resting-place for such an embodiment of science and art, if the natural history collections were removed, it would affect that intention, and he should alter his will.*

For many years past Dr. J. E. Gray, as keeper of the Zoological collections, has, in his annual report to the trustees, called attention to the urgent necessity for providing additional space for the natural history specimens, those displayed in the galleries being as far back as 1848 inconveniently crowded, while many valuable specimens and collections were obliged to be stored in the vaults beneath the museums. Thus, in 1816, when Cuvier visited this country, mainly with the object of examining the only known specimen of the skull of the right whale, he had to be conducted by the light of a lantern to the lower regions of the British Museum. If any osteologist of the present day desired to inspect that skull of a right whale in a wrong place, he must descend to the same vault, and examine it by the same light, as in Cuvier's day. Since Professor Owen's appointment as superintendent of the natural history collections he has persistently urged the pressing necessity for additional galleries, or a new museum in some other district, as it was utterly impossible, under the existing state of things, for the officers of that institution to do justice to the national collections, for the proper keeping of which they are responsible to Government.

In 1858 both the trustees and the Government officers seemed to fancy that the only satisfactory way out of the difficulty was by providing a new museum for the natural history collections, and availing themselves of the space left vacant for the equally pressing wants of other departments; Professor Owen being requested to submit an estimate of space required, and a plan for a new national museum of natural history. This he laid before the trustees March 16th, 1859, including therein modifications of his scheme, to suit ground immediately adjoining the British Museum, or a site on the Gore estate *now* occupied by the west galleries of the International Exhibition, and the machinery sheds in Prince Albert's Road. Meanwhile a memorial had been forwarded to the Chancellor of the Exchequer by nine of our leading naturalists—viz., Bentham, Harvey, Henfrey, Henslow, Lindley, in the interests of botany; and Busk, Carpenter, Darwin, and Huxley, in those of zoology—dated November 18th, 1858, requesting a full consideration of the requirements of naturalists before any scheme or re-organisation was finally decided on, and stating their own convictions as to the arrangements best adapted to meet the twofold object of the advancement of science and its general diffusion among the public; and to show how far the scientific museums of the metropolis and its vicinity, in their present condition, answer their purposes, and to suggest such modifications and additional arrangements as appeared requisite, and to render them more thoroughly efficient. The opinions expressed in this memorial may be summarised by specifying the museum deemed necessary to meet the above stated object:—

1. A general and comprehensive typical or popular museum, in which all prominent forms or types of animals and plants, recent or fossil, should be so displayed as to give the public an idea of the vast extent and variety of natural objects, to diffuse a general knowledge of the results obtained by science in their

* See the "Treasury Minute" quoted in Panizzi's letter to the superintendent and keepers of the Natural History Departments, March 6th, 1862, Parliamentary Papers, 1864, Vol. XXXII.

† *Vide* Report of Select Committee on the British Museum, Parliamentary Papers, 1860, Vol. XVI.

* Since Sir Roderick's death this magnificent specimen of avanturine granite and work of art has been transferred to the Museum of Practical Geology, of which he was Director.

investigation and classification, and to serve as a general introduction to the student of natural history.

2. A complete scientific museum, in which collections of all obtainable animals and plants and their parts, whether recent or fossil, and of a sufficient number of specimens, should be disposed conveniently for study; and to which should be exclusively attached an appropriate *library*, or collection of books and illustrations relating to science, wholly independent of any general library.

3. A comprehensive economic museum, in which economic products, whether zoological or botanical, with illustrations of the processes by which they are obtained and applied to use, should be so disposed as best to assist the progress of commerce and the arts.

4. Collections of living animals and plants, or zoological and botanical gardens.

As zoologists and botanists, the memorialists offered no opinion as to the best disposition of the valuable mineralogical collections in the British Museum, and the economic collections in the Museum of Practical Geology.

The memorialists suggested that all the zoological collections with a select zoological library, together with a typical or popular museum of botany, for the convenience of those resident in the metropolis, should be placed under one direction, while the herbaria of the British Museum should be consolidated with the Kew collection, and be removed to a permanent building to be provided for their accommodation at Kew, and these, with a select botanical library, should be placed under one direction. That the directors of the Zoological and Botanical Museums should be directly responsible to one of Her Majesty's ministers for the proper management of the several departments. That the Museum of Economic Zoology at South Kensington should be further developed, and that the Museum of Economic Botany should be retained at Kew. That the existing collections should be separated into popular typical and student's scientific collections, and that while the former should be accessible to the general public every day in the week, the latter, with their respective libraries, should likewise be daily available to students of zoology and botany only. The economic and living collections should be available to the general public. The Typical and Economic Museums should be fully displayed in spacious galleries, in large buildings, in light, airy, and accessible positions. The scientific collections for the special use of working naturalists need only occupy small space in convenient studies, and be so arranged as to allow of the specimens being taken from their receptacles for direct examination.

This memorial, in connection with Professor Owen's estimate of space and plan for a new national museum of natural history, led to the election of the Select Committee of the House of Commons of 1860 to ascertain the requirements, created by the necessity for an increase of space, of the British Museum, and to the introduction of a bill to empower the trustees of the British Museum to remove the natural history collections, and other objects to any suitable place, notwithstanding the pressing necessities of the case as stated by Professor Owen, Dr. Gray, and other keepers of the natural history collections, as given before the committee, in correspondence between the Treasury and the trustees and their officers, and in the report of Professor Owen and the keepers of the Natural History Departments, March 16th, 1862. This bill was thrown out on the score of expense at the debate on the affairs of the British Museum, May 19th, 1862. It is amusing to note how thoroughly unconversant men of education and of the highest political status can be in regard to the requirements of science, and with the unity of natural history classifications. In his estimate and plan of March 16th, 1859, Professor Owen pointed out the necessity of acquiring skins and skeletons of the whale tribe, as illustrative of the greatest bulk attainable in the present epoch, and as one of the peculiarities of the Mammalian class, especially as the largest species, the right whale (*Balæna Mysticetus*) may become extinct, through its extensive slaughter by whale fishers, for the Museum only possessed the skull previously referred to, stowed away out of sight in the cellars. Further, he had estimated the length of the skeletons of the right whale at 95 feet, sperm whale 75 feet, bottle-nose whale 40 feet, grampus 30 feet, finner whale 20 feet, but by reason of their vast size such specimens, which would be of the greatest value to the naturalist, he could only expect to find accommodation for in "a national museum." He estimated the length of gallery for the *entire* Mammalian series at 850 feet. In the debate Mr. Gregory, who opposed the bill, exclaimed, "850 feet for the exhibition of whales!" in the same vein as Dominie Sampson gave vent to "prodigious!" Viscount Palmerston in his speech said, "Let me propose a compromise to my honourable friend: let him, when the House shall go into committee on the bill, introduce a clause prohibiting any whales. I have no doubt whales are objects of great interest, but sooner than go to the expense of paying £50,000 when we can get land for £10,000 an acre, I for my part shall be willing, with my honourable friend, to exclude whales altogether from disporting themselves in Kensington Gardens." This was said in all earnestness, and not, as might be supposed, in a spirit of banter.

In his plan of 1859, Professor Owen was understood to express a conviction that in a national museum the whole series of natural forms should be fully displayed to public gaze. Professor Flower, in commenting on this idea, observes:—

"Let the reader imagine what a public library would be if the books, instead of being shut up and arranged on the shelves for consultation when required, had every single page framed and glazed and hung on the wall, so that the humblest visitor as he passes along the galleries has only to open his eyes and revel in the wealth of literature of all ages and all countries, without so much as applying to a custodian or opening a case. There is something truly heroic in the conception of such a scheme; but laying aside all questions of space and cost, what would be its real utility to those who are able to appreciate and make true use of its contents! All the inconveniences, all the impossibilities, I may say, of a library arranged upon such a plan would be found in a museum containing anything like an adequate number of objects for the purposes of really enlarging the boundaries of scientific zoology, in which every specimen contained in it would be exposed to the gaze of all who chose to enter its walls" ("Nature," May 26, 1870).

In the leader of *The Times* of May 21st, 1862, commenting on the debate of the 19th of May, the writer observes—"Let Mr. Owen describe exactly the kind of building that will answer his purpose, that will give space for his whales, and light for his birds and butterflies. The House of Commons will hardly, for very shame' sake, give a well-digested scheme so rude a reception as it did on Monday night." But this Professor Owen had already done, not only in his revised estimate given in his report of March 6th, 1862, but in a lecture given at the Royal Institution, April 26th, 1861, fully reported in the *Athenæum* of July 27 (*et sequitur*), afterwards reprinted in a separate form, which reached a second edition in 1862,* and is now out of print. In that work Professor Owen enters fully into the various considerations that should guide the curator to a proper estimate of the requirements of all the great divisions of the three kingdoms of Nature. Therein he says, the first principle in the arrangement and allocation of such objects is, that each class should receive its due proportional amount of elucidation to the extent which the acquired specimens of a museum at the time may admit, and according to the degree in which the principle of variety is manifested in the class. "A museum of Nature does not aim, like one of art, merely to charm the eye and gratify or improve the sense of beauty and of grace." Many forms accord with our apprehension of the beautiful, such as richly plumaged birds, pearly shelled mollusks, brightly painted insects, branched corals, drooping fronded ferns, stately palms, gorgeous flowering plants, and glittering minerals. But there are other forms of unwieldly bulk, or repulsive aspect, that equally claim the study of the naturalist. "What then is needed for a co-equal or justly proportional representation of all the classes of animals (plants and minerals), to the extent in which a nation may possess or have opportunities to acquire the specimens of them?" First and chiefest, adequate exhibition space: how is this to be estimated? *First*, by the number of known species of the class; *secondly*, by the extent of exhibition space occupied by the proportion of the class which may be properly exhibited in any existing museum; *thirdly*, by the proportion of examples obtained, but not exhibited; *fourthly*, by the ratio at which such specimens have accrued in a given number of years; *fifthly*, by the circumstances or con-

* "On the Extent and Aims of a National Museum of Natural History." By Professor Owen, F.R.S.

ditions on which the ratio of future increase may be computed. Such requisite data I have as far as possible gleaned from the work of Professor Owen, and the various reports, etc., previously referred to and tabularised, not only for the purpose of saving space, but that the whole of such data may be taken in at a glance, for facilitating comparisons.

* 1, OSTEOLOGICAL specimens would be distributed in the vertebrate classes in the following manner: Additional length of 550 feet to MAMMALIAN GALLERY; 500 feet (with eggs, nests, etc.) to AVIAN GALLERY, and 250 feet between the REPTILIAN and PISCEAN GALLERIES. * 2, FOSSIL ANIMALS and (* 3) PLANTS would be distributed over the RECENT zoological and botanical series, and a STRATAGRAPHICAL COLLECTION that would have to be established. * 4, Teratological Specimens would be distributed over the Animal, Vegetable, and Mineral collections, and are included in the estimate for space. * 5, THE LIBRARY, or at least that portion embracing special descriptive natural history, should be distributed in the studies attached to each class gallery.

† 1, Models, Specimens, etc., illustrating the generative functions, embryological, developmental, and parthenogenetic phases of the several groups, to the extent of at least 500 typical examples, should be distributed in the galleries or studies, as an essential portion of any modern Natural History Museum. † 2 and 3 are essential branches of a complete natural history series, but as yet our National Museum does not include stratagraphical groups of fossils, or a collection of rock specimens.

B 1, 2, 3, comprising British Natural History, together.

E 1 and 2, illustrating the geographical distribution of the varieties of the human race, in connection with the most characteristic animals, plants, and representative species of the various geographical regions, might judiciously be associated with the Elementary Series, E 3, in the Rotunda of Typical Natural History, as introductory to the general Representative Collections—which building should also contain the Lecture Theatre (E 4) and the Guardian's Residences (R).

MINING AND QUARRYING.—XXIII.

BY GEORGE GLADSTONE, F.C.S.

ZINC.

ORES—ASSAYING—CALCINING—SMELTING—PURIFYING—SPELTER—SHEET-ZINC—VARIOUS USES.

THE ores of zinc which are to be found within the limits of the British Isles do not equal in importance those of some other foreign countries; and accordingly, although the various applications of zinc have greatly increased within the last few decades of years, the home production of the metal has had to struggle against the superior advantages of some of the foreign sources of supply.

Almost every one must be familiar with the Vieille Montagne zinc, which comes here from large works of that name in Belgium. Silesia also used to furnish us with great quantities, and latterly Spain has contributed her rich stores of this metal, while the United States of America are ready to furnish any quantity of the oxide that may be desired.

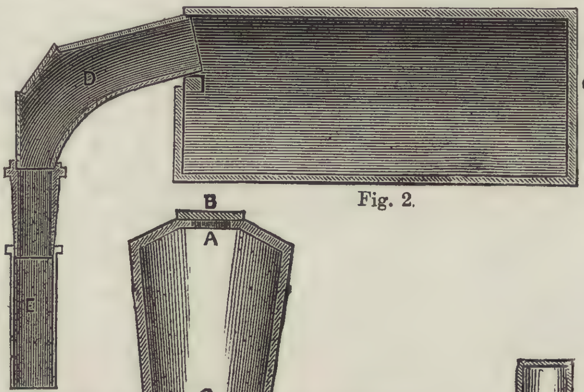

Fig. 2.

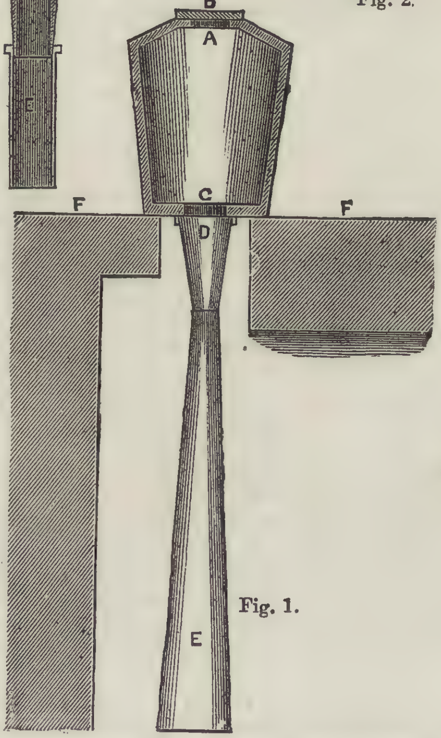

Fig. 1.

Fig. 3.

There are only four descriptions of ore which are of any commercial importance. The first of these, so far at least as England is concerned, is the sulphide, ZnS, commonly called blende on account of its brilliance, or "black-jack" by the miners because of the intense blackness of the crystals. Theoretically it should contain 67 per cent. of the metal, but it is usually associated with a large per-centage of sulphide of iron, and other minerals, to which its black colour is due. It occurs principally in the carboniferous limestone, in the same veins as the sulphide of lead. The two are therefore often mined simultaneously, the blende serving as a subsidiary source of income to the lead mine. The largest home supplies are derived at present from the lead districts of North Wales and of the Isle of Man, but it is also raised in Cornwall, Devon, Derbyshire, Northumberland, and some other places.

Next in importance comes the carbonate, called "calamine" by mineralogists. This used to be in great demand by the makers of brass on the old principle described in the last article; but it is now a comparatively scarce mineral in England, and the competition of the foreign metal has seriously interfered with the working of it. This is the prevailing ore at most of the great Continental works.

Silicate of zinc is very often found associated with the carbonate, and it is considered to produce a very pure metal.

The oxide of zinc occurs in large quantities in the State of New Jersey, U.S., where it is used in the preparation of zinc paint.

When the ore is brought to "grass" it has to be carefully separated from the lead ore with which it is generally mixed, and the two present a sufficiently great difference in outward appearance to enable this to be done at a glance without any fear of mistake.

The blende being thus made into parcels, an assay is taken to ascertain the proportion of metal in the ore. This may be done in various ways. One plan is to precipitate the zinc as a sulphide from an ammoniacal solution, by the addition of a solution of sulphide of sodium of known strength; and the quantity of sulphide of sodium required for the purpose will thus give by calculation the quantity of metallic zinc which was in the solution; and the weight of ore from which this was originally made being also known, the per-centage of metal is easily ascertained. The presence of silver, lead, or cadmium, small quantities of which are often found in the blende, will not affect the result.

Another plan, which cannot be so thoroughly relied upon for exactness, though sufficiently so for most practical purposes, consists in dissolving out the oxide of zinc from a given quantity of calcined blende, by means of carbonate of ammonia, and then ascertaining the loss in weight, which will represent the amount of the oxide contained in the sample taken.

The per-centage of metal may also be ascertained by the loss in weight in fusing the calcined ore in a crucible with charcoal. A certain quantity of the ore is mixed with about one-fourth its weight of charcoal powder, of a quality which will be known to leave a certain weight of ash; and after exposure to a high temperature for about half an hour, the contents will on re-weighing, and making allowance for the ash left from the charcoal, be found to have lost weight; this will represent the amount of oxide of zinc which has been volatilised.

We now come to the processes of reducing the ore to the metallic state. They are generally known as the English, the Silesian, and the Belgian; but they are all one in principle, the differences consisting in the mechanical arrangement. The metal in all cases is distilled out in retorts, of one pattern and arrangement or another.

Preparatory to this, however, the ores are crushed between iron rollers, or ground fine, and washed, so as to separate all earthy matters. Then they are calcined in reverberatory furnaces for about twenty-four hours: the most approved plan of doing this is to have a double-bedded calciner, the one overlying the other, and this may be heated with the waste gases from the reduction furnace. The ore is first dried on the top of the calciner, then allowed to fall through an opening into the upper bed, where it remains from six to twelve hours according to the nature of the ore, during which time it should be well rabbled; after this it is raked through a hole into the lower level, where the heat is much greater, and where the ore remains for a similar period. As soon as the first charge passes forward to the lower bed, a fresh supply is introduced into the upper, so that a constant succession is kept up, and all the heat of the furnace is thus utilised. When blende is the ore used, twenty-four hours is about the time occupied by this process, but calamine will not take more than about one-half.

The next step is the reduction of the metal. For this purpose a series of retorts and receivers are required, and a furnace.

In all the processes referred to, the retorts are made of refractory clay, and are made at the reduction works; but they vary considerably in form. Fig. 1 is a section of the English model, Fig. 2 of the Silesian, and Fig. 3 of the Belgian. The former is a circular pot with an opening, A, in the top, for putting in the charge, covered with a lid, B; and another opening, C, at

the bottom, for the exit of the metallic fumes which pass through the pipes D and E into a receiving trough, and condense during the passage. The second is a long narrow chest, flat below and rounded above, with only one opening for all purposes, the pipes D and E for carrying off the fumes being fitted in after the charge is introduced. The Belgian consists of a cylinder of clay, like a drain-pipe, closed altogether at one end, and partially so at the other. The appendages D and E correspond to those similarly marked in the two other diagrams.

In respect of size they differ quite as greatly as they do in form; and this renders a very different furnace arrangement necessary in each case, so as to ensure a proper economy of fuel. An English pot contains a charge of about 350 lb. of ore, a Silesian retort about 70 lb., and a Belgian about 25 lb. It must not be supposed from their names that the former is only used in England, and the others in their respective countries; for pots made in all these countries may be found standing side by side in the same works.

The retorts are made of fire-clay, well worked up with the remains of old pots ground fine, and when sufficiently kneaded the clay is built up on the inside of the mould, and well beaten to prevent the occurrence of any cracks or air-holes, just as in making the pots for the glass works; and when complete they are carefully dried and annealed prior to use.

The English furnace is in the form of a kiln, and is made to contain six pots. These stand on the floor of the kiln, F F (Fig. 1), immediately over a corresponding number of openings which lead to vaulted chambers below, in which (being kept cool) the zinc readily condenses. The pot being in position, and the short pipe D being fixed on, it is now ready for charging. Some billets of wood are placed over the hole at the bottom, upon them a quantity of coke, and then the calcined blende in four separate parcels, alternating with layers of coke. The lid B is then put on and luted down, and the furnace is heated. Presently a brownish-coloured flame issues from the pipe D, which afterwards changes to a light blue, and which is indicative of the zinc commencing to come over, and of the time having arrived for fixing on the long pipe E, to prevent its becoming dissipated. Below this a tray is put, into which the condensed zinc falls in a gentle metallic shower. When the drops succeed each other very slowly, it would involve too great a waste of fuel to continue the operation. The whole is usually extracted in something less than three days from the time of charging, and the result, if an average quality of blende is used, will be about 150 lb. of metal from each of the six pots.

The Silesian furnace is square, with a long narrow fire-grate running through the middle of it, below the level of the floor; with the furnace-door at one end, and the chimney at the other. On each side of the grate, with their backs, G, towards the fire, stands a row of twelve of the retorts shown in Fig. 2, and the flues are so arranged that the fire passes all round and over the twenty-four retorts before entering the chimney-stack; the whole of the retort, down to the junction of the nozzle D with the condenser E, being enclosed within the furnace. In this case each charge is worked off in twenty-four hours. The first four are occupied in raking out the remains of the last, and in re-charging the retorts, during which time the fire is allowed to slacken; it is then got up to nearly a white heat, and maintained at this until the operation is about over. The volatilised zinc passes through the nozzle and the condensing tube into a receiver below, as already described. Each retort yields on an average about 24 lb. of metal.

The Belgian furnace is again quite differently arranged. As many sometimes as ninety of the little retorts (Fig. 3) are arranged in rows one above another, the front of the furnace being furnished with a series of shelves, with a corresponding notch at the back for them to rest upon; the fire-grate is immediately below, and the heated gases pass between all these rows of retorts before reaching the flue at the top which leads to the chimney. The spaces between the retorts in front are filled up with clay, to prevent the escape of the heat in that direction; the back of the furnace is solid. They are often built back to back, as a matter of economy. The retorts are charged every twelve hours, and the lower ones, being exposed to a much greater heat than the upper rows, receive a much larger charge than the latter. The zinc is not only condensed, but also collected in the receiver E (Fig. 3), the end of which is nearly closed for that purpose.

The rough zinc obtained by these several processes has to be re-melted, to be purified and made into cakes. This is done in iron pots; the zinc is well stirred, and the scum which floats upon the surface is carefully skimmed off, after which the metal is poured into moulds. If it should contain any lead, it is allowed to stand for some little time until it cools down to near the solidifying point of zinc, when the lead will collect at the bottom of the pot.

Cadmium is very generally to be found in the rough zinc, but it is easily separated, as it is a highly volatile metal; and all that is necessary, therefore, is to keep the zinc in a molten state for a sufficiently long time in an open furnace.

Metallic zinc in cakes or ingots is known commercially under the name of spelter, and as such it is largely exported to India and elsewhere.

It was only about the beginning of the present century that it was found possible to roll zinc into sheets, because it is highly crystalline, and only possesses a slight degree of ductility. It is brittle under the hammer both at the ordinary temperature and at 400° Fahrenheit, but between the boiling-point of water and 300° Fahrenheit it is sufficiently tenacious to be rolled out into sheet or drawn into wire. This discovery was of no little importance, as the value of zinc is so moderate as compared with the other metals which could be treated in the same way. Accordingly, sheet zinc is now very largely used for roofing, and making gutters, spouts, and pipes; and it has this great advantage over copper, that the slight oxidation which soon takes place over the surface perfectly protects the metal below from the atmospheric influences; so that as far as exposure to the weather is concerned, it will remain unchanged for an almost indefinite period. It has also the advantage over lead in that, being harder, a much thinner sheet can be used; and that the oxide does not cause water that is exposed to its influence to become poisonous. For these reasons many domestic utensils are made of zinc, though it cannot be conveniently used for any purpose in which it might be subject to high temperatures. Although the price of the material and cost of fixing is more than double that of the coarse asphalte felting used for roofing purposes, it is far cheaper in the end where durability is required, as the metal will not require renewal for many years, and the constant application of tar which is required to keep the felting water-tight is altogether dispensed with.

The valuable applications of zinc as a constituent of useful alloys have already been described under the headings of iron and brass; but there are several other minor uses which must not be overlooked.

Both the oxide and the sulphate are used in medicine; the oxide is also used sometimes as a substitute for a lead salt in the manufacture of crystal glass, and in colouring pottery.

It is also employed in the place of lead in the manufacture of painters' colours, and it is much to be recommended on account of its harmless character. The oxide of zinc is prepared in America for this purpose on a very extensive scale, by reducing the ore in reverberatory furnaces, and burning the zinc vapour which is evolved, the light fumes from which are carried into a chamber made of canvas which is kept moist, and on the inner surface of which they are condensed in the state of oxide.

As pure zinc melts at about 800° Fahrenheit, and is very limpid, it forms a convenient material for making large castings; the edges and other fine parts will come out very sharp from the mould, so that but little subsequent trimming up will be necessary; and by artificially bronzing it, an agreeable colour can be given to its surface.

There is one very important application of zinc which has been reserved to the last, because it is of a totally different character from the rest—viz., its use in electricity. It is the most electrically positive of all the metals that can be conveniently used, and accordingly it finds its place in every form of galvanic battery that has been brought into practical use, from the original voltaic pile down to the very extensive and elaborate apparatus described in the first paper on the "Electric Telegraph." For the negative pole different inventors have employed various metals, such as copper, silver, platinum, etc., but in every case zinc is adopted as the positive. The metal for this purpose should be as pure as possible, and well rolled, so as to be compact and free from holes, which would tend to an irregular consumption of the metal, and render necessary a more frequent renewal of the plates.

OPTICAL INSTRUMENTS.—XX.

BY SAMUEL HIGHLEY, F.G.S., ETC.

ARTIFICIAL SOURCES OF LIGHT (*continued*).

Photogenic Arrangements.—Before leaving the subject of magnesium and zinc lights, it may be as well to put on record, as suggestive to experimenters, certain chemical means of generating intense lights, which, however, as yet have only been used as lecture-room experiments, and not as practical applications. Thus, by digesting metallic zinc in iodide of ethyl, we obtain a volatile liquid which takes fire spontaneously in the air, and is known to chemists under the name of "zinc-ethyl." It can be distilled in an atmosphere of hydrogen, and if this gas be made to pass through the liquid it will carry off some of the zinc-ethyl, and when ignited will burn with a magnificent white flame. It is probable that ordinary illuminating gas would answer as well as hydrogen for this experiment. The light produced in this way can be employed to take photographs, but its actinic properties are not equal to the effects produced by burning magnesium. Of the same nature is *magnesium ethyle.* Dr. Lyon Playfair made the suggestion to me of dissolving magnesium ethyle in petroleum, and burning it in a suitable jet. As with magnesium and zinc ribbon, white clouds of magnesia would be produced during combustion. Then we have the *chloro-chromic light.* This is produced by passing dry hydrogen, or carburetted hydrogen, through the vapour of chloro-chromic acid, and burning the impregnated gas with a steatite burner. Chloro-chromic acid is easily prepared thus:—Fuse 17 parts of bichromate of potash with 10 parts of common salt, and pour out the mixture upon a slab of cold marble. Break into lumps, and distil with about 40 parts, by weight, of sulphuric acid. Take care that the vapour given off is properly disposed of, and not inhaled, as it is very irritating, though not so much so as bromine vapour. Place the resulting chloro-chromic acid in a small Woulff's bottle, or, what is better, a Woulff's arrangement made out of a capped, wide-mouthed ether bottle, in which a cork fitted with an ingress and egress tube is made to replace the glass stopper when required for use. The ingress-tube is connected with a reservoir of hydrogen, under a sufficient pressure, by india-rubber tubing, in the course of which a chloride of calcium drying-tube is inserted. The ingress-tube should be inserted so as just to reach the surface of the chloro-chromic acid—not deeply inserted in the liquid, to bubble through it, but simply to sweep away its fumes. The egress-tube is fitted with a steatite fish-tail burner, or small incorrodible argand burner, as the fumes attack metal. The chloro-chromised hydrogen burns with an intense white light, which gives off clouds of oxide of chromium; it cannot be burnt for long unless connected with an up-draught. Dr. Monckhoven speaks of burning this flame "in a current of oxygen; oxide of chromium is produced at a very high temperature, and at the same time a flame of such extraordinary chemical power that chloride of silver paper held at a distance of eight inches blackens sensibly in thirty seconds, *or about as quickly as in full daylight.*"* Chloride of titanium treated in the same manner gives a blue flame of extraordinary chemical power. In 1863 I exhibited, at a lecture at the Society of Arts, an intensely brilliant and actinic flame, by passing carburetted hydrogen through a long column of bisulphide of carbon vapour, burnt in a flat argand burner four inches wide. Like those previously described, the fumes given off (in this case those of sulphur) were the drawback to its utilisation. As a lecture-table experiment it is very striking.

Bude Light.—In this arrangement oxygen is introduced into the centre of an argand burner, thus replacing the ordinary current of atmospheric air. The argand burner may be supplied with oil or house gas, and the result is a brighter light than is obtained under ordinary circumstances. It is believed that the "oxy-hydric light" recently exhibited at the Crystal Palace is a modification of the bude light arrangement devised and named by Goldsworthy Gurney. Gurney's arrangement also embraced the system of concentric rings of house gas, with strong up-draughts of air brought into contact with each small jet of gas, by means of cones of glass and chimneys, disposed to the best advantage by careful experiment, and large metallic reflectors placed over the chimneys just above the brilliant zone of white light thus produced, so as to cast it downwards. The term "bude light" is, however, usually applied to the first arrangement, where oxygen is made to replace a simple supply of atmospheric air.

Argand Lamps.—In the burner invented by Argand a column of air is introduced into the centre of a lamp flame, and an up-draught created by means of a chimney, the length of which is adjusted to secure perfect combustion. This principle of burner may be arranged to consume gas or liquid. If spirit or oil is consumed, a wick becomes necessary. Wicked lamps may be arranged under two heads—"Suction Lamps" and "Pressure Lamps." Suction lamps may again be divided into two groups, viz., "Simple Suction Lamps," wherein the wick descends to the bottom of a simple reservoir, and consequently the capillary action of the wick has to raise the liquid to the flame from an ever varying level; and "Fountain Lamps," wherein the spirit or oil is raised from a constant level by means of a hydrostatic arrangement of the reservoir. "Pressure Lamps" force the oil (for which this form of lamp is only suitable) by means of a pump, driven by clockwork in Carcel's lamp, and by a rack and coiled spring* in the Moderator lamp, to the top of the wick and the verge of the flame in greater quantity than can be burnt, and so cause a constant overflow into the reservoir beneath, which prevents the rapid charring of the wick, and less heat being conducted away from the flame by the metal-work. To increase the liquidity of oil, the reservoir, in the form of a ring, has been placed around and above the burner, as in Parker's and the Sanumbra lamp. To bring the air in more immediate contact with the *exterior* surface of the flame, a thin metal cone has been employed. To throw the air into closer contact with the inner edge of the flame, an inner tube has been inserted in the centre of the argand burner. When a great body of light is required, as for lighthouse purposes, double concentric wicks have been employed. To avoid danger when light hydro-carbon oils are used, a non-conductor of heat—such as boxwood—has been inserted between the metal-work of the burner and the inflammable spirit, as in Young's Vesta Lamp. To prevent an overflow of more than a small portion of liquid in case of a lamp being overturned, an inner wall has been inserted in Silber's simple suction lamp, so as to isolate the mass of petroleum from the wick.

The general principles of construction of argand burners for consuming liquids may be thus summarised under these four heads:—1. A constant and steady supply of oil or spirit at the exact rate of consumption. 2. The means of adjusting the flame to the point of perfect combustion. 3. The adjustment of the interior and exterior currents of air upon the wick, to secure perfect combustion, according to the nature of the substance and the size of the burner employed. 4. The disposition of the reservoir, so that its shape or position shall not interfere with the proper distribution of the light emitted.

Having summarised the general principles of construction of argand burners, I purpose describing a type of each form suitable for hydro-carbon spirit, oil, solid paraffine, and gas.

Hydro-carbon Argand Lamps.—Volatile paraffine oil with a specific gravity of 0·700 to 0·865, heavy paraffine oil with a specific gravity of 0·865 to 0·900, and solid paraffine, the so-called paraffine wax, with a specific gravity of 0·900 to 0·930, the products of the fractional distillation of the crude liquid and tarry matters which come over in the primary distillation of peat turf and bituminous schists, of which the Boghead schist gives the richest yield, and petroleum, the purified natural product of the American coal measures of Ohio and Pennsylvania, give lights of great intensity when burnt in properly constructed lamps. The photogenic oils produced from various sources, and at different temperatures, that figure under different names in the market, though varying somewhat as to chemical constitution, have their specific gravity and boiling-points so close to each other that it is a matter of great difficulty to isolate them, to allow of an examination of their properties. They are tolerably equal as to their photometric value, though I am not aware that any exact photometric comparison has yet been made, or at any rate published.

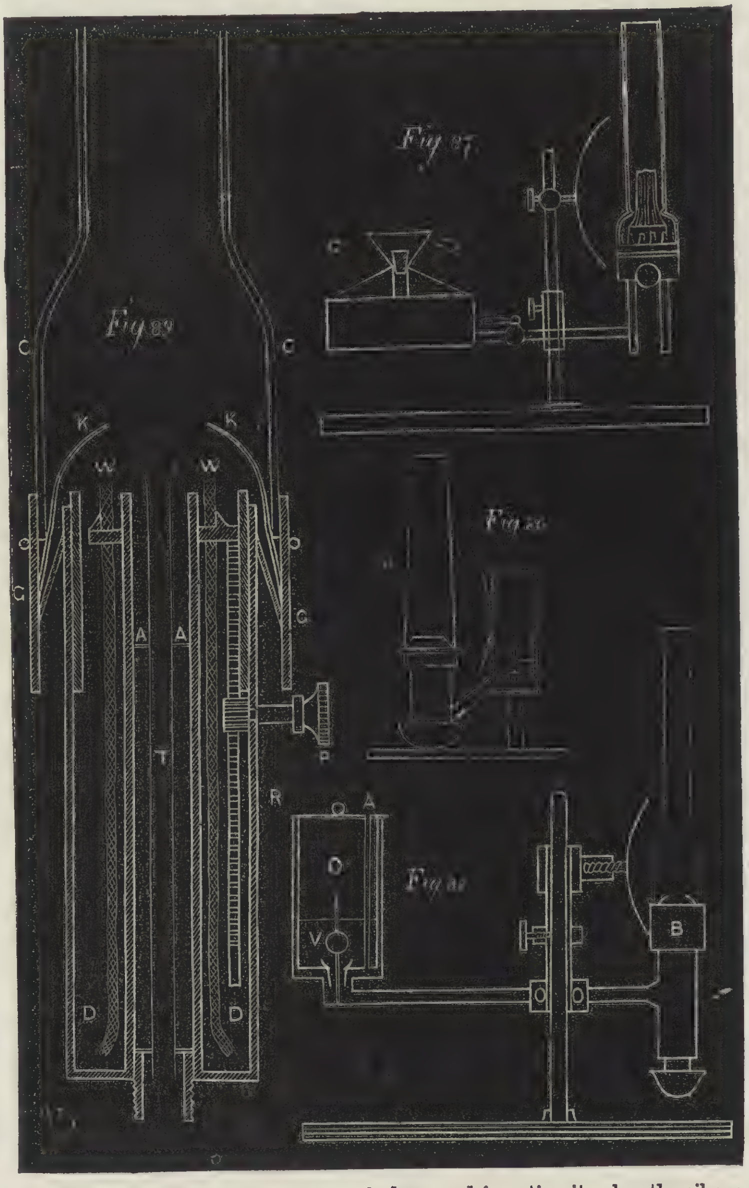
Though extensively used in America, and the countries of Northern Europe, a strong prejudice still exists in England against the use of paraffine and petroleum oils. This arises

* *Photographic Society's Journal*, p. 166. December 18th, 1869.

* This is termed, from its inventor, a "Priest-pump."

chiefly from a dread of the assumed explosive qualities of all mineral oils, and in a less degree on the score of the unpleasant odour given off more or less by these liquids. By a selection of suitable samples, and properly constructed lamps, these drawbacks to their use may be surmounted. Danger can only arise from the employment of mineral oils which ignite at low temperatures, as suitable samples may have a match placed in contact with their surface without igniting, and, if spilt upon a table and floor, would not become dangerous till vaporised by the heat of the room. Danger may arise from improper storage, for if left open to the atmosphere of a small room any vapour arising would mix with the air and form an explosive compound. The sale of dangerous samples—viz., mineral oils having a low boiling-point, the vapour of which inflames below a temperature of 90° Fahrenheit—is forbidden by the Act of Parliament of 1868, except under proper restrictions; nevertheless, care should be exercised when purchasing paraffine oil, as unscrupulous or careless dealers may be met with.* The unpleasant smell is mainly due to imperfectly constructed lamps that do not effect perfect combustion, or to careless trimming and neglect in wiping the oil from the metal burner or reservoir. Again, it may arise from the wick being turned down too low, instead of being adjusted to what may be termed the standard point of illumination of any given lamp, when the flame would neither be too high nor too low for effecting perfect combustion of the material supplied to the wick.

After trying every kind of hydro-carbon oil that has a character for intensity of light for scientific purposes, I give the preference to refined petroleum having a specific gravity of 0·695, and a boiling-point about 340° Fahrenheit, as it is almost inodorous, and does not give off that greasy kind of vapour that all paraffine oils generate when a lamp is shut up in a lantern for some days, and which bedews the metal-work, saturates the wooden parts, and creates a most unbearable stink when the lamp is again lighted—a smell which is rendered still more unpleasant if, for the purpose of increasing the density of the flame, one ounce of camphor is added to a quart of paraffine, an odour which cannot be covered by the addition of any of the scented essential oils.



Hydro-carbon lamps are used for magic lanterns, photographic self-registering meteorological apparatus, etc. The simplest forms are those of suction lamps, shown in Figs. 86, 87. In Fig. 87 the reservoir, instead of being immediately beneath the wick, is placed behind, so that the mineral oil may not be heated, as the reservoir thus arranged can be placed outside the lantern. It will be observed that in an arrangement of this kind the liquid must ever be sinking to a lower level.

Fig. 88 represents one of the most perfect arrangements, the burner being shown in detail in Fig. 89.

The lamp is adjustable on a rod like that previously described under the head of my "convertible jet." The burner, B, is supplied by a "fountain reservoir," O, the two parts being connected by a brass tube that passes through a boss in the adjusting tube. The reservoir, O, consists of a metal cylinder that has an opening at its lower end, which can be closed by a ball-valve, V. This fits inside an outer cylinder, that is attached to the connecting tube, and acts the part of a funnel to carry the oil from O to the burner B. The reservoir is filled by removing it from the lamp and inverting it, when the oil can be poured into the open mouth at V. The wire that passes through the ball of the valve is then seized between finger and thumb, and pulled up into its socket, when the reservoir is turned over and quickly inserted into the outer cylinder; when the end of the wire of the ball-valve touches the bottom of the tube, the ball is raised, which allows the oil to flow out, an equal quantity of air at the same time rising through the oil to the top of the reservoir, O. As the oil is consumed it sinks below the aperture of the reservoir, when another portion of air enters, and again ejects an equal quantity of oil, which of course finds its level in the receiver of the burner, B, and so, by the automatic action of this "bird fountain" reservoir, a constant level is maintained. To secure a current of air to

* In the Schedule to the "Petroleum Act Amendment" of 1868 "Directions for applying the Flashing Test to Samples of Petroleum Oil" are given, and the prescribed apparatus described; but I may state that it has not proved efficient, and an improved instrument will probably be authorised under a new Act of Amendment, wherein a covered petroleum pan will replace the present open arrangement, which allows the vapour as formed to be wafted away by currents of air passing over the exposed surface of petroleum, and so causing the Parliamentary test to be very unreliable. Other improvements will allow of the absolute temperature of the petroleum to be more accurately determined.

the immediate neighbourhood of the valve, an air-tube, A, passes from the outer to the inner end of the reservoir, though this may be dispensed with, if the reservoir is made to fit the outer cylinder loosely, to allow air to pass between them to the mouth of the valve at V.

The burner is shown in section in Fig. 89. W W represents the cylindrical wick supported in the cylindrical wick-tube, D D, and adjustable by means of the rack-and-pinion arrangement, R P. A small tube, T, is supported in the central air-way by three pins, A A, placed at equal distances on its outer side. The object of this tube is to throw the up-current of air into more immediate contact with the *inner* side of the wick. G G represents the gallery that supports the glass chimney, C C, and a thin metallic dome or cone, K K, that draws the air into more immediate contact with the *outer* side of the wick. The height of the chimney is a very important point in construction, for on that depends the adjustment of the up-draught in such quantity and at such a rate as to secure perfect combustion, for, according to the proportion of carbon contained in the mineral oils, so they require a greater or less supply of air for their proper oxygenation.

If through inattention on this score the volatilised oil is only partially burnt, there will be wasteful consumption of the liquid. The unpleasant odour often noticeable with paraffine oil is frequently due to the same cause. The diameter and height of the chimney influence the size, height, and form of the flame, sometimes contracting it into a cone, and then reducing its illuminating power. With the self-same burner four times the amount of light may be produced, when fitted with a series of unsuitable and suitable chimneys. The point of constant level for the liquid below the top of the wick is a matter of constructive importance. As previously stated, when heavy vegetable oils, such as colza or rape-seed oil, are burnt, the lamp is arranged to bring a constant and overflowing supply to the verge of the flame. Not so with mineral oils: with these the level may be some two or three inches below the top of the wick, as the object in this case is to vaporise the liquid by means of the hot metal of the wick-holder or receiver, and so convey it to the flame in an almost gaseous condition, heated nearly to the point of ignition before it comes in contact with the air that is impinged on the inner and outer side of that flame. The importance of this detail of construction may be judged of when it has been found that by raising the level of the oil an inch or more above the proper point, a decrease of from 30 to 50 per cent. in illuminating power has ensued. The wick best suited for petroleum is a rather loosely plaited cotton; this should be most carefully cut the first time of burning, after which it is better to rub off the charred portion with the tip of the forefinger, then cut off any projecting fibres with a very sharp pair of shield scissors, specially made for lamp-trimming. Petroleum possesses the advantage over ordinary oil that the wick chars very slowly, and consequently gives the standard amount of light for a much longer period of combustion. Like the Carcel lamp, it might be used as a standard source of light for determining the illuminating power of coal-gas and other burners in photometric testing. The pinion P, that raises or depresses the wick W, by its action on the racked support R, should be inserted in the wick-tube a little above the level of the reservoir, to prevent any leakage of that very mobile liquid.

In a paper read before the Society of Arts, Dec. 21st, 1870, Mr. A. M. Silber gave in the following tables the results of some interesting experiments conducted by Mr. Valentine at the College of Chemistry, on burners of the usual construction, and those made according to the principles previously described:—

TABLE I.—SHOWING ILLUMINATING POWER OF ORIGINAL ARGAND BURNERS, CONSUMING COLZA AND PETROLEUM OIL.

DESCRIPTION OF LAMP. (Argand Burners.)	Illuminating power expressed in sperm candles.	Illuminating power expressed in cubic feet of common coal gas = 15 candles.	Hourly consumption of oil in grains.	Cost of oil for one week's consumption of 42 hours.	Cost of gas at 3s. 9d. per 1,000 cubic feet, for one week's consumption of 42 hours.	Proportional cost of gas and oil.

Do. (altered)	50	—	1,965	—	—	—

From the last column in Table II. we find that for No. 1 Burner (altered) the oil is 35 per cent. cheaper than gas, while for No. 2 Burner (altered) it is 27 per cent. cheaper.

It is interesting to note that the larger argands give, proportionally, less light than the smaller-sized burners—a ratio which is the reverse of that observed in the case of argand gas burners. The central air-deflecting tube exerts considerable influence in correcting this shortcoming in the burners of larger size. The larger burners also consume, proportionally, more petroleum than the smaller burners. This is probably due to the passing of some portion of the oil in the form of incompletely burnt or unburnt vapour through the mantle of the flame.

PHOTOGRAPHY.—X.

By J. C. Leake.

PRINTING IN CARBON.

For many years photographers have been steadily working in order to produce a process which should remove the one great objection to ordinary silver-printing—namely, its want of permanence. Although it is true that prints produced by this process need not of necessity fade, yet it has been proved in practice that it could not be absolutely trusted as to permanence, one print out of a large batch perhaps fading in the course of a few months, while the remainder continued unaltered for years. This want of certainty as to the durability of photographs was of necessity a great drawback to the art, especially where it was applied to purposes of book-illustration, the reproduction of works of art or valuable manuscripts, and was, of course, more important as photographs increased in dimension, and became proportionately more expensive. To such an extent had this difficulty been felt that the sale of ordinary photographs of large sizes had perceptibly diminished, and but for the invention of the system of printing in carbon, would probably have ceased altogether; few persons caring to purchase a picture costing perhaps some pounds, to which was attached a probability of loss at an early period. Hence it had become important, if it was necessary to save the art, especially in its higher branches, to devise some method of obtaining prints which could be relied upon for permanence, and this has happily been most effectually accomplished.

Like all other branches of photography, the perfecting of a carbon process has been the work of considerable time; and many persons have contributed improvements of importance, the latest being those of Mr. J. R. Johnson, whose process, termed the autotype, may be considered as nearly perfection as can be expected for many years to come. Of course there are many processes which vary in detail; but as that of Mr. Johnson is by far the most simple, considering the perfection of the result, as well as from the fact that it offers unusual facilities to the amateur, we shall in this paper confine our remarks to this alone, referring those who may wish for further information upon this matter to one or more of the text-books published upon the subject, especially to Mr. G. W. Simpson's "Printing in Pigments."

Before proceeding to describe the manipulations required in the practice of carbon-printing, it will be well to explain in outline the principles upon which it is founded, and which differ so much from those of the ordinary silver-printing that the operator must abandon these latter at the outset. It has been known for many years that gelatine, after having been impregnated with bichromate of potash, is to a certain extent sensitive to the action of light. This sensitiveness is not manifested in the same way as upon the ordinary silver-sensitised paper, by a darkening of the film, but by the fact that the portion upon which the light has acted becomes insoluble, while that which has been protected from this action remains, like ordinary gelatine, freely soluble in warm water. It stands to reason, therefore, that if a film of gelatine, sensitised by bichromate of potash, be placed under a negative and exposed to light, some portions will be rendered insoluble, while others may be removed by washing in warm water, the result being an image in varying thicknesses of the film; the highest lights, which have been entirely protected, being removed altogether. This, however, would be simply an image in relief, without light and shade, which, although useful in some processes, would not in itself form a picture. In order to form a picture in light and shade, however, all that is necessary is to add to this gelatine some colouring matter, which may be retained by the film in its varying thicknesses; when, of course, those portions which are the thickest will represent the darker portions of the picture, while the lighter parts will be altogether dissolved out, all the intermediate shades being duly represented by the various quantities of pigment retained by the film. This is precisely what is effected in Mr. Johnson's process. A film of gelatine, containing a suitable pigment, is spread upon paper, and is sensitised upon a bath of bichromate of potash. When dry, this pigmented paper is placed under a negative, and exposed to the action of light. Upon removal from the printing-frame the print is attached to a suitable support, during the removal of the unaltered gelatine and pigment. A properly prepared paper is then secured to the film, and this with the film is, when dry, removed from the supporting surface, when the picture is complete and ready for mounting.

One of the chief obstacles to the common adoption of the carbon-printing process, up to this time, has been the difficulty of preparing the layer of carbonised gelatine, which must, of course, be most carefully effected. This, however, need no longer stand in the way, as the Autotype Company are prepared to supply this tissue ready for use at a far lower cost than it could be made by the operator. The pigmented paper, as supplied, consists of a layer of gelatine spread upon paper, and it may be obtained of varying tints to suit the subject of the photograph. The gelatined side of the paper will be found to closely resemble the material known as American leather-cloth, having a dark colour and glossy surface. As supplied, this tissue is not sensitive to light, and in this respect it resembles ordinary albumenised paper. It is prepared in long rolls, and much larger sheets may be obtained than those of albumenised paper. For use it should be cut to the required size before sensitising.

The sensitising solution is prepared by dissolving in common water bichromate of potash, in the proportion of twenty grains of the salt to each ounce of water. A sufficient quantity of this solution is to be placed in a flat dish, when the sheets of prepared paper may be immersed one at a time, taking the utmost care to avoid the formation of air-bubbles. Each sheet should be turned over several times, to ensure a uniform action of the solution, and several sheets may be immersed at the same time. After one or two minutes have elapsed, the whole of the sheets may be turned over in the solution, and the one first inserted then removed and suspended to dry. It is one of the great advantages of the tissue prepared by Mr. Johnson, that this drying may be accelerated by heat, while in many of those heretofore prepared the application of heat simply rendered the film more soluble, and the greatest difficulty was experienced in keeping the pigmented gelatine upon the paper at all, the whole coming off in a sludgy mess, and leaving the paper quite bare.

This difficulty is not likely to occur when Mr. Johnson's preparation is used; but in the case of a tissue such as we have mentioned being met with, we have found that it may be remedied by *floating* the sheets upon a bichromate solution of twice the strength mentioned above, and with the gelatined surface upward, so as not to touch the solution at all, the film being allowed to receive the bichromate by absorption. In this way the most soluble tissue may be sensitised without injury to its surface, although the difficulty of drying will, of course, still remain. It need scarcely be observed that the sensitising process must be conducted in a darkened room, and as the bichromated gelatine is very much more sensitive than albumenised paper, greater precaution must be taken to exclude all light during this process, as well as during the drying; in fact, the more nearly the tissue is treated as a sensitive collodionised plate, the more perfect will be the resulting print. When the tissue is perfectly dry it will be ready for exposure to light under the negative.

Before placing the tissue upon the negative, however, a border of opaque paper should be pasted round its edges, in order to secure the margin of the print from the action of light. This is necessary in order to secure a margin of unaffected gelatine, which may serve to secure the film to the plate during the development, or rather the removal of the unaltered gelatine. This precaution is absolutely necessary, or the film will break up during the process. The sensitised tissue must, therefore, be cut of sufficient size to allow of this unaltered margin being

left, or the development cannot be conducted in safety. The exposure of the tissue to light may be made in the usual manner, but of course the progress of the print cannot be watched as in silver-printing, as there is no apparent change in the film. It may, therefore, be supposed that the production of prints by this process is merely guess-work in this particular. Such, however, is not the case, as the action of light and the consequent progress of the printing may be most accurately determined by means of the actinometer. There are several forms of this instrument, any of which may be used, but that invented by Mr. Johnson seems to possess in a high degree the advantages of simplicity and certainty. This little instrument consists of a tin box, with a small slit in the lid about an inch in length and one-fourth of that in width. The lid of this box is painted the same colour as that assumed by albumenised paper upon exposure to light. Inside this box is arranged a slip of Carrier's sensitised albumen paper. By means of a simple mechanism a portion of the paper is brought under this aperture, and when exposed to light it of course quickly darkens to the colour of the painted lid. The method of applying this to carbon-printing is extremely simple. Thus, supposing we have a very thin negative to print, the sensitive tissue being placed upon it in the pressure-frame, the whole is exposed to light in the usual manner. At the same time a portion of the sensitive paper in the actinometer is brought under the aperture in the box, and exposed side by side with the print. As soon as the paper has assumed the chocolate colour, matching with the top of the box, the print is removed from the frame; and if, upon development, the exposure is found to have been correctly timed, the negative is marked with a figure 1. Should it, however, require longer or shorter exposure, this fact is indicated by a figure in the margin. Thus, if two or three tints of the paper be required, the negative is marked with the number of changes in the actinometer, and printed accordingly. By the adoption of this method prints may be made with absolute certainty of correct exposure, provided the correct time necessary has been marked in the first instance. In this particular the carbon process is superior to the ordinary method of silver-printing, as no allowance has to be made for the somewhat irregular reduction which occurs in the fixing and toning baths usually employed.

The exposure to light having been carried out as above described, the next operation will be that of attaching the film to some suitable temporary support during the development of the image; which latter process, as we have before explained, consists of removing the unaltered gelatine and pigment. For this purpose a sheet of white ground opal glass will answer, or still better, one of the porcelain "slates" in common use. Mr. Johnson uses finely-ground plates of zinc; and, in fact, any material having a white substance, that is insoluble in water, and has a slightly roughened surface which may serve to facilitate the adhesion of the film, will answer perfectly. Before attaching the film to either of these surfaces, they should be cleaned, and rubbed over with a dilute solution of wax and resin in turpentine, the merest trace being allowed to remain. If this precaution be neglected, the film will probably adhere so closely to the plate as to defy removal, except by the destruction of the print. The plates being thus prepared, the prints should be immersed in cold water. Very shortly the curling inwards, caused by the expansion of the paper, will be succeeded by a tendency to curl outwards. At this period the print should be removed from the water, and placed gelatine-side downward upon the supporting plate, which has first also been wetted. The superfluous water should then be removed by scraping the paper down upon a plate with a scraper or "squeezer," made by securing a slip of india-rubber between two slips of wood. A little time may now be allowed in order that the print may absorb moisture, when it will be found that the proof adheres tightly to the glass or metal plate. No injury is effected by some little delay in developing the prints after they have reached this stage (say three or four hours), but they should not be allowed to become dry.

The plate with the print attached may now be immersed in water, raised to the temperature of about 100 degrees, or as warm as the hands can comfortably bear. In a few minutes the coloured gelatine will begin to ooze out at the edges of the paper, which will also show signs of detaching itself from the plate. In effecting this detachment, on no account must any force be used, as that would injure the impression. Hot water may be applied a second time if required, but this is seldom necessary; a little patience will usually be rewarded by success. After the removal of the paper, the plate holding the film should be freely rinsed with warm water, when the picture will gradually emerge from the sludgy mass of unaltered gelatine and pigment. This washing should be continued until the water flows clearly off the print, showing that the whole of the unaltered and consequently soluble gelatine has been removed. There is room for the display of some skill and tact in effecting this process of development, as a print which shows any signs of under-exposure may be often saved by removing it from the hot water and plunging it into cold water for a few minutes; afterwards continuing carefully the action with water which is only slightly warmed. On the other hand, an over-exposed print may be reduced slightly by continuing the action by means of very hot water; and the operator will find that this simple process of development is easily modified, as may be required by the condition of the print.

Should the exposure have been correctly timed, and the development properly effected, the plate with the picture upon it should be allowed to become dry before proceeding to transfer it to paper. For this purpose a properly prepared paper is required, which is supplied by the Autotype Company. The transfer process is easy if the proper paper is used, and due precautions employed in its use. One side of the transfer paper is coated with a substance which secures the perfect adhesion of the film, and which becomes soft after soaking in boiling water. The sheets should, therefore, be cut to the requisite size, and immersed in boiling water in a flat dish, until the coated surface becomes soft and pulpy. Having arrived at this condition, it may be laid wet upon the film, and smoothed down with the scraper as directed before. When the paper is thoroughly dry (and on no account before), the removal from the plate may be attempted. If started at the corners, the film will usually strip off easily, in some cases spontaneously; when, of course, the operation is complete, and the print may be mounted in the usual manner.

It frequently happens that carbon-prints present a dull surface, which is offensive to those who have been used to the high gloss of albumenised paper. In this case the defect may be remedied by applying to the surface of the finished and mounted print an encaustic paste, made by dissolving white wax in benzole to the required consistence. This paste should be applied by means of a soft linen rag, and afterwards the surface may be polished with a soft silk handkerchief. In conclusion, we may remark that, although in description this printing process may seem complicated and tedious, it is not found so in practice; and that the undoubted permanence of the proofs would well compensate for extra labour, even if this were involved, which it is not.

SILK CULTURE.—VI.

By Alexander Wallace, M.D.

CULTURE OF THE BOMBYX YAMA-MAÏ IN JAPAN.

Inasmuch as the culture of the *Bombyx Yama-Maï* in Europe is still somewhat of an experiment, notwithstanding the partial success which has attended the efforts of the Baron de Bretton and others in Europe, and as it is pursued in Japan on a definite method, it will be desirable to reproduce here the best existing evidence on this point taken from the Third Report, by Mr. Adams (of her Majesty's Legation in Japan), on Silk Culture in Japan, being an account of a tour made by him in those districts where the culture of the *Yama-Maï* is systematically carried on:—

"From Shimonita we proceeded over the Wami Pass to Owaké, in Shinshiu, and thence by the Nakasendô over the Wada Pass to Lake Suwa, from there by Shiwojiri to Matsumoto, our object being to gather information respecting the *Bombyx Yama-Maï*, or oak silkworm, which is reared in the open air not far from the latter place.

"We arrived at Matsumoto on the 16th of June. It is a castle town of over 3,000 houses, lying on the eastern side of a broad level valley of high elevation and light soil. Immediately to its north a low range of hills runs partly across the valley, so that at first sight the town appears to be situated at the north-

east corner of a plain eleven or twelve miles in length, and six or seven in breadth, surrounded by high hills. Further down, the valley re-opens, but is narrower; and above the hills, which on the western side rise abruptly from the plain, a snowy range of granite mountains is visible, dividing the province of Shinshiu from that of Hida.

"At Matsumoto we were informed that we should have to proceed twelve or fourteen miles further along the valley, in order to reach the centre of the most favoured district for the culture of the *Yama-Maï*. Accordingly, on the following morning we rode along rough roads and across swift torrents which are often impassable, till we reached the village of Furumaya on the opposite or western side of the valley. There we put up at the house of a head-man, Mokuzagemon, himself a rearer of the worm, and from him, as well as from Benjirô and Tozagemon, of the villages of Tateashi and Aragama, we gained much interesting information. Their accounts tallied entirely in substance. It appears that there are sixteen villages, the inhabitants of which form an association called the 'Matsukawa gume,' and are entirely engaged in the culture of the *Yama-Maï;* that this culture was first initiated about forty years ago, and since then had gradually taken greater dimensions, till the number of cocoons annually sold by the association alone is computed at not less than 20,000,000. The three men stated that the number which they severally reared each season averaged 170,000, 100,000, and 80,000, the price of each thousand being estimated at about four riyos (equivalent now to nearly four dollars); also that the cocoons, as well as the silk, used to be bought principally by merchants who came from Gifu, in the province of Mino. Now, customers also arrive from Echizen, Oshiu, Echigo, Yonezawa in Dewa, and from other places. The best sort of silk is sold, as we are informed, at about 840 riyos a picul; the inferior sort at about 530 riyos a picul. A stout kind of netting is manufactured from silk, and it is also made up with other raw material, such as cotton.

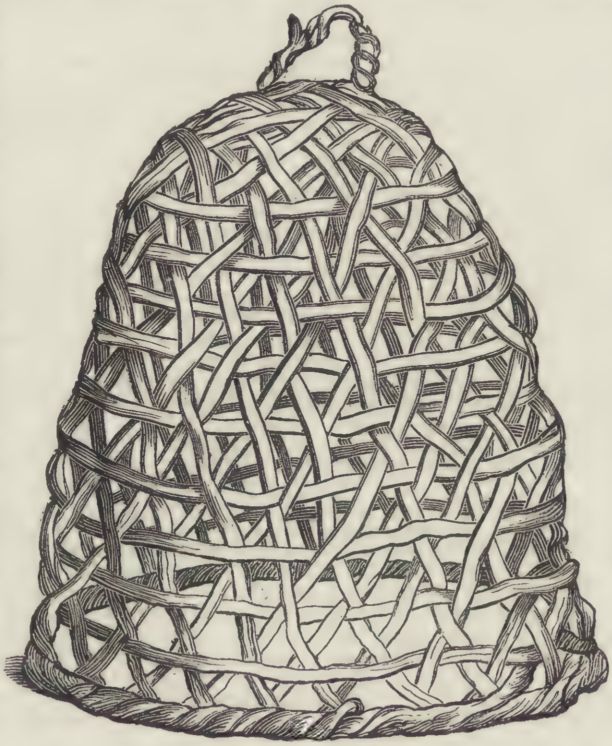

Fig. 8.—CAGE OF BAMBOO STRIPS ON WHICH THE EGGS OF THE BOMBYX YAMA-MAÏ ARE DEPOSITED.

"Close up to the western ranges of hills are a number of plantations of the 'Kunogi,' which is considered by the rearers of Furumaya and its neighbourhood to be the best food for the *Yama-Maï*. Its leaf is pronounced to be that of the *Quercus serrata*. The worms can be fed on other varieties of oak-leaves, but those of the 'Kunogi' alone are used for the purpose in this district. The plantation at Furumaya is less than a square mile in extent, and is thickly covered with plants of the species in question, some mere shoots of a year's growth, others varying from one or two to five or six feet, and others even taller. These plantations were said to extend at intervals for a distance of fifteen miles along the west side of the valley. The most approved method of propagating the 'Kunogi' was stated to be by sowing seed in a separate piece of ground, and then taking up the young plants and transferring them from these nurseries to the plantations. We were told that they are cut down close to the roots every three or five years, in order that fresh shoots might be given out. The soil is light and very sandy. The region is cold, and the leaves are often injured by the frost. The land belongs to peasants, who let it out in lots to different breeders, and there is a sort of rough surveillance, especially just at the period of spinning, but no particular watch seems to be kept, nor any thieving from man to be apprehended. The real thieves appear to be sparrows and other birds, and though some scarecrows are put up, and guns are said to be let off at times, no serious attempt is made to put a stop to such ravages. The leaves, too, are infested with other caterpillars, and we were told that red ants, though not prevalent in this particular locality, did damage. Black ants, too, were noxious when numerous, but nothing was done to prevent them from going up into trees, where we saw them sometimes swarming about the *Yama-Maï* in great numbers. In fact, in this, as in every other matter, the general principle of letting things take their course, and of leaving the issue to Providence, was plainly and painfully manifest.

"The larvæ were mostly in the fourth and fifth stages, and it was a curious and most interesting sight to watch them clinging to the branches and leaf-stems, and to observe how completely their colour corresponded with the leaf on which they most delight to feed. Their bodies were of a pure and almost transparent green, with a bright line running down the sides, ending in a brown patch, the two quicksilver-like spots on each side being plainly visible. Diminutive blue spots were also to be seen at intervals along the body. So much did every colour and streak resemble the plants to which they clung, that it was some time before our eyes became sufficiently practised to distinguish them at all without close examination. The annexed sketches (Fig. 7) will give an idea of the larvæ upon the trees.

"The eggs of the *Yama-Maï* are deposited by the female on the bars of cages made of plaited bamboo strips, of the bell-like form delineated in Fig. 8. This is probably towards the end of July, and the cages are hung up one under the other, in rows of ten, under the eaves of the roof, where ventilation can be secured without exposure to sun, rain, or smoke.

"In the tenth month (November—December) it is generally the custom to take the eggs off the cages with the fingers, and place them in hempen trays of oblong form, with wooden rims about three inches high. Care must be observed that the eggs are not crowded one upon another. The trays are placed upon the verandah. A cold atmosphere is essential at this stage. Sometimes the eggs are not detached from the cages, and the latter are placed in a shed outside the houses, where good ventilation can be secured. The walls of the shed are formed of a coarse matting composed of reeds, and the roofs should be constructed of such material that no rain can penetrate inside and injure the eggs.

"About the end of the second Japanese month (say the beginning of April) the eggs are collected in small hempen bags, which are placed in boxes pierced with holes, in order to admit of proper ventilation. These boxes are either suspended out-of-doors amongst the trees, where no sun can reach them, or kept in a cold cellar, where they are put into deep holes dug in the ground. This operation is only necessary when the hatching has to be retarded, because the buds of the 'Kunogi' have not come out. The eggs, in short, have to wait for the buds, which are expected about the eighty-eighth day after the Japanese new year (say at the end of April or in the first ten days of May), though they may be much later. As soon, however, as the buds have come out, all the eggs, whether from outside or

from the cellar, are brought into the house, and fixed with paste made of barley, or, still better, of buckwheat, on the middle of slips of paper five inches long and a quarter of an inch broad. About ten eggs are placed upon each paper, and all the slips are then taken to the plantation and tied to the branches of the 'Kunogi' in a single knot, which the nature of Japanese paper readily admits of, the two ends standing out at right angles to the branch. The paper thus surrounds a small section of the tree, the eggs lying on the external surface. The slips are placed in such a manner that the eggs may have a northern aspect, and not be exposed to the rays of the sun. One slip is sufficient for a small plant; two or three may be attached to a large one. In four or five days the hatching will commence, and it continues for five or six days more; the young caterpillars, on leaving the shells, immediately crawl from the papers upon the 'Kunogi,' and seek the leaves. We saw a number of these papers still remaining on the trees as the action of a charcoal brazier, are reeled. Those which rattle on being shaken are considered to be in good condition, and such of them as are to be reserved for seed are placed in trays, and moths emerge in about twenty-five days from the time of spinning. The remainder are of course subjected to heat, in order to kill the chrysalids, and are reserved for reeling.

"The moths emerge between four in the afternoon and night, and the great majority of the first moths are males. The proportion was stated to us to be 300 males to 10 females. The males are then secured in the bell-shaped cages already mentioned, and as the females emerge, they are distributed among the males. It would be best, we heard, to place but one couple in a cage: in practice, however, several couples were put into the same, otherwise there would not be sufficient cages. One of the men said he had as many as 500. The bottoms of the cages are then closed with paper. The coupling commences in the

Fig. 7.—SKETCHES SHOWING THE SIMILARITY OF CATERPILLAR OF BOMBYX YAMA-MAÏ TO LEAVES ON WHICH IT FEEDS.

they had been tied before the hatching, with the empty shells sticking to the surfaces, and we untied some and brought them away with us as specimens.

"The length of time between hatching and spinning, during the whole of which the larvæ remain in the open air, passing through four periods of rest, is reckoned at about sixty days, more or less, according to the temperature. We were told that the first rest commenced on the seventh day, and continued for two days; that the succeeding three periods of activity and torpor were severally longer than the first, and that the spinning commenced about ten or eleven days after the fourth rest.

"Three days after the commencement of spinning, said our informants, the hinder part of the cocoons is seen to be stained a white colour. This comes from the secretion of the *Yama-Maï*, which it emits after having finished spinning. The cocoons are then taken off the 'Kunogi,' together with the leaves to which they are attached, and a small portion of the branches. They are then brought into the house, and placed upon shelves. About ten days subsequently, the leaves are stripped off, and the cocoons, held by the lower and broader ends, are shaken. Those which do not rattle are considered to contain dead chrysalids, and after having been dried through evening, and lasts ten or twelve hours, after which the males are thrown away and die. It happens now and then that other males, coming from a distance, fly to the bars of the cages and couple with the females inside; these, however, are looked upon, not as legitimate husbands, but as interlopers, and their presence or absence does not enter into the calculations of the rearers of this district. The females then lay their eggs, as already stated, on the bars of the cages. This operation lasts four or five days, the average number of eggs to each female being estimated at from 150 to 200. The females then die. The best eggs are those laid on the first two or three days, and it is considered preferable that the males which emerge on one evening should couple with the females which emerge on the following evening. The same process which has already been described is then adopted with the new eggs.

"With regard to other diseases, they stated that after the fourth rest dark spots sometimes came out upon the worms, which subsequently die before spinning; that they are also subject to attacks of diarrhœa, which prove fatal; that another disease shows itself by a watery fluid exuding from the pores, the worms turning a brown colour and then dying. No particular names appear to be given to these maladies. Our

informants also said that if a considerable amount of rain falls whilst the egg papers are attached to the 'Kunogi' in the open air, the eggs are apt to be spoiled.

"We were shown a species of creeping plants called 'tonzuru,' with leaves resembling those of the convolvulus, and a dark stem, which sometimes cling to the 'Kunogi.' If the *Yama-Maï* eats of these leaves it is poisoned, and dies at once."

Sufficient evidence has now been given respecting this silkworm to show that there is a fair chance of success in suitable localities, and we are inclined to believe that the solution of two points will greatly help experimenters to the desired success. 1. It seems desirable that the culture of this worm should be tried on a large scale in a wood of some extent favourably situated; the worms might be fed in the open air, on the low-growing scrub, where the loftier trees could afford them shade without interfering with ventilation. A few streams running through the wood would be an advantage, and the aspect should be north rather than south. Lastly, not less than 10,000 eggs should be operated upon. 2. The *Quercus serrata* and other Japanese oaks differ very greatly in growth and appearance from our indigenous species. The Turkey oak (*Quercus cerris*) and the allied varieties most resemble the Japanese kinds, and certainly seem to be preferred by the worms. Large plantations of this oak I can remember at Burnham Beeches, near Slough, some twenty years ago: a locality, I should imagine, very favourable for an experiment. It might be worth while to keep this point in view. Another Japanese oak, which was sent to me in acorn, and on which the *Yama-Maï* is said to feed, has a very large leaf, much resembling that of the *Quercus ruber*.

It must be evident, from the information which has already been given on the culture of the silkworm, that it would be a very desirable acquisition to any country, and that could we, through its medium, turn the leaves of our oak coppices into silken fibre, it would be an enormous gain to this country. There are difficulties yet to be surmounted; but inasmuch as most Japanese plants and seeds flourish in Great Britain, I cannot but believe that with a little more information we shall be able to naturalise in the cooler and moister localities of Great Britain and Ireland this *Bombyx* and its valuable product, the strong raw silk that the moth produces.

FORTIFICATION.—XI.

BY AN OFFICER OF THE ROYAL ENGINEERS.

DEFENCE OF ISOLATED BUILDINGS AND POSITIONS.

It occasionally happens that in times of insurrection, and also in the ordinary operations of war, small bodies of troops are forced to shut themselves up in isolated buildings, and to continue their defence for some time. The short time that would probably be available under such circumstances must generally preclude the possibility of collecting sufficient supplies to enable the garrison to stand a siege, even if the buildings happen to be of sufficient strength to resist a continued and serious attack. Hence it cannot often happen that any very prolonged resistance would be possible, although in the Indian mutiny there certainly were several instances of its having been done; the most memorable examples, perhaps, of the defence of a single building being that of a house at Arrah, held by a few men against the Dinapore mutineers, and the defence of the Residency at Lucknow, which, with its neighbouring buildings and enclosure walls, formed a large isolated post, and withstood a siege of some months.

There is no doubt that if a building has been well chosen, and its defensive capabilities made the most of, a very formidable resistance may be made against greatly superior numbers, when the assailants are not assisted by artillery fire. This latter condition, however, rarely happens in the fighting between regular troops, and hence the great difficulty of determining what should be done in each case, the total destruction of the building and its defenders being a mere question of time, provided the possession of the post is of sufficient importance to the enemy to induce him to concentrate the fire of a large number of guns upon it.

In any well-built house, not only are the walls bullet-proof, but there are usually ample materials within it with which to barricade the doors and windows, so that, provided every part of it is thoroughly seen and flanked by some other, it will be almost impossible for the enemy to get sufficiently close to blow an opening in the walls by exploding bags of powder or discs of gun-paper (dynamite) against them. Most buildings are constructed with projecting porches, outhouses, walls, or balconies, which may be readily converted into flanking defences. It does not, however, often happen that these means exist for such a complete defence in every direction that it would be impossible for a small party of men to place powder-bags against some of the walls without being seen. Wherever such a deficiency exists it must be supplied by temporary constructions, or such an accumulation of obstacles must be made round the weak point that any close approach would be impossible, at all events without so much preliminary work as to arouse the garrison and draw on the working party the fire from numerous loopholes. It may at first sight appear a theoretical and fanciful idea to provide flank defence for such short lines as the gable ends of houses, etc.; but it must be remembered that if infantry, unassisted by artillery, are attacking other infantry who are in possession of a loopholed and fortified building, the weapons of the assailants are almost powerless against the defenders, whereas every shot fired deliberately and in almost perfect safety from behind a loophole should take effect outside. The advantage, therefore, lies entirely with the defence, and the only chance remaining for the attack will lie in being able, by a surprise of some sort, to send a few men forward to place bags of powder against the walls, the explosion of which will form an opening sufficiently large to enable the assaulting troops to rush in.

This operation of placing the powder is very simple, and to perform it only three or four men and a very short time are necessary; but being so few in number, and each man having certain definite work to do, it is essential that they should be able to perform their task without casualties, an event that would seem impossible if even one or two men are placed in a secure position for flanking the wall with revolvers or breech-loading rifles.

The two most ordinary modes of obtaining this flank defence are by "tambours" and "machicoulis galleries." The former are a species of kaponier, with or without a roof, formed of stockade work, and projecting sufficiently from the wall to flank it by the fire from several loopholes. As in all stockaded buildings, the labour necessary for their construction is considerable, and the liability to destruction by artillery fire is very great. They are, therefore, often impracticable, and cannot be adopted; although in cases where there are ample means and time available they may be of great use. The Prussians employed them frequently in their lines of investment for flanking long walls which were too extensive to be powerfully held without some such assistance, and which if unflanked would have afforded cover to the enemy without materially checking his advance. The long wall forming the enclosure of the "Haras," near Garches, in the lines round Paris, was defended in this way.

The defence by machicolated galleries is a very old one, and may be seen in most old castles or fortified buildings of the Middle Ages, where approach to the foot of the wall is prevented by the fire from loopholes in the floor and sides of small projecting balconies supported on corbels near the top of the building. The modern machicoulis is a wooden balcony with bullet-proof front and sides, supported on beams which project through holes in the outer walls sufficiently far to allow of a vertical defence by means of pistols and short rifles. It is troublesome to construct, and so easily destroyed by artillery, that if the close approach of the enemy can be prevented by any other arrangement, it will often not be worth while to employ it as a means of defence. A bullet-proof screen or shutter placed in an inclined position, like a sun-shade, at a window or other opening, may with less labour be arranged so as to hide the defenders from view, and at the same time admit of a vertical defence for the wall.

In the choice of a building for defensive purposes, next to the important question of flank defence, its liability to be set on fire, and the means by which this difficulty may be met, should be carefully considered. There must be an ample water supply, thatched roofs and inflammable out-buildings must be removed, and all hay-ricks or stacks of firewood near to it must be burnt or destroyed, as a conflagration on the windward side

of a house at the moment of attack would vastly increase the difficulties of the defenders, even if it did not result in setting fire to the building itself. There should be a clear space for some distance round the house, affording no cover for the enemy's marksmen, and its position should be such that, while it commands the roads by which the enemy will probably advance, it is not itself commanded by the roofs and windows of other more lofty buildings within range. As regards the work to be done inside the building: in the first instance carefully barricade and loophole the basement and ground floor, constructing and accumulating as many obstacles as possible round the outside. Care, however, must be taken that in the endeavour to obtain a powerful fire the lower walls are not so weakened by breaking numerous loopholes through them that the general stability of the building is affected; for it must be remembered that under the fire of artillery portions of the walls will be carried away, and that the weight of the roof, floors, etc., eventually may have to be borne by only a portion of their original supports.

It is generally considered that the garrison of the lower storey should be more numerous than that of the upper; and doubtless if without danger to the building sufficient numbers of loopholes can be made to employ the available number of men, there is an advantage in so doing, as the fire at that level will probably be more destructive than the plunging fire from above. As a rough guide to the number of men wanted, exclusive of the reserve, it is generally assumed that one man for every six feet of wall-space upstairs will suffice, and that the men are somewhat closer packed below; a considerable reserve being always kept in hand to replace casualties and perform various duties, such as cooking, etc. No rule of this kind can, however, be of much real value, as so much must depend on the shape and size of the building and the circumstances and object of the defence.

Loopholes at the angles of a building have a greater range, and enable fire to be directed on the sectors of undefended space in front of the angles, but they are more difficult to form than the ordinary ones. The great increase of power that has resulted from the use of breech-loaders renders it less necessary than formerly to crowd the men closely together, and every effort should be made to ensure their being able to use their rifles with freedom and effect. In the flanking defences, where the men have only to fire in one fixed direction, and where it is very important to get as much fire as possible from a given length of flank, there seems no reason why they should not be placed as close together as when standing in the ranks, provided long horizontal loopholes can be made for them to fire through.

In walls three feet or less in thickness, the neck or narrow part of the loopholes should be on the outside, and not less than three inches wide. The bottom of the loophole or sill should be about 4 feet 3 inches from the floor or banquette, and when considerable depression is required this height must be reduced. Pickaxes, crowbars, and hammers are required for making loopholes; and in ordinary brick walls, from nine inches to two feet thick, a couple of men should make a loophole in from ten to twenty-five minutes. The increased penetration of modern rifles renders the task of rapidly providing bullet-proof protection for the doors and windows of a defensible building more and more difficult. Boxes filled with earth, and sandbags or pillow-cases filled with earth and carefully built up, will answer the purpose, if they can be obtained in sufficient quantities. Doors and window-shutters can be rendered partially bullet-proof by nailing several extra thicknesses of planking diagonally across them until the required height of cover is obtained. When it is remembered, however, that our new infantry weapon, the Martini-Henry rifle, is capable of penetrating three thicknesses of three-inch fir planking at fifty yards, it would appear almost hopeless to try to obtain security by this means. Logs of wood, rolls of carpet, chests of drawers filled with earth, etc., can all be made use of with more or less success, and if perfect protection cannot be obtained, cover from view will often be of much use. It is important that the enemy should not be able to see whether the loopholes are manned or not, and therefore by day there should not be too much light in the rooms, and at night the less number of lights in the building the better.

Much has been said by various writers on the advisability of preparing for a defence of a building from room to room, and for a retreat from the lower floor by means of ladders to the upper rooms, from the floors of which a fire can be maintained on the enemy below, who are unable to follow, owing to the removal of the ladders and ordinary staircases. Such obstinate defences as this have undoubtedly often occurred, and therefore it would be presumptuous to say that under certain circumstances it may not be advisable to adopt similar measures again. It does, however, seem clear that if the assailants, in spite of the fire from the building, can succeed in forcing an entrance, and if, in spite of the equality of the fighting when they can only enter two or three abreast, they are able to drive the defenders to take refuge upstairs, it will not be long before they are able either to explode bags of powder in the lower rooms or to set fire to the house, which would probably at once put an end to the defence. It would, therefore, appear more advantageous to devote every effort to render the approach to the outside of the house difficult, rather than to elaborate a system of internal defence, which may possibly never be required. The foregoing remarks have been made chiefly with reference to a single building, but they will also apply generally to any group of buildings which has to be defended by infantry as an isolated post. Of course, where the buildings are not already connected by walls, out-houses, etc., the enclosure must at once be completed by means of stockades, abattis, etc., and where this has been done the same general arrangements as have been described would be adopted.

Isolated groups of buildings or villages may have to be defended under such very different circumstances that it will be impossible to do more than notice a few of the most ordinary cases. They may be occupied to assist the rear-guard of an army in covering its retreat, or the leading detachments of an attacking force may seize them, simply in order to enable them to hold their ground until the mass of their troops can be brought up. They may also have to be defended because they form important advanced posts in front of a large defensive position occupied during a general action. The defensive object in each of these cases being somewhat different, the nature of the practical work to be done in each case will also to a certain extent vary.

In the two former cases the object is obviously to gain time, and as the direction of the attack they are likely to receive is known, they need not necessarily be treated as closed works, but rather with reference to defence in certain directions only. In other respects, however, the conditions are dissimilar, for in the case of a rear-guard it may occasionally be necessary for the buildings to be obstinately defended to the last, even if by so doing the garrison is annihilated or taken prisoners, though of course the retreat of the defenders should as a rule be carefully provided for. This is essentially one of those cases where preparations for a successive defence from house to house, and from every advantageous point along the line of retreat, can and should be arranged. In retreating, the main body of the force will have passed through the village some time before the rear-guard arrives; consequently the officers in command have the opportunity of examining its capabilities for defence and designing their scheme, the necessary working parties and tools for carrying out which they probably have the means of supplying. This process should be repeated at convenient intervals along the line of retreat, and the rear-guard itself will be guided by orders received from the main body how long to continue its resistance at each point and when to retire.

The measures to be taken by an advanced guard occupying a village temporarily will differ from the foregoing inasmuch that the commander has probably no previous knowledge of the place, has probably a very short time in which to arrange his plans, and no resources as regards tools or materials besides those carried by his own men, as the inhabitants will most likely have fled. Here it is evident that every effort will in the first instance be made to strengthen the front and flanks of the village without barricading the streets, etc., in any very solid way, lest by so doing the subsequent advance of the main body should be delayed. With a rear-guard, on the contrary, as the roads and streets can only be of use to the enemy, any obstacles whatever that will delay his advance must be employed. The regularly-organised advanced guard of a large army would probably have a sufficient force of engineer officers, and men to do any requisite work but during a long general action the

success at some one point may cause the enemy temporarily to retire from a village, in which case, if there are no engineers at hand, it should be at once seized and fortified by the nearest battalions of the attack, when great judgment will be required to turn the small amount of work possible to the greatest account. Any success of this kind should be promptly supported by numerous bodies of engineers from the reserve, carrying with them the tools and implements most likely to be of use; and if, owing to the fire, they are unable to work at strengthening the front line, they should be actively employed in retrenching the position and loopholing houses, which will enable the troops to remain in the village even after the outskirts have been re-captured by the enemy.

When the buildings to be defended are in front of a line of battle, there probably have been some few hours available for preparation, and an ample garrison can be left for their defence. The difficulty, however, is to devise any arrangement that will enable them to hold out for several hours under a concentrated artillery fire, and surrounded by the enemy's troops. Being nearest to his position, they will have to withstand the first brunt of the attack, and are sure, for a time at least, to be cut off by the wave of attacking troops as it rushes forward to assault the main position beyond. In these cases it is evident that they must be capable of resistance in all directions, and also that a means of communication on the side next the position should invariably be made, by which, when a favourable opportunity occurs, reinforcements of men and ammunition may be sent to their assistance. The celebrated farm buildings of Hougoumont and La Haye Sainte, that played so conspicuous a part in the battle of Waterloo, belong to this catagory; and in the late war in France there were numerous examples of buildings defended under similar circumstances—for instance, the farm-house of St. Hubert, about 1,000 yards in front of the French left centre at Gravelotte, and the farm of La Bergerie, near Mont Valerien, which was so stoutly defended by a company of Prussian infantry against the last great sortie from Paris, 19th of January, 1871.

The defence of the village of Le Bourget, and numbers of others round Paris and Metz, will be found most instructive examples for any one really wishing to study the subject. Fairly reliable facts as to time, men employed, etc. etc., and a description of what was done, may in all such cases be gathered from the official French and German accounts.

In some cases the buildings in a village or town are so grouped as to be rapidly capable of conversion into a strong fortified post; while in others these conditions are most unfavourable—as, for instance, where the houses form one long street, enfiladed from the enemy's position, and liable to attack on either flank. Under these latter circumstances, it is clear that the enemy's artillery will in a short time render the defence of the end houses of the street an impossibility, and that any attempt to hold them would be futile. It would seem best in such a case to hold, in the first instance, an advanced line of trenches traced so as to avoid enfilade as much as possible, and when obliged to leave these to retire to houses, which being further up the street, are not so likely to be ruined as the end ones. These houses must have been previously determined on, and loopholed, the barricades in the street being so placed as to be commanded by them. The houses so chosen should if possible be isolated from the others on the side next the enemy, or if this is not possible, the floors and partition-walls of the houses next to them should have been cut away, to prevent the enemy working from house to house after he has once gained the end of the street. If the barricades are manned, the assailants will avoid a direct advance up the streets, and will endeavour to command and turn them by fire from the roof and windows of the houses they first get possession of. If the defence has been carefully prepared, these houses should have been previously mined, so as to be blown up as soon as the enemy's troops appear to have occupied them in force. To avoid this, no buildings should if possible be occupied by large crowds of troops until they have been examined by the engineers, with a view of detecting the mines, and disconnecting the wires or powder hose with which the charges would be fired. As regards barricades, they should be made at places where they are flanked, and where, if possible, they are screened from direct artillery fire, and there should always be a means of retiring round them, through the houses right and left.

In the attack of a fortified village, the assailants will endeavour by a series of false attacks to deceive the defenders as to the point on which the real attack is to be made. The troops, however, making the feigned attack should be sufficiently numerous and well organised, that if they find a weak or unguarded point they can really assault the place. The artillery will be used as usual to enfilade the longest lines, dismount the guns, and destroy the flank defences and obstacles. The fire of the defenders will be kept down by the artillery and by the leading division of the attack, who advance in skirmishing order, closely followed by a large working party of engineers, to destroy the obstacles, and prepare an entrance for the stormers.

In order not to give the defenders time to assemble it is very necessary that the attacking troops should advance as rapidly as possible, but before entering the village it is of still greater importance that until the working parties have cleared the way there should be no confusion or mixture of the troops having separate duties to perform.

After once an entrance has been effected, all previous arrangements must be more or less upset; and the success of the attack will depend on the vigour with which it is pushed forward, and the numbers with which it is supported. While the storming party is forcing its way onward, a working party should be employed in fortifying any houses or buildings favourably situated for covering the retreat in case of a reverse. Subject, of course, to variations depending on the circumstances of each case, the following is the general organisation of an attacking column:—(1) Skirmishers; (2) engineer working party; (3) escalading party, carrying ladders, ropes, grapnels, etc.; (4) storming party of infantry, followed by supports and reserves. The intervals to be observed between these, as well as their numbers, will entirely depend on circumstances. The hour for these attacks is usually just before dawn, as this allows of the assembly of troops and first advance possibly being made unseen, and of the subsequent operations being facilitated by the increasing daylight.

TECHNICAL DRAWING.—LXVIII.

DRAWING FOR BRICKLAYERS.

THE methods of breaking joint in short portions of walls built according to the common English bond having been thus illustrated, it now remains to treat of the system to be adopted in effecting the same object at the corners of buildings where two external walls meet at right angles.

In this case it is proper, commencing as usual from the corner header, at the external angles to introduce a set of closers, covering an extent equal to the whole thickness of the particular wall of the two (that is, if the two walls be of unequal thickness, which may often occur in practice) to which that header belongs; while closers need not, however, be disposed in a continued straight line, but checkerwise, so as to approach towards the re-entering angle, but without actually reaching it, and thus none of them will be seen in the inside of the building. They must all be laid parallel to each other.

Figs. 559 and 560 represent this arrangement, showing two successive courses of the corner of a building formed by the meeting of two walls each supposed to be three bricks thick.

In this arrangement it will be observed that of the two walls which meet each other at the angle, one shows a stretching course, whilst the other shows a heading course on the same level, and *vice versâ;* and these two arrangements meet each other at those parts of the brickwork where the three closers, which are equal in all to the length of three bricks (the thickness of the wall), extend entirely across the wall.

In building English bond a variety may be introduced by using so many three-quarter bats instead of whole bricks as corner headers at the extremities of every heading course as will make up the thickness of the adjoining wall; and in this case no closers are required.

Figs. 561 and 562 represent the plan of the corner of a building in which the walls are three bricks thick, and where this arrangement has been followed. In each heading course six three-quarter bats are used near the angle, which extend over a space equal to three bricks—that is, the thickness of the wall. In this case it is evident that all the joints will be perfectly broken without the aid of closers. These three-quarter bats are visible in Fig. 562, in which it will be seen that the

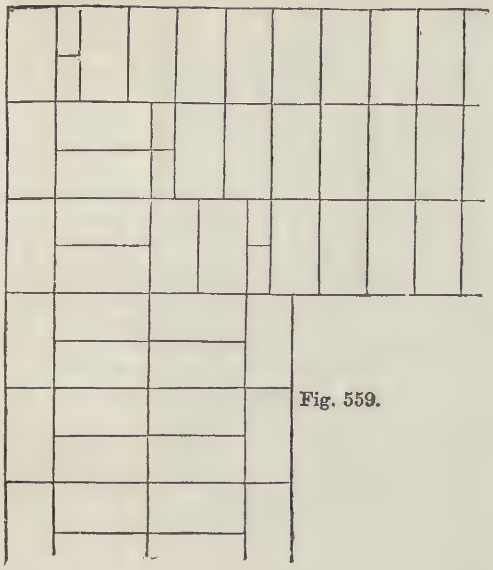

Fig. 559.

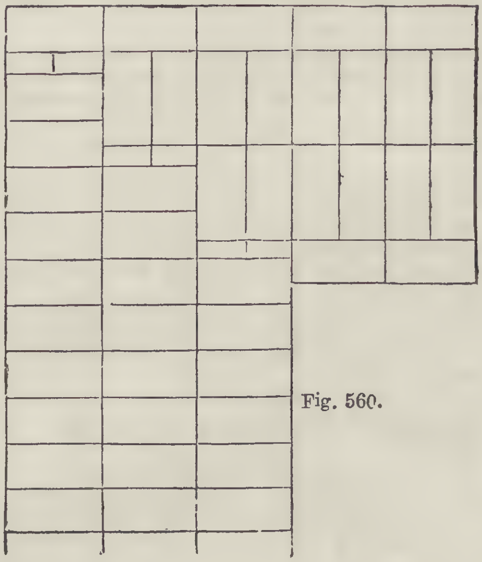

Fig. 560.

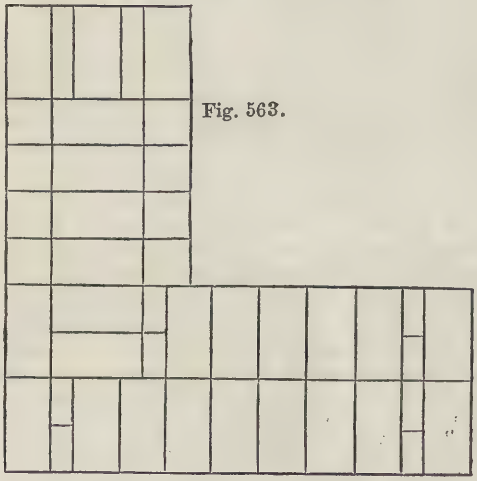

Fig. 563.

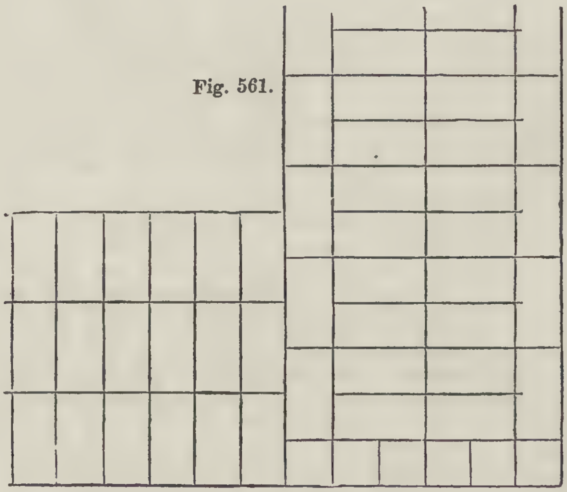

Fig. 561.

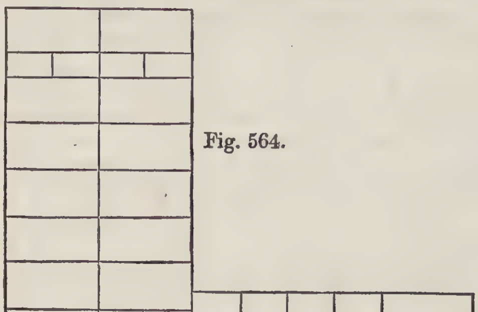

Fig. 564.

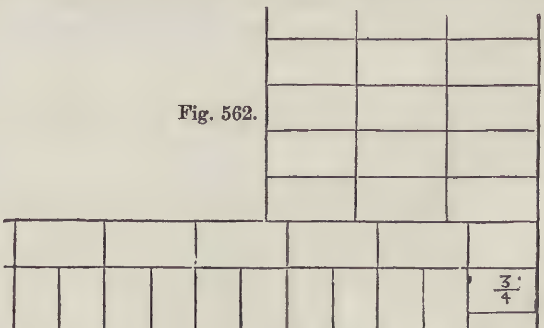

Fig. 562.

corner header of one wall shows as a short stretcher in the stretching course on the other side of the angle.

HEADING BOND.

A brick wall may be built all heading bond—that is, without using any stretchers at all, excepting in alternate courses at the corners of the building, as "quoins," as they are technically called, and at the various other angles or breaks occasioned by projections and recesses, or by the openings for doors and windows.

Figs. 563 and 564 represent the plans of two successive courses thus executed. One corner of the building is shown with the walls extending on each side as far as two openings, which may be supposed to be doors or windows.

Although from its neat appearance this style has been preferred by some architects, it is not generally considered so good as the common English bond, for as compared with that it merely consists in breaking every external stretcher into a couple of bats, as shown in Fig. 564, which certainly cannot be an advantage.

SEATS OF INDUSTRY.—XXVII.

LIVERPOOL.

BY WILLIAM WATT WEBSTER.

ALTHOUGH the manufactures of Liverpool are comparatively trivial, there is no town in the world that illustrates so clearly, and upon so extensive a scale, the indirect influence of manufacturing enterprise upon national prosperity. To its intimate connection with Manchester, Oldham, Bury, Bolton, Ashton, and other great manufacturing centres in the north of England, Liverpool owes, in a great measure, the proud position it occupies as the second town in the kingdom as regards population, and the first port in the British Empire, and consequently in the world, as regards the extent of its foreign trade. It is an integral and highly important part of the manufacturing system of England, and the story of its rise and progress, especially in later times, forms an interesting and instructive chapter in the history of British industry.

The etymology of the name Liverpool has given rise to much conjecture; but no satisfactory explanation of it has been given. In the earliest authentic records of the town that have been preserved, it is called Lyr-pul, and it has been suggested that the name is derived from the Gaelic word Lyr, "the sea," and that Lyr-pool means the "harbour of the Mersey." On the assumption that Leverpoole is the original orthography, the name has been associated with the family of Lever, which in ancient times flourished in the county, and also with the cormorant in the corporation seal, which is known in heraldry as a laver or liver. Previous to the Conquest, Liverpool was but a small and obscure fishing village; it is not mentioned in the Domesday Book. Ten years after William of Normandy landed in England, it is believed that a castle was built on a promontory between forty and fifty feet above the river, by Roger of Picton, on whom the Conqueror bestowed the whole district between the Ribble and the Mersey, and that the houses built round the base of this promontory formed the nucleus of Liverpool. There is a tradition that Henry I. conferred a charter of corporation on the town in 1129; but the charter of Henry II., dated 1173, is the first authentic record in its history. This document declares that "the estuary of the Mersey shall be for ever a port endowed with all the liberties belonging to a port of the sea, and that the men of Lyr-pol near to Toxteth may come and go from each side of the sea with their ships and merchandise, free and without obstruction," the sea here referred to being, of course, the Irish Sea. Henry II. also erected a number of what were called burgage-houses, whose tenants were the primitive freemen of Liverpool, and the Crown continued to draw the rental of these houses up to the time of Elizabeth. In 1207 King John granted a new charter, and in 1229 Henry III. made Liverpool a free borough with a merchant's guild and house, and conferred on its burgesses like liberties and privileges to those enjoyed by their brethren in London, Bristol, and other towns, no stranger being allowed to trade or settle there without the sanction of the municipal authorities. For two centuries this smallest of the chartered towns of England was so poor that it sent no representative to Parliament, and for five centuries it can hardly be said to have had a history. During the latter long period, the wardership of the castle was retained by members of the Molyneux family; and about the year 1360, a tower that had been erected in the previous century, as an outguard to ensure the safety of the castle, came into possession of the Stanley family, and this building was afterwards an occasional residence of the Earls of Derby. In the reign of Henry VI. the Stanleys and the Molyneux had a violent feud, which required the intervention of the Government; and about this period the knightly family of More, of Bank Hall, had a mansion in Liverpool and large possessions in the vicinity. In 1524 Leland describes the town in his "Itinerary" in the following terms:—"Lyrpole, *alias* Lyverpoole, a pavid towne, hath but a Chapel, Walton a iiii miles of, not far from the Se is paroche chirch, the King has a castelet there, and the earls of Darbe hath a stone house there. Irish marchaunts come much thither as to a good haven. At Lyrpole is small custume payed that causith marchauntes to resorte. Good marchandis at Lyrpole, and moch Yris yarn that Manchester men do buy there." Forty-one years later Stow states in his "Survey" that Liverpool consisted of seven streets, containing 138 houses, and that its population numbered only 690. There were then in the harbour twelve ships, with an aggregate burden of 223 tons, and a total crew of seventy-five men. In a petition to Queen Elizabeth, dated 1571, reference is made to the place as "Her Majesty's poor decayed town of Liverpoole;" but Camden, writing in 1586, gives a more cheering description of it, noting, among other things, that it is "the most convenient and most frequented passage to Ireland," and remarking that the town was "more celebrated for her beauty and populousness than for her antiquity." It would appear that the merchants of Liverpool had trading connection with the continent of Europe at this date, for it was Humphry Brooke, one of their number, who gave Queen Elizabeth's Ministers the first intimation they received of the sailing of the Spanish Armada; but its chief trade was at that time, and for a long period afterwards, with Ireland. Chester, however, continued to be the principal seat of commerce with Ireland till about the middle of the seventeenth century. The transfer of this trade from Chester to Liverpool began by merchants of the former town using the latter as their port, the Dee having gradually become unnavigable for the larger class of ships, and for many years Liverpool was considered a sort of sub-port of Chester. In 1602, the inhabitants of the latter town asserted that "the town of Liverpool was but a creek of the port of Chester," and for many years they claimed a sort of lordship over Liverpool. In 1626 a new charter was granted to Liverpool by Charles I., making it a city, James Strange, Lord Stanley being its first mayor; but up till 1647 the port was subject to Chester officers. After the Irish rebellion of 1641, a number of Irish Protestants settled in Liverpool. During the civil war the town acquired great political importance. In 1644 it was defended by Colonel More against the army of Prince Rupert for three weeks, but was taken by storm: the royalist cause, however, being shortly afterwards utterly ruined by the defeat at Marston Moor, Liverpool again came into possession of the Parliament. Cromwell favoured the place as the most convenient port of embarkation for Ireland, and during the great plague and fire of London in 1665 and 1666, many merchants from the metropolis took up their residence in Liverpool. In Blome's "Britannia," dated 1673, it is stated that amongst the inhabitants of Liverpool are "divers eminent merchants and tradesmen, whose trade and traffic, especially into the West Indies, makes it famous," and "the sugar bakers and great manufacturers of cotton in the adjacent parts" are mentioned. During the reign of Charles II. Liverpool made great progress, owing to the opening up of America to British enterprise, and its merchants early took an active part in the slave trade, sending out ships to Africa for negroes, conveying them to America, and bringing back sugar, tobacco, and other goods, in exchange for their live cargoes. It was from Liverpool that William III. set sail for Ireland in 1690, three days before the battle of the Boyne. Nine years later, when it was erected into a separate parish, Liverpool had a population of about 5,000.

Liverpool advanced rapidly during the eighteenth century, chiefly by means of the trade its merchants carried on in slaves and tobacco. The first slave ship fitted out on the Mersey was dispatched in 1708; but by the year 1752, 101 Liverpool merchants were engaged in this infamous though lucrative traffic. Between the years 1700 and 1709 inclusive, the average annual

importation of tobacco into Britain amounted to 12,880 tons, and Liverpool had a larger share of this trade than any other port in the kingdom, half the shipping and more than half the wealth of the town being embarked in it. To afford facilities for this trade, a wet dock was constructed in 1709, which was not only the first in Liverpool, but the first in the kingdom. By the year 1760 there were seventy-four vessels belonging to Liverpool, with an aggregate burden of 8,178 tons, engaged in the slave trade, and it continued to increase during the forty-seven years that elapsed before England ceased, in 1807, to participate in this iniquity. During the ten years from 1795 to 1804, when the slave trade reached its culminating point, it is calculated that the merchants of Liverpool shipped no fewer than 323,770 slaves from Africa to America and the West Indies. That this traffic was highly profitable to them, may be inferred from the fact that at the time it was being carried on, the greater part of the West Indies belonged to Liverpool merchants. The outbreak of the French war in 1756 put a stop for a short period to the slave trade, and the slavers of Liverpool were turned into privateers. At first they gained some slight success, but before the close of the war Liverpool suffered severely by way of retaliation, it having been blockaded by French privateers for seven weeks in 1758. In the course of the eighteenth century, the natural advantages of Liverpool for the prosecution of commerce were greatly enhanced by the construction of an immense system of canals. The first effort to improve the natural facilities for inland trade was the building of the Irwell and Mersey navigation (for which an act was obtained in 1720), by means of which raw cotton and cotton goods were conveyed to and from Manchester; and shortly after the completion of this work, the Weaver navigation was undertaken, which afforded an easy means of bringing the salt of Nantwich and other places in Cheshire to Liverpool, which speedily became an important article of export, and employed a large amount of shipping. These works were followed by the Sankey Brook navigation, completed in 1768; the Bridgewater canal, opened in 1773; the Trent and Mersey, or Grand Trunk canals; and the Leeds and Liverpool canal, which were finished in rapid succession; so that by the year 1816, Liverpool possessed a complete system of water communication, direct or indirect, not only with the great manufacturing towns of Lancashire, Cheshire, and Yorkshire, but also with the south coast, and, in fact, with nearly every part of England. These canals have realised large profits to their shareholders, and they still bring in considerable revenues, notwithstanding the competition of the railways. It is worth mentioning that between the years 1777 and 1782, there were launched on the Mersey some fifteen war-vessels, of considerable tonnage, and carrying from sixteen to fifty guns, constructed to the order of the Government. As a matter of course, the population of the town kept pace with the growth of its trade. Between 1710 and 1760, the number of its inhabitants increased from 8,160 to 25,780, and the shipping belonging to the port increased from 84 vessels in the former of these years to 1,245 in the latter. By 1781 Liverpool had a population of 35,000, and possessed 2,300 ships; and by 1791 its population had augmented to 50,000, and its shipping to 4,200 vessels. In 1801 the population was 77,700, and the commercial fleet numbered 5,100 vessels.

But the most important factor in the prosperity of Liverpool has yet to be noticed, for it has been still more indebted to cotton than to slaves and tobacco put together. The beginnings of the cotton trade of Liverpool were exceedingly small. In a local newspaper, dated 3rd of November, 1758, the following advertisement appeared:—"To be sold by auction at Forbes and Campbell's sale-room, near the Exchange, this day, at one o'clock, twenty-five bags of Jamaica cotton in five lots;" and from that time cotton was regularly brought to Liverpool from the West Indies, although for a long time in exceedingly small quantities. In 1770 the imports into Liverpool included 6,030 bales of cotton from "the West Indies and from foreign countries, with the addition of three bales from New York, three bags from Georgia, four from Virginia and Maryland, and three barrels from North Carolina." Twenty-one years later only 64 bales of cotton came to Liverpool from America, but the total quantity imported from Portugal and the West Indies in 1791 amounted to 68,404 bales. In 1794, however, the supply from America had risen to 4,668 bales, and from that date American cotton came into the port in steadily increasing quantities till it largely exceeded the imports from the East, and became the staple article of the commerce of Liverpool.

It was not till Hargreaves, Arkwright, and the other inventors and improvers of cotton manufacturing machinery had created and developed the cotton manufactures of the north of England, that the cotton trade of Liverpool attained gigantic dimensions. In the year 1824, the quantity of cotton imported into Liverpool was 578,323 bales, and of this total 413,724 bales came from the United States of America. The total imports of cotton into England in 1830, from all quarters, amounted to 793,695 bales, and of this quantity no less than 703,200 bales came to Liverpool. Ten years later, 1,164,269 bales of cotton were brought to Liverpool, and in 1851 the quantity had increased to 1,748,946. It may be stated here that the quantity of foreign and colonial produce imported into Liverpool in 1858 was 1,384,353 tons, against 1,374,937 tons into London, and that the foreign exports from the former port amounted in the same year to nearly £35,000,000, or considerably more than one-half of the total value of the exports of the three kingdoms for that year, and more than twice that of London. The number of vessels that entered the port of Liverpool in 1851 was 21,071, representing an aggregate of 3,737,636 tons burden, and the dock dues amounted to £269,020, and the customs receipts to £3,510,033.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXIX.—RICHARD REYNOLDS.

BY JAMES GRANT.

This celebrated iron-smelter, and ultimately the inventor of the *iron rail* which is now used on all railway lines, was born at Bristol in the year 1735. Though educated in the peaceful persuasion of the Society of Friends, to which his parents belonged, when but a lad he felt a strong desire to become a soldier, and would have enlisted but for the dismay such a step must have occasioned his friends. Ere long this fancy or enthusiasm died out, and assuming "the drab," he settled down into a quiet and industrious Quaker.

After serving an apprenticeship to the iron trade in Bristol, he went to Coalbrookdale on business; while there he became acquainted with the Darby family, who had long been iron and brass founders in that district, so rich in mineral treasures. The Darbys were also "Friends," and received young Reynolds hospitably, and eventually he married Hannah, daughter of Abraham Darby, known as "the second," three of that name—father, son, and grandson—having been smelters and malt-mill makers in succession at Coalbrookdale since the first year of the last century.

Richard, through this connection, undertook the management of the iron and coal works at Ketley and Horshay. At the latter place he resided six years, and on the death of his father-in-law, in 1763, he removed to Coalbrookdale, and took charge of the more extensive iron-works there. By the wealth and enterprising spirit of the Darbys, these had become greatly enlarged, and found remunerative employment for a rapidly-increasing population. The firm did not confine their operations to the Dale, says Mr. Smiles, but extended their works far beyond its boundaries, and built foundries in London, Bristol, and Liverpool, with agencies at Newcastle and Truro for the disposal of the steam-engines and other iron machinery then in use for clearing deep mines of water, and many of the pumping-engines made on Newcomen's design were constructed at the works of the Darbys.

"Civilisation is economy of power," according to Baron Liebig, "and English power is *coal!*"

The increasing demand for iron gave an impetus to coal-mining; the works increased in magnitude and number, till the whole of that part of the glen through which the Severn flows, between two hills, presented a *tout ensemble* which, with the forges, engines, furnaces, and machinery of iron, constitute a spectacle of the most interesting and bustling description; and when the steam-engine had been perfected by James Watt, and enabled powerful blowing apparatus to be wrought by its agency, the production of pit-coal being rendered cheap and expeditious, inventions stimulated each other, and trade at Coalbrookdale enormously increased.

The rich coal and iron district there includes the Dale, and

extends east to Lillieshall and Bridgnorth, north-west to Wellington, and thence by the wooded Wrekin, south-west to the road from Much Wenlock to Bridgnorth; on the west the boundary is broken by the Severn; but the area thus described consists of a platform raised 400 feet above the river at Madeley, and 500 feet above the sea. At all these points the coal-measures are fully developed, and next in importance to the beds of these are the layers of argillaceous carbonate of iron.

Up to the time when Richard Reynolds took charge of the works at Coalbrookdale, the conversion of crude or cast iron into malleable or bar iron had been effected entirely by means of charcoal. The process was carried on in a finery almost exactly like a smith's forge, "the iron being exposed to the blast of the bellows and in constant contact with the fuel. In the first process of fusing the ironstone, coal had been used for some time with increasing success; but the question arose, whether coal might not be used with effect in the second or refining stage. Two of the foremen, named Cranege, suggested to Mr. Reynolds that this might be performed in what is called a reverberatory furnace, in which the iron should *not* mix with the coal, but be heated solely by the flame."

Though doubting the success of the experiment, Reynolds encouraged the Craneges to attempt it in April, 1766, and the result of their invention surpassed the expectation of the three. The iron put into the furnace was old bushes, which are always made of the hardest metal, and the iron drawn forth was, according to Reynolds's own statement, "the toughest I ever saw. A bar, 1¼ inch square, when broke, appears to have very little cold short in it. I look upon it as one of the most important discoveries ever made, and take the liberty of recommending thee (Thomas Golding, of Bristol), and earnestly requesting thou wouldst take out a patent for it immediately."

His advice was followed, and a patent to the Brothers Cranege, as inventors of the process, was secured for them on the 17th of June, 1766; but other inventions superseded it, and thus it eventually was of no benefit to them.

Among the important improvements introduced by Reynolds at the Coalbrookdale Works was the invention and adoption by him for the first time of *iron rails*, in lieu of wooden tramways along those roads by which the metal and coal were conveyed to the furnaces and to the landing-places on the Severn. The first idea of constructing railways is supposed to have been entertained between 1620 and 1650, when they were roughly constructed of wood, and one of this kind existed at Preston Pans, in Scotland, for when the Highlanders routed the King's troops there, in 1745, the cannon of Sir John Cope were captured *on the railway*, or tram-road. Reynolds observed that the wooden rails soon decayed, were liable to be broken, thus interrupting business and incurring great expense for repairs; and to obviate these inconveniences, in 1767, he took up all the wooden rails and replaced them by plates of iron, thus fairly inaugurating the era of the iron railroad, and his example was followed on all the old tramways throughout the three kingdoms.

It was at his works that the *first* bridge of iron the world had ever seen was constructed in 1779, after long care and forethought, as an attempt had been made some twenty years before to span the Rhone at Lyons, and proved a signal failure.

The erection of the bridge was perhaps due to the energy and enterprise of his wife's kinsman, young Abraham Darby, who having become proprietor of the Manor of Madeley, and finding that the owner of Broseley, on the opposite side of the Severn, was equally anxious to bridge the stream where it divided their possessions, and where its banks were steep, and the old ferry dangerous, set about procuring plans for the erection without delay. Empowered by Parliament, a company was formed; shares were taken by the adjacent owners, the Rev. Mr. Harris, Mr. Jennings, and Mr. John Wilkinson—the latter a man of great enterprise, and builder of the *first* iron ship. Abraham Darby was the principal subscriber; and Mr. Pritchard, of Shrewsbury, prepared a plan, which, according to Mr. Smiles, is still preserved. It proposed to introduce cast iron in the arch of the bridge, which was to be in span 120 feet, but only as a sort of key, occupying but a few feet at the crown of the arch; this very sparing use of cast-iron indicating the timidity of the architect in working with new material. Thus, had his plan been adopted, "the problem of the iron bridge would still have remained unsolved."

It was set aside, and another arch *entirely* of cast iron was prepared at the works under the superintendence of Mr. Darby and Thomas Gregory, foreman of the pattern-makers, and arrangements were made for carrying it into effect. The abutments were built in 1778, and the following year saw the bridge —with an arch 40 feet high, and 100 feet in span—opened for traffic. The model of this structure is still preserved by the Society of Arts. "If we consider that the manipulation of cast iron was then completely in its infancy," says Mr. Stephenson, in the *Encyclopædia Britannica*, "a bridge of such dimensions was doubtless a bold as well as an original undertaking, and the efficiency of the details is worthy of the boldness of the conception."

Its site across the Severn was judiciously chosen, and such is its utility that now a thriving town named Ironbridge has sprung up around it on that which was formerly waste land; "and it is probable this bridge will last for centuries to come," adds the author of "Lives of the Engineers:" "thus also was the use of iron as an important material in bridge-building fairly initiated at Coalbrookdale by Abraham Darby, as the use of iron rails was by Richard Reynolds. We need scarcely add that, since the invention and extensive adoption of railway locomotion, the employment of iron in various forms in railway and bridge-structure has rapidly increased, until iron has come to be regarded as the very sheet-anchor of the railway engineer."

When the Government, in 1784, proposed to levy a tax on pit-coal, Richard Reynolds urged upon Mr. Pitt, then Chancellor of the Exchequer, and upon George Lord Gower, afterwards second Marquis of Stafford, the extreme impolicy of such a barrier to progress.

In that year sixteen "fire-engines," as those of steam were then named, were at work in the Dale, eight blast-furnaces, and nine forges, in addition to air-furnaces and mills at the foundry; and these, with the levels, roads, and twenty miles of railway, gave work and food to a vast number of people. Reynolds did not wish it to be understood that he sought for any special protection for home-made iron, notwithstanding the low price at which it could be imported from Russia and from Dannemora in Sweden. "From its most imperfect state as pig-iron," he remarked to the Earl of Sheffield, "to its highest finish in the regulating springs of a watch, we have nothing to fear if the importation into each country should be permitted without duty." The nobleman he addressed on this occasion was that Earl of Sheffield who was President of the Board of Agriculture, and well known in the literary world as a writer on political economy; and the subsequent history of the iron trade has fully justified the anticipations of Reynolds.

When the latter became more advanced in years, he began to long for retirement; he had no desire to possess wealth, yet it had flowed upon him, and he resolved to relinquish his shares in the iron-works at Ketley to his sons, William and Joseph. The former, a man of science and an excellent mechanic, was the first to employ inclined planes, consisting of parallel railways, to connect and work canals of different levels; and Telford, the engineer, handsomely acknowledged the great assistance he received from him in planning the iron aqueduct by means of which the Llangollen branch of the Ellesmere Canal was carried across the Dee at the height of 126 feet above a deep ravine through which the river flows at the width of 2,600 feet. The necessary coilings were all made at the Ketley works.

In 1804 Richard Reynolds finally left the scene of his long labours in busy Coalbrookdale, and returned to his native town of Bristol. There he spent the close of his years in works of charity and benevolence; and though a rigid Quaker, he was fond of painting, poetry, and music. "Many were the instances of his princely, though at the time unknown, munificence. Unwilling to be recognised as the giver of large sums, he employed agents to dispense his anonymous benefactions. Thus he sent £20,000 to London to be distributed during the distress of 1795. He had four almoners constantly employed in Bristol finding out cases of distress, relieving them, and presenting their accounts to him weekly, with details of the cases relieved."

In the eighty-first year of his age, this good old man died at Bristol, on the 10th of September, 1816, and was followed to his grave by the poor of the city, while clergymen of all denominations joined in the remarkable procession. His obsequies were celebrated in the peculiar but unobtrusive manner adopted by the Society of Friends.

MAP AND PLAN DRAWING.—I.

By C. C. King.

DIFFERENCE BETWEEN MAPS AND PLANS—SHAPE OF THE EARTH—PROJECTION OF MAPS—TRIANGULATION.

Map or plan drawing is the delineation on paper of any part or parts of the earth's surface. The term *map*—derived from the Latin *mappa*, "a cloth," probably because maps were originally drawn for convenience' sake on this material—should be, strictly speaking, confined to a representation of an extensive tract of land, when it is called a terrestial or geographical map; but should the area consist chiefly of the sea or any other large space of water, its delineation is termed a hydrographical map or chart. When we simply endeavour to depict on paper any small area which would not, on account of its size, be materially influenced by the curvature of the earth, then we designate it a plan, that is, anything drawn upon a plane.

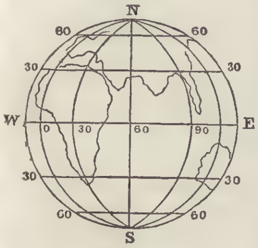

Fig. 1.

Maps and plans, therefore, as terms, are questions of degree, the former applying to large areas, the latter to smaller ones. Thus we speak of the *map* of England or Europe, the *chart* of the Atlantic Ocean or the Bristol Channel; but the *plan* of an estate, a village, or a house. A survey of a county is also a map; but as this under ordinary circumstances enters into very careful detail, and depicts with great accuracy, not merely the more important, but also the minor features of the district, it is entitled a topographical map, that is, one describing minutely all the natural and artificial peculiarities of the ground.

The object of all map-drawing is to exhibit the character of the country or countries, their boundaries, and the positions of their towns, villages, or great physical features, with such accuracy that they shall bear on our delineation both the same relative proportions and the same relative distances apart as they do on the actual globe. This is simple enough if the figure on which the copy is made is similar in form to that whence the copy is taken, the difference between the two being only one of scale. That is, it is easy to portray the surface of the earth on a similarly constructed sphere. But to lay down all the distances and details on the plane represented by our paper, so as to give them all their relative values, is a matter of considerable difficulty, and hence various methods have from time to time been devised to enable geographers to picture with accuracy the surface of the world.

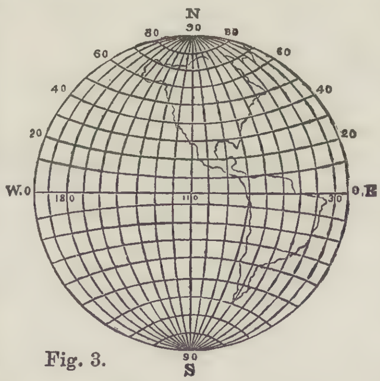

Fig. 3.

The shape of the earth is a sphere, or more properly speaking, an oblate spheroid; and for the convenience of geographical description its surface has been assumed to be intersected by a series of equidistant circles parallel to the equator, called *parallels of latitude;* and again by great circles passing through the poles, and dividing the equator into 360 equal parts, or geographical degrees. These are designated *meridians of longitude.* The geographical latitude and longitude, therefore, of a place are the co-ordinates which fix its true position upon the terrestrial sphere; and for the purpose of this determination the meridians of longitude are numbered from 1 to 180 east and west of that which is assumed to pass through Greenwich in English maps, and the parallels of latitude are enumerated north and south from the equator from zero to 90 at the poles. Other meridians and parallels for every intermediate minute and second of each division or degree are supposed to exist, though they are not drawn, and thus the position of any place on the earth's surface can be determined relatively on the map.

It must be remembered that in depicting any country or area, it is first necessary to construct, so to speak, a framework or scaffolding to which the relative positions of the physical or artificial features can be afterwards referred; and as this framework is represented in map-drawing by the meridional arcs and the parallels of latitude, the first aim of the draughtsman is to determine their position accurately on his paper. Having these carefully indicated, he can trace without difficulty the country he desires to portray; the exact position of any points he may afterwards select as centres, whence to extend the examination of the ground, being readily determined by the intersection of the meridians and parallels of latitude passing through them.

There are three methods of accomplishing this—(1) by projection; (2) by Mercator's projection; and (3) by the method of development. These various methods we shall now proceed to explain in detail, as fully as the space at our command will allow.

Projection is practically a means of representing in perspective the circles of latitude or longitude, and contains further three different plans for arriving at this result—viz., orthographic, gnomonic, and stereographic or central. They all labour, however, under the same disadvantage—clearly exemplified in the maps of the Eastern and Western Hemispheres found in the commencement of every atlas—that of distorting somewhat those parts of the area which lie towards the outer portions of the circumscribing circle. They are, therefore, rarely used, except in the cases above mentioned; and it will be sufficient merely to point out briefly the principles adopted in their construction.

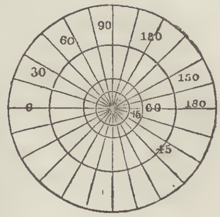

Fig. 2.

The orthographic projection assumes the eye of the observer to be at an infinite distance from the plane which, interposed between it and the sphere, is to receive the projected copy, and hence the visual rays to the various points are parallel to each other, and also perpendicular to the plane, which is technically called the "primitive." The result is to produce a representation of the world in which the meridional arcs are elliptical in form, having the meridian of Greenwich as the major axis, and the radius of the circle multiplied by the sine of the longitude as a minor axis; while the latitudinal arcs are shown by straight lines, the distances of which from the equatorial arc are determined by multiplying the radius of the circle by the sine of the latitude, and measuring them off on the first meridian north and south of the equator. This projection is usually made on the plane of the equator, or that of a meridian (Fig. 1).

The gnomonic or central delineation assumes the eye of the observer to be at the centre of the sphere, and is most commonly employed to depict the regions around the pole, when it is termed a "polar projection." In this case the meridional lines radiate at equal angles from the pole, and the parallels of latitude become concentric circles, whose distances from the pole are = radius × cot. latitude (Fig. 2).

The stereographical projection is used in most atlases to show the Eastern and Western Hemispheres, and it is supposed that the eye is situated on the surface of the sphere, which is considered to be a transparent solid, the plan being made on a plane at the opposite extremity of the diameter. All the arcs in this instance, except the central meridian and the equator, take the form of circles or portions of them (Fig. 3).

These systems are only applied in laying down a hemisphere or any large portion of the sphere, and are, therefore, not applicable to the circumstances under which maps are usually constructed. Reference to any atlas will show how much the shape of the continents is distorted, and this would naturally render these principles of projection of but little use where careful regard to relative proportion, especially in small details, was essential.

The first attempt to describe the earth's surface as a plane was made by Gerard Kauffman in 1512, and is called Mercator's projection, but the principles on which it is based were not fully explained till 1599, when Mr. Wright of Cambridge

examined them and made an exposition of them in his "Correction of Certain Errors in Navigation."

He depicted the surface as a true plane on which the meridional and latitudinal arcs were drawn as parallel straight lines respectively at right angles to one another. The former are equidistant, but by a mathematical rule the latter increase in distance as the latitude increases, in the same proportion as the lengths of the degrees of longitude on the respective parallels of latitude on the map are increased, owing to the fact that the meridional lines are represented as parallels instead of as arcs of great circles meeting at the poles. On the *sphere* the degrees of longitude measured on the parallels of latitude decrease in proceeding north or south; but on the *map* they are the same, on account of the parallelism of the meridians, so that it is necessary to make the distance between the lines representing the latitudes such that the same relative proportion between the length of a degree of latitude and one of longitude at any given point shall be the same on the map as on the sphere—in fact, that the bearing and distance of one place from another on both map and globe shall correspond (Fig. 4).

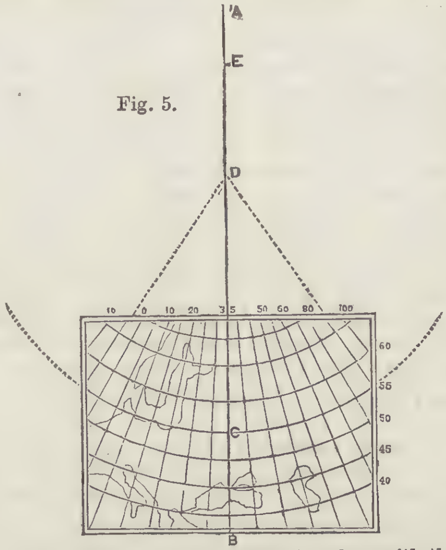

Fig. 5.

The method of development is the principle on which all ordinary maps are constructed, and it will therefore be desirable to examine it more carefully. There are many different plans of development, such as globular, cylindrical, and conical, but they are all similar in their principle—that of representing the earth on such a geometrical figure that it will not be altered by being unfolded or developed as a plane. A sphere cannot be thus developed without destroying it; but a cone or cylinder can be unfolded without altering the value of anything described upon its surface.

The conical method is most generally adopted, and it assumes the surface to be mapped to be a portion of a cone whose vertex is somewhere in the prolongation of the pole, and which either touches the sphere in a circle which is the middle parallel of latitude of the country to be delineated, or falling within the sphere at this circle passes without it at its extreme parallel. The surface of this portion of the cone when developed or unfolded forms the sector of a circle, and pictures with great accuracy the area to be examined (Fig. 5).

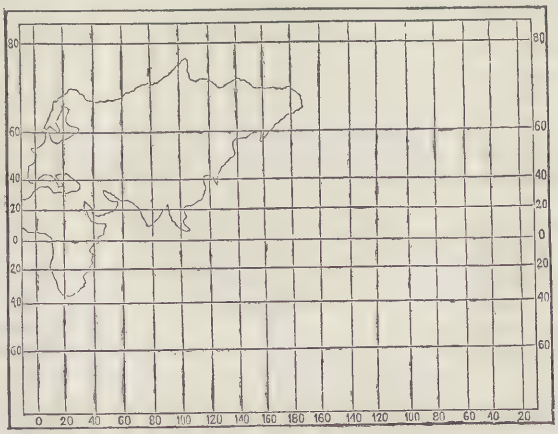

Fig. 4.

The method of describing it on paper is as follows:—

Draw any line A B for the central meridian of the map, and take the point C as a convenient position for the central parallel of latitude. Divide A B into any large number of equal parts, each of which is, on a chosen scale, to represent the degrees and minutes of latitude. Assuming the equator to be divided into 360 equal parts or degrees, this will give the radius of the terrestrial sphere as 57·3 of these, which measure from C to E. Take C D = the cotangent of the middle latitude of the plan reduced to a radius of 57·3 of the degrees of latitude already marked.* This point D will give the centre whence the arcs of latitude will be described through the points on A B. Divide the arc now described through the point C into equal parts, such that the length of a degree of longitude (the division required) : the length of one of the degrees of latitude already described : : cosine of the middle latitude : the radius. Connect these points with the centre D, and the meridians for the given area are obtained.

We have now on paper a relatively correct representation of the meridians and parallels of latitude of the country we are going to map, and we can definitely fix the position of any point on it by its latitude and longitude, and thus obtain a starting-point for the further delineation of the ground. The principle on which all surveying is based—whether the more accurate representation undertaken by a state to show the boundaries of its territories, with its towns and villages, or the simpler topographical maps for military or statistical purposes—is that of uniting all the important points, physical or otherwise, on the area by a system of triangles commencing from a carefully measured base, which forms the side of the first triangle. These are further intersected by a network of smaller triangulations, which will fix all the secondary points on the surface, and finally the details of the ground are completed by measurement and the theodolite, or by sketching them with the aid of some other portable instrument. The degree of care with which this is done depends both on the scale to which the drawing is made, and the purpose for which it is intended. Thus, a military plan or map showing physical details on a large scale, made on actual service, is, though sufficient for the purpose for which it was designed, not essentially extremely accurate, though it may be made so if much time is provided for its construction.

It is evident that the value of this work of triangulation lies in the exactitude of the base-line, and the determination of the true position of the starting-point at one of its extremities. Extreme care in measurement, and a most painstaking repetition of observations are essential, for errors committed at this period of a survey are not merely continued but increased as the work proceeds. With such nicety has this determination of the base-line been conducted in the trigonometrical survey of England, that we find that a base measured on Hounslow Heath in 1791, was on re-measurement proved to coincide exactly in its mean length with the calculated dimensions assigned to it by a triangulation starting from a different base. A still more startling instance of the degree of accuracy which can be arrived at, is that of the measurement of a "base of verification" in Ireland, when, after carrying the triangulation across St. George's Channel, the distance between two points on either side of one of the Loughs was trigonometrically calculated. On measurement it was discovered to differ by only some two or three inches from this calculation.

The value of precision in the determination of a base-line is

* This is readily done by means of the sector. Open the arms of the instrument until the distance between the points marked 45° on the line of tangents (described by T) is equal to the given radius C E. The distance between the points denoting the angles on the line of tangents whose *tangent* is to be found will give the required radius for describing the arcs of latitude. It may be mentioned that the cotangent of the middle latitude is = *tangent* of (90° − middle latitude), and that this tangent is the one employed in finding the radius from the sector.

evidently most important, and whether in an extended survey or a rough sketch or reconnaissance, it should be fixed and measured with all the care that can be bestowed on it. Time is never lost by so doing.

The ground selected for it should be as extensive as possible, and should admit of a large series of prominent points and objects being seen from both ends of it. The more level it is, the more carefully can the base be measured, and the less necessity will there be for reducing it to an accurately horizontal plane. Having chosen an area that fulfils these requirements, one extremity of the base is accurately fixed by observations giving its exact latitude and longitude, and thus we have not merely a known point of departure on the terrestrial sphere, but are enabled to mark it definitely on the projected delineation of the surface we propose to transfer to paper.

MUSEUMS: THEIR CONSTRUCTION, ARRANGEMENT, AND MANAGEMENT.

BY SAMUEL HIGHLEY, F.G.S., ETC.

VIII.—NATIONAL MUSEUMS (*continued*).

1. *The New British National Museum of Natural History.*—Eight years after the date of that final estimate of space required, from the data herein contained, the Premier and the Chancellor of the Exchequer declared, on the annual report and estimates of the officers of the British Museum being brought before Parliament, May, 1870, that it was the intention of the Ministry to carry into effect, without any further delay, the erection of new buildings to contain the natural history collections, and so ease the other departments of the British Museum from their present engorged condition. This museum is now (1876) approaching completion, and has been erected on the site of the Great International Exhibition of 1862, at South Kensington. The building will be admirably lighted, the windows being large and close together, as is requisite in an edifice devoted to such purposes, and it will form one of the handsomest structures of which the metropolis can boast. According to an official plan of the Gore Estate published in the Report of 1862,* the ground on which it stands consists of $16\frac{1}{2}$ acres, giving a clear parallelogram of 1,100 feet long by over 550 feet wide.

In the Report of 1860 it was stated that while land immediately adjoining the British Museum could not be obtained under £50,000 per acre, the Commissioners of Her Majesty's Commissions of the Great Exhibition of 1851 were willing to dispose of their land on the Gore Estate for such a purpose at £10,000 per acre. In consequence of the great delay, the value of the land, it is asserted, has been increased, by the interest that has accrued through the land standing vacant so many years since that offer was made by one Government department to another.

The objection that was in former days raised against a site at South Kensington, as too uncentral a position for the convenience of a large portion of the inhabitants of London, is removed by the completion of the outer circle of the Underground Metropolitan Railway system, so that it is really more easily accessible to those in the outskirts of the metropolis than to those living in its centre, though the various means of access may be regarded as tolerably well equalised for all.

In 1860 Mr. Panizzi stated that the average number of visitors to the exhibited collections at the British Museum was considerably over 2,000 a day, and it may be noted that the average attendance at the International Exhibition of 1871 was over 8,000 daily. What would have been the number finding their way to South Kensington daily, had that Exhibition, as in the case of the British Museum, been open to the public gratuitously? The South Kensington Museum has also been visited by vast numbers of people.

2. *Classes that National Collections have to provide for.*—*First* for consideration are the working scientific and artistic students, who would consult the various specimens collected and arranged for their use, in the same way as the literary students avail themselves of the books in our public libraries, under suitable regulations; *secondly*, technical students, who by examination of the specimens and attendance at lectures and demonstrations, wish to make themselves practically acquainted with the materials they employ in their trades or professions; and *thirdly*, the mass of the public, who merely visit such museums to pass the time, and find amusement. Of the lower order of visitors, Dr. Gray says that on the public days and holidays they stream quickly through the rooms without evincing any intelligent interest in what is set before them. Of this type I recently came across a very fair example in the mineralogical gallery of the British Museum. A boy was attracted by the brilliancy and brightness of colour of the sulphur group. "What's these, mother?" he inquired of a woman whose rotund body and equally rotund basket indicated materialistic rather than scientific tendencies. "Them's curosites, my dear," she replied; and this probably is an average conception of a large portion of the wage class who do their "outing" at our public museums. On the other hand, Dr. Gray also testifies to the intelligence of hundreds who come from the north, east, and south of London, especially from Spitalfields, with specimens of eggs and insects to compare and name. With this class the collection of British zoology is the most popular in the Museum. Professor Maskelyne speaks of the intelligent observations he has heard made by men of the working class on specimens arranged in his department. Mr. Robert Hunt and Professor Huxley testify to the intelligence and attention of the working men who attended the evening lectures at the School of Mines, and the latter observes in his evidence given before the Committee on Public Institutions,* "Even in difficult arguments they follow the whole case, and show the most perfect possession of the facts, by the questions they ask at the end of each lecture." This class, it should be noted, prefer consulting specimens displayed to the public, and rarely like to trouble the keepers with a request to consult the unexhibited collections in the private studies. A great number of teachers bring their pupils to see the collections. The experiment of opening the Museum late on Saturday afternoon did not prove successful, the number of visitors only averaging 500, instead of 2,000, on that day, but this may have arisen through it not being so generally known that Saturday had been made a public day, as on Mondays it has been densely crowded by the wages classes.

3. *Distribution of the Collections.*—To meet the requirements of the three classes herein specified, we find a generally recognised conviction that the working or scientific naturalists could best be accommodated in private studies, where every facility should be given for examining, and in suitable cases handling, the preserved skins, preparations, osteological specimens, herbariæ, minerals, etc. These studies should also form the store-rooms for all specimens least suited for public exhibition that can be packed away with great economy of space in the drawers and trays of cabinets, or in store-boxes, and should be in immediate communication with such portion of the public galleries as may be devoted to the same class of objects, also with the rooms set apart for the keepers of that class. In the studies should be stored what may be called *author's types* (in contradistinction to the term *typical forms* and *typical species*): these are the absolute specimens employed by an author when describing in book or periodical the natural history characters of an object. Thus the fishes in Yarrell's collection at the British Museum are the author's types, as connected with his standard work on "British Fishes;" such types, Dr. Gray observes, "are neither intended nor adapted for exhibition." In the studies should be kept, in preference to a central library, all books of reference, memoirs, papers in periodicals, etc., connected with the class of objects to which such rooms are devoted. At the British Museum "the books cannot be brought to the specimens nor the specimens to the books." A scientific library may be useful without specimens, but not a collection of natural history specimens without books. Both Dr. Gray and the late Sir William Hooker testify to the advantage of working over show specimens for determining natural history characters. Thus unstuffed skins, disarticulated skeletons, and dried plants, may then be placed in the student's hands with little fear of injury, and in that condition occupy a minimum of space. Dr. Gray states that a collection of birds

* Parliamentary Papers, 1864, Vol. XXXII.

* Parliamentary Papers, 1860, Vol. XVI.

equal to that in the Avian Gallery of the British Museum (300 feet by 50), occupying wall-space equal to 13,500 feet, may be stored in boxes in a room having no greater area than 900 feet; that the collection of insects is kept in cabinets in a room having an area of 1,500 feet, but if displayed in table cases would require a superficial area of 65,000 feet; that the Cumming collection of shells, the most complete in the world, only occupied two small rooms in a private house, but if displayed, would require a gallery "quite as large as that in which the birds and shells of the Museum are at present exhibited."

The class of technical students is only represented in this country by those who have attached themselves to the School of Mines, though we have a Museum of Economic Botany at Kew, and the germ of a Museum of Technical Zoology in the Food Collection at South Kensington Museum. But this class requires something more than a museum: it needs a teaching staff also, and a separate existence from a purely Scientific National Museum of Natural History. As there are professors of chemistry, physics, applied mechanics, mechanical drawing, mineralogy, mining, metallurgy, and zoology, with suitable illustrative specimens, models, etc., might not the sphere of this establishment be extended, so as to include instruction on botany, together with technical botany and zoology? If it has been determined to remove the entire teaching staff of the School of Mines to the new "Science Schools" at South Kensington, why might not this extension of its original sphere of action be made at a time so favourable for re-organisation? The mutual proximity of the scientific and economic collections is an obvious advantage. Whether the technical illustrations of the Kew Museum should be removed to London is a question that ought to be calmly discussed in the mutual interests of technical students and botanists generally. The Food Museum in the South Kensington Museum is on the spot to be utilised to the greatest advantage by the professors of the Science Schools, or of the Technological Museum, under whatever authority it may be placed.

The third class for which the directors of a National Museum have to provide—viz., the general public—is that which requires the greatest consideration, as to the best means of silently conveying information on the general structure of natural objects, their place in the scheme of Nature, and the "life-history" of living forms, in the most attractive manner. This series ranging from the mineral to man would, together with the specimens kept in store in the studies, embrace the entire *classified collection of natural forms*, mineral, vegetable, or animal; but beyond this, there should be an *introductory collection*, which should include specimens, models, diagrams, etc., to illustrate the terms used in defining the external and internal characters, parts, and forms of minerals, plants, and animals, and those epitomes of the characteristics of the great divisions of the mineral, vegetable, and animal kingdoms that are known as "type forms," such as are defined in Huxley's "Introduction to the Classification of Animals," and Rolleston's "Animal Forms," both but recently published. At the present time the specimens in the British Museum are jumbled, vertebrates and invertebrates in the same room, as birds and shells, mammals and corals, reptiles and crustacea. With ample space at command all naturalists advocate a progressive series extending from the simplest inorganic crystal up to the highest organised animal—man, but that only a selected series need be exhibited publicly, which it has been the fashion to term a "typical collection;" but as Professor Owen very justly observes, "Those who are the loudest in advocating the restriction of exhibited specimens to 'types' have contributed least to lighten the difficulties of the practical curator in making the selection," and very pertinently raises the question as to what species should be selected as *the* "type" in various groups of the animal world he specifies. Others term what is aimed at as the "representative" system of arrangement. It is agreed that a national zoological collection should include the male, female, and young at one or more stages of maturity, the skeleton of the same, or parts thereof, winter and summer coats, plumage, eggs, nests, etc., of vertebrates, the metamorphic phases of invertebrates, every known variety of species obtainable (of vast importance in connection with Darwinian views), monstrosities, and distorted forms, etc.; but Professor Owen speaks of exhibiting only a portion of such treasures to public gaze, in which the curator must be guided "by the principle of selection." The fact is, the problem has never been worked out, as to what really is essential for public exhibition in a National Museum; but the change from Bloomsbury to South Kensington will give an opportunity for exercising the judgment of our practical curators, in determining what specimens, under what arrangement, would best represent in "Life-history Groups" our existing state of knowledge on natural history, and in such a manner as to make that other revelation of the Deity, "THE BOOK OF NATURE," written in stone tomes, on the leaves of plants and on the skins of animals, readable by the masses of the people.

TECHNICAL DRAWING.—LXIX.

DRAWING FOR BRICKLAYERS.

FLEMISH BOND.

FLEMISH bond implies brickwork so arranged that the bricks in every course present the appearance of a header and a stretcher alternately, from one end to the other, and in successive courses. Every header is placed over the centre of a stretcher below it. Closers are placed next to the corner headers in alternate courses in the manner and for the purpose already explained.

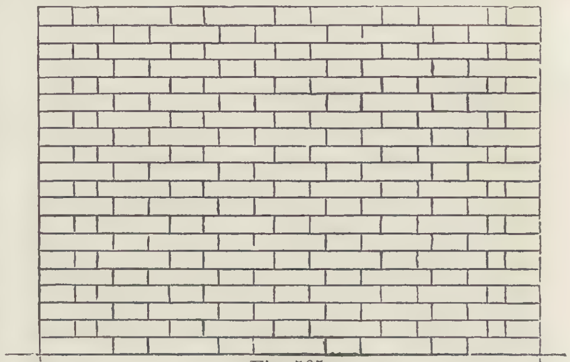

Fig. 565.

Fig. 566.

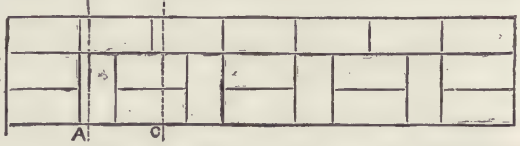
Fig. 567.

The appearance of a wall built in Flemish bond is therefore that shown in Fig. 565.

We again adopt as our illustration a portion of a wall equal

Fig. 570.

Fig. 571.



to seven bricks in length, one brick thick, and terminating with perpendicular ends. Figs. 566 and 567 are the plans of two successive courses of such a wall, and Figs. 568 and 569 are sections on the lines A B, C D.

It will be evident that in this wall both sides will be alike; but in walls of greater thickness two different arrangements may be adopted, called *single* and *double Flemish bond.*

SINGLE FLEMISH BOND.

In a wall built in what is called single Flemish bond, the bricks are so placed that whilst Flemish bond is seen on the

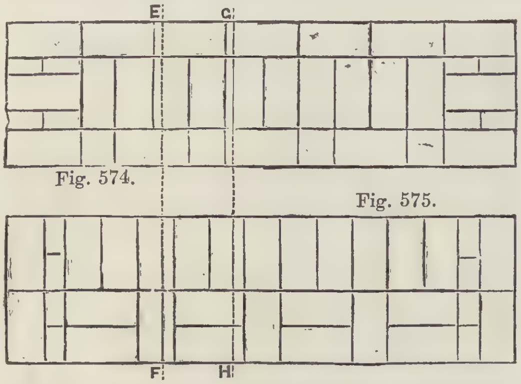


Fig. 574.

Fig. 575.

one side, the bond on the other is English, which arrangement is only applicable to walls of more than one brick in thickness.

In such cases the Flemish bond, as being considered the most pleasing, appears, of course, on the face of the wall, or external surface of the building, which is eventually the only side generally exposed to view.

Common single Flemish bond is merely a modification of

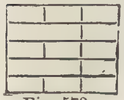

Fig. 573.

Fig. 572.

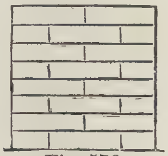

Fig. 576.

Fig. 577.

English bond, which may by some be considered more ornamental, but which is certainly not so strong.

As in English bond, there are in this method heading and stretching courses alternately; the stretching course consists merely in using bats or half bricks, instead of whole bricks, in every alternate course in the face of the wall, as shown in

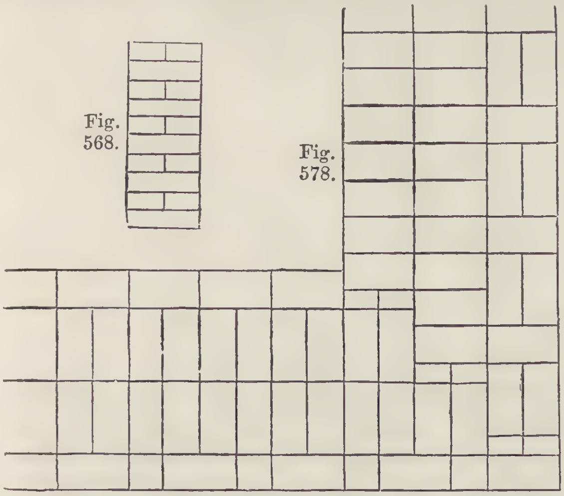

Fig. 568.

Fig. 578.

Fig. 570. In the heading courses real headers or whole bricks are used in the face of the wall, between which every stretcher is backed with a second brick also laid as a stretcher (Fig. 571). With this exception of using double stretchers in the heading courses, the same arrangement is followed as in English bond of filling up all the remainder of a thick wall with headers. The rule of not breaking the horizontal joints is also observed in this method.

Fig. 572 is the section on A B, and Fig. 573 the section on C D of the wall of which Figs. 570 and 571 are the plans of alternate courses, the wall represented being of a brick and a half in thickness.

Figs. 574 and 575 are plans of two successive courses of a wall of the same description, but two bricks thick.

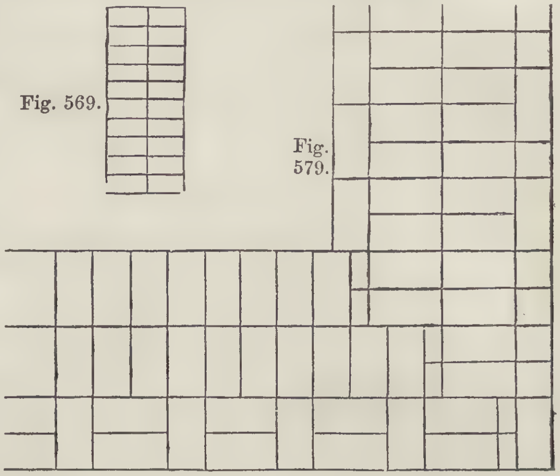

Fig. 569.

Fig. 579.

Fig. 576 is a section on E F, and Fig. 577 a section on G H.

Figs. 578 and 579 represent the plans of two successive courses of the corner of a house in which the walls are supposed to be three bricks thick, built according to the common single Flemish bond, and having the closers checkered in the usual manner.

SANITARY ENGINEERING.—XX.

MOULE'S PATENT EARTH-CLOSET SYSTEM.

In a series of preceding papers we have treated in some detail of the practical methods of dealing with sewerage where water is employed, and where a system of drainage is provided by means of which all soil, as it is specially designated, is washed away. In all these cases, as far as the immediate tenant or occupier of a house or cottage is concerned, the sewage, with its attendant value (no supposititious matter, but one which can be easily calculated and expressed in its equivalent of pounds, shillings, and pence), is removed from the premises by means of the drainage; and unless, under some of the more extended disinfecting processes recently introduced, the entire sewage of a hamlet, town, or borough is otherwise dealt with, the value of all these matters as manure runs to waste.

We have now to explain a totally different set of circumstances. In Moule's earth system water is not only not required, but the presence of more than a certain per-centage of moisture materially interferes with the efficient action of the process. Instead of water being employed to wash away, earth is employed to absorb and deodorise. Practical experience proves that it does this most thoroughly and effectually; and, therefore, the conditions under which a closet has to be constructed are totally different in detail to those given in our preceding papers. It has been ascertained by repeated experiments on an extended scale that about a pint and a half of dry earth thrown on to the surface of a vessel containing what is usually called an ordinary "dejection" is amply sufficient in quantity to absorb all noxious effluvia and ordinary gas products; and the objects of the special patent are the mechanical means adopted to apply this first principle efficiently in the necessary detail.

The dryness of the earth used and its absorbent qualities are the first requisite. Sand, especially of the description called

by architects and engineers "sharp," is useless, because it is non-absorbent; the sharper, in technical phrase, the sand is—the more fragments of quartz or comminuted flint it contains—the more its powers of absorption and deodorisation are diminished, and the less fit does it become for the special object under notice. Dry loam finely powdered, or dry clay in a similar condition, are the materials that should alone be used;

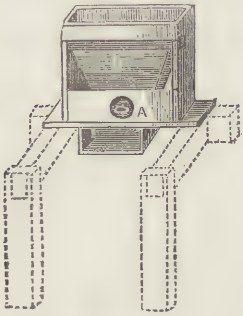

Fig. 30.

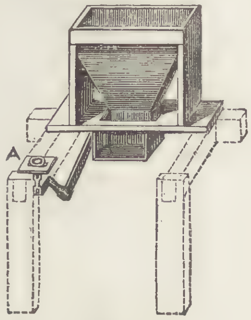

Fig. 31.

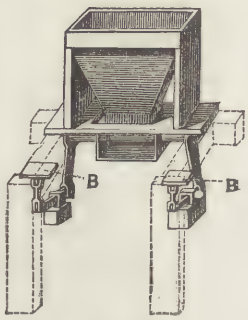

Fig. 32.

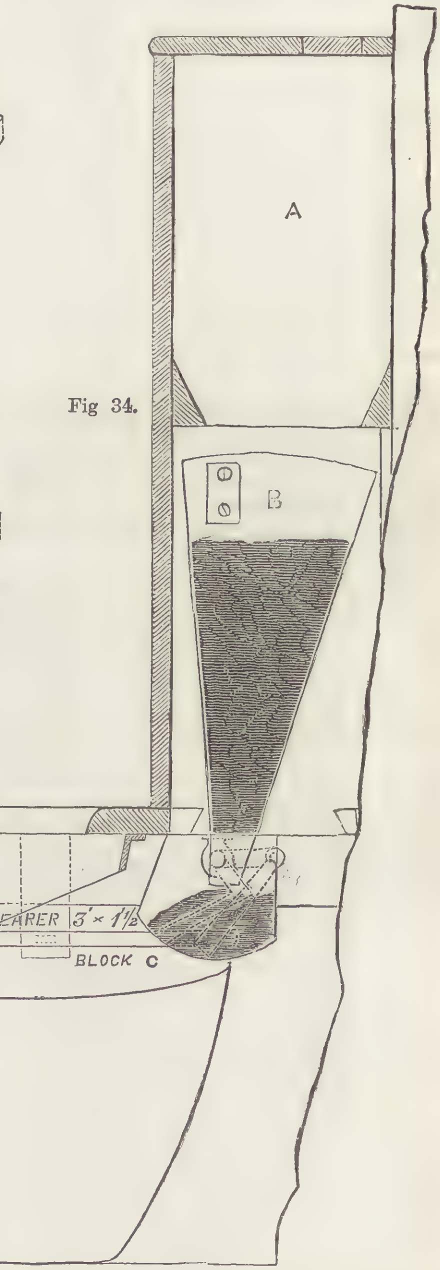
Fig 34.



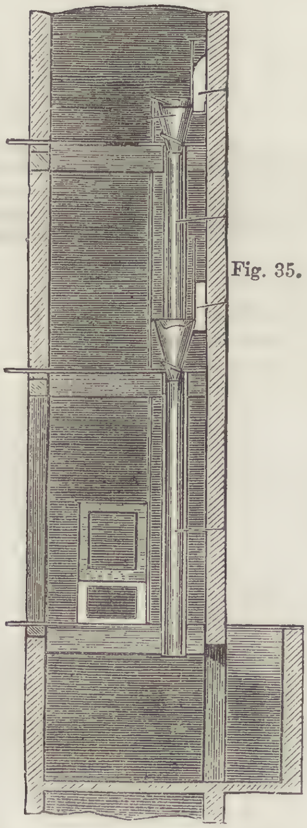


Fig. 35.

and there is this curious feature, that they may be re-dried after each operation, and this without any objectionable result, and when dried used again. This may be repeated continuously, even up to twelve or more times, each time considerably increasing the value of the material as a manure. In the sequel we intend to quote various figures from competent authorities as to the value of the result thus obtained.

The general principle of the patent thus explained—*i.e.*, the employment of earth as an absorbent in place of water as a diluent—we may proceed to say that the use of these closets is legalised by the new "Sanitary Amendment Act," of July 31st, 1868, and that, therefore, there is no statutory reason against their general introduction. It will be evident that in many situations where water is not easily procurable, or where the general arrangements for water-supply, as understood in our metropolitan and provincial towns, are incomplete, their introduction will be attended with advantage. In large and crowded city districts, where there is already a complete organisation under the present system, the same opening does not exist, and difficulties lie in the path of the extended introduction, not on the ground of any defect in the general principle adopted, but arising solely from the fact that the necessary facilities for the rapid removal and utilisation of the resulting products are not at hand.

For small towns, hamlets, and villages with deficient water-supply, of which there are so many throughout the country, the system may be safely recommended, as here not only do the

facilities exist for readily obtaining a supply of dry earth or loam at a moderate outlay, or no outlay at all, but the field for the utilisation of the products lies at the very door, in the garden or the field adjoining.

Having thus dealt with the general principle, we now proceed to detail. The outward appearance of the closet is in construction exactly in accordance with our usual habits; seat, riser, and lid may be taken as identical with those in every-day use; but here the resemblance ends. Instead of the almost endless system of pipes, the cistern, the traps, the valves, etc. etc., usually required, the only requisite is a vessel in the form of a hopper, made generally in galvanised iron, to contain the dry earth, which is the absorbing and deodorising agent. The subjoined sketches will show the form in which it is applied, and the various mechanical working details will now be explained.

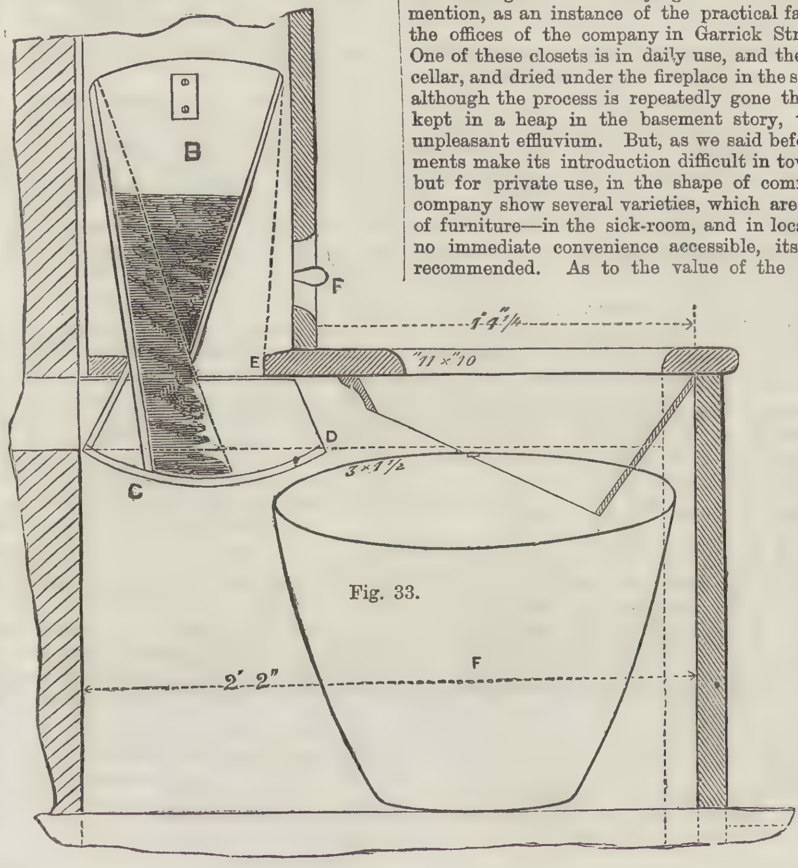

Fig. 33.

Fig. 30 represents the simplest form of closet of this description, showing the vibrating hopper, the handle that moves it, and the bearers that carry the seat and riser of an ordinary closet. The general arrangement, the space required, and the mechanical action, will be explained in some of the following cuts. A is the handle, by means of which the vibrating hopper, B, discharges the requisite volume of dry earth into the receiver below. In Fig. 31 the principle is the same, but instead of the direct pull from the handle the matter is so arranged that by means of a lever an action is obtained similar to that of an ordinary closet. The pull-up handle is at A. Fig. 32 is an adaptation of the same principle to a self-acting closet, as it is technically termed—*i.e.*, one in which, by the hinged action of the seat itself, by the simple weight of the body, the same result is obtained as by the simple handle (Fig. 30) and the pull-up action (Fig. 31). B, B are the plates attached to the seat, which, rising by a self-acting motion when relieved from weight, discharges the requisite quantity of dry mould by the methods we shall now describe.

In the section in Fig. 33, B shows the hopper containing the dry earth, with the handle, as shown in Fig. 30. When the handle is pulled the vibrating hopper is moved forward to the dotted line indicated by the point E, the bottom edge traversing the line from C to D, and discharging the certain quantity of loose earth into the receiver, F. On the handle being pushed back, a fresh charge of earth falls from the hopper, and it may be used again immediately.

We next give another arrangement of the same kind (Fig. 34), in which the vibration given to the hopper is only a quarter of an inch, with a view of loosening and shaking down the dry earth, the discharge into the receiver being made by the "chucker," as it is called, fixed at the lower mouth of the hopper. The shaded lines show the position of the earth when the closet is at rest, and the dotted line at point C indicates the extent of the motion of the chucker, which resembles in its action a hinged scoop. In this case an arrangement is also shown by which a fixed reservoir, A, is provided above the hopper, B, which can be filled with earth at stated intervals, thus keeping the hopper supplied.

Having, then, in the preceding remarks practically illustrated the matter in hand, we will now proceed to give one or two cautions as to the use of these closets.

1. The earth must be dry and sifted.
2. One charge must always be thrown into the receiver before use.
3. No slops must be thrown down.
4. In every case, either with pull or handle, or self-acting, the action should be given with a jerk, so as to throw the earth freely forward.

With regard to the drying of the earth after use, we may mention, as an instance of the practical facility of the process, the offices of the company in Garrick Street, Covent Garden. One of these closets is in daily use, and the earth is kept in the cellar, and dried under the fireplace in the show-room itself; and although the process is repeatedly gone through, and the earth kept in a heap in the basement story, there is no trace of unpleasant effluvium. But, as we said before, existing arrangements make its introduction difficult in towns on a large scale; but for private use, in the shape of commodes—of which the company show several varieties, which are really elegant pieces of furniture—in the sick-room, and in localities where there is no immediate convenience accessible, its use may be safely recommended. As to the value of the resulting manure in country districts, Mr. Gadsden, who farms 600 acres of land in the neighbourhood of Halton, "has no hesitation in estimating its minimum value at £3 per ton." Mr. Taylor, of Dorchester, a manufacturer of agricultural implements, and a manure merchant, supplies the earth for the closets and urinals of the Dorset County School, and he considers the value of the manure, when used but once in the closet, to be worth £2 to £3 per ton. He also considers that it increases in value in proportion to the number of times it passes through the closet. Similar opinions may be quoted in great numbers.

As instances of the practical use of the principle on a large scale, we may quote the Camp at Wimbledon, Broadmoor Criminal Lunatic Asylum, the County School at Dorchester, and many others. Under date 11th of July, 1867, the Government authorities of India write: "Not only has Mr. Moule's system been very generally adopted, but it has been found to be a public benefit of great value." Into the details of its application to urinals, public and private, slops, kitchen waste, and foul water generally, our space will not allow us to go. We conclude with an illustration (Fig. 35) showing how this principle can be adapted for use on different storeys and at different levels, and the products received in a vault in the basement. Our readers who are familiar with drawings will readily understand the illustration without our explaining the details.

For every and all situations, or to supersede our present method of flushing and water-supply, it would be Utopian to recommend the earth-closet system; but we may say, without hesitation, that under many conditions its introduction would be attended with manifest advantage to the public.

MINING AND QUARRYING.—XXIV.

BY GEORGE GLADSTONE, F.C.S.

LEAD.

SUPPLY OF ORE—GENERALLY ARGENTIFEROUS—GEOLOGICAL AND GEOGRAPHICAL DISTRIBUTION—AGE OF LEAD WORKINGS—CHARACTER OF LEAD VEINS—DRESSING THE ORES—ASSAYING.

In the mining and metallurgy of lead, Great Britain takes the first rank amongst the nations of the world, about one-half of the entire supply of this metal being the produce of the British Islands. While speaking of lead too, it is impossible to pass unnoticed the remarkable fact that silver, in greater or less quantity, is almost, if not always, associated with it; so that although silver mining as a distinct operation does not exist in this country, Britain ranks second only to Spain among the nations of the Old World in respect of the production of this precious metal.

It will be impossible, therefore, in speaking of lead, to avoid frequent reference to silver, though the writer will endeavour to keep the two subjects as distinct as possible.

It seems now to be conclusively established that gold also is always associated with lead, though in such small quantity as rarely to be worth consideration.

There is but one ore of lead which is of commercial importance, the sulphide (PbS), commonly called galena; and the metallurgic processes we shall describe will therefore relate to this ore alone, though many other combinations exist in Nature. The latter are interesting rather as mineralogical specimens: they never occur in England in sufficient quantity to render any special metallurgical processes necessary. The commonest of them is cerussite or lead spar, which is a carbonate of lead, forming large, transparent, and generally colourless crystals, or sometimes fibrous or earthy masses. The sulphate occurs in spots where the sulphide has been affected by the action of the weather, but where no carbonate of lime has been present to convert it into the preceding. The carbonate accordingly is generally found where the lodes of galena occur in the sedimentary limestone rocks, and the sulphate in the older argillaceous deposits. The phosphate and arsenate of lead are frequently associated near the outcrop of the lead veins.

Galena occurs in this country principally in the clay slates and limestones ranging from the Lower Silurian to the Carboniferous formation inclusive. The latter rock has hitherto supplied about two-thirds of the entire produce of the British Isles, though recently some very rich deposits have been opened up in the Lower Silurian rocks of Montgomeryshire and Cardiganshire. Thus the great lead district of the North of England, of which Alston Moor is about the centre, lies in the Carboniferous limestone; that of Derbyshire in the same. The long-wrought Welsh mines, which are also remarkably rich, are partly in the Carboniferous limestone and partly in the Lower Silurian slates; those of Devonshire and Cornwall are in the killas or clay slate of the Devonian age; those of Lanarkshire and Dumfriesshire in the same; those of the Isle of Man in Silurian limestones; whilst the Irish form an exception to the rule, and are chiefly in granitic rocks.

On the Continent there are large deposits in Germany, Sweden, Spain, France, and Greece. Some of those in the two former are, however, so remarkably rich in silver, that the mines are actually worked principally for the sake of the latter metal; the lead, though of course far greater in bulk, being, as it were, only a secondary product. A very large district in the United States of America is rich in lead ores, and as the population increases in that region (extending both westward and southward from Lake Michigan), the working of these is attracting increased attention; the day indeed is probably not far distant when the United States will be one of the largest lead-producing countries in the world.

The history of lead-mining in this country goes back to a remote antiquity. There is no question that lead was extensively worked by the Romans; reference to its abundance in Britain is not uncommon in their historical writings; many of the old workings are situated in districts which they occupied, and indubitable Roman remains have been found in them. Moreover, pigs of lead of Roman age have frequently been disinterred, and there is even strong evidence that the working of the lead mines has been continuous from that period till now, in the curious fact that the ancient pigs are of the same size and form, and bear the same distinguishing marks as those of the same district in the present day. Lead, too, was very extensively used by the Romans, and they seem to have been well acquainted with a variety of purposes to which it could be applied with advantage. Thus, in visiting the houses of the luxurious inhabitants of ancient Pompeii, the traveller will now find behind the elegant fresco paintings that adorn the walls of the reception-rooms, that a layer of sheet lead has been placed between the brickwork and the stucco to preserve the latter from damage by wet. In our metallurgical processes it is evident that we have considerably improved upon the ancients, so that the refuse slags from their furnaces are often found to be rich enough in metal to be re-smelted with advantage. Thus in some parts of Somersetshire where the ore is not worked now, there are smelting establishments for the sole purpose of using up the refuse from former works; and a considerable portion of the lead now manufactured in Spain and Greece is in like manner derived from what was thrown aside as valueless by the ancients.

The lead mines in this country are rarely of any great depth. Some of those in Northumberland, where the rock is liable to very great throws in consequence of the whin dykes which disturb that part of the country, are 600 feet deep, but they are generally much shallower. One or two of the mines in Devonshire are of considerable depth. On the Continent, however, there are several which are remarkable for their great depth. The Samson mine at Andreasberg, in the Harz district, for instance, is no less than 2,733 German feet deep, while several others in the immediate neighbourhood are of scarcely inferior depth.

The ore occurs in regular lodes, but these are often spread out into what are called flat veins. These are masses of lead ore which have penetrated from the lode itself between the bedding of the limestone; they never extend any great distance from the true lode, but often contain within a comparatively small space a large mass of metal. If a bed of sandstone should part two layers of limestone which is traversed by a metalliferous vein, the portion flanked by the sandstone will be found to be very much poorer in metal than that on either side of it. In Derbyshire and other places a lode is often cut off entirely for a space by the intrusion of a trappean rock; but unless the intruder forms too thick a mass to render it worth the expense, the miner will cut through it for the sake of reaching the lode again on the other side.

The veins of galena are of very various thickness; sometimes they are split up into parallel branches, connected by thin strings or leadings of ore; at other places, as at Hudgill Burn, there is a solid vein seventeen feet thick. The character of the lodes is very similar to those already described under tin and copper; except that the galena is not diffused through the gangue, as in the case of the former. The lead ore occurs in a massive crystalline form, associated with layers of sulphate of baryta (called cawk in Derbyshire), calcareous and fluor spar, in the Carboniferous rocks; and more commonly with quartz in the older formations. The fluor spar is especially prevalent in Derbyshire, and it is valuable in metallurgical operations as a flux.

The general direction of the lodes is east and west; though there are several notable exceptions. Thus at Holywell, in Flintshire, a very strong lode occurs in the cross course; and some of the rich silver-bearing lodes of the Isle of Man also run north and south. In Devonshire several lodes take the same direction, and at the point of intersection with the east and west veins they are usually highly argentiferous; they are rarely found to approach closely to the eruptive rocks as those of tin and copper do.

There are also some deposits of lead ores, principally a mixture of the sulphide and carbonate, not much worked in England, but to a considerable extent on the Continent, which are quite different in their character. They occur, too, in a rock of more recent formation, the New Red or Trias. The copper-bearing stratum of Alderley Edge, in Cheshire, contains particles of lead ore disseminated through it; and sandstones of the same age in other parts of the country present occasionally the same peculiarity. In Rhenish Prussia there occurs a very valuable deposit of a similar character. The sandstone bed is about 120 feet thick, but only some layers of this are sufficiently

permeated with the grains of galena to be worth excavating. In some places it is quarried, and in others the workings are carried underground. At Kommern alone upwards of 1,200,000 tons of the sandstone have been excavated in one year, yielding about 22,000 tons of dressed ore: it is argentiferous, though only yielding a low per-centage of silver.

Lead ore, on being brought to "grass," has to be dressed in order to prepare it for the smelting operations; and the processes which it has to undergo for this purpose bear, at some establishments, a considerable resemblance to those already detailed when describing the dressing of tin ores. It is first sorted and cleaned, in the course of which the lumps of foreign ingredients, spar, baryta, etc., are thrown aside; then it is crushed or ground to a coarse powder, which is usually done now by passing it between a pair of cylinders turning in opposite directions, and driven by water-power. The cylinders are fed with ore from a hopper above, into which the contents of the wagons are tipped as they are drawn from the mine: the hopper is subjected to a slight vibratory motion by the action of the machinery with which it is connected, and this is sufficient to keep up a constant supply of ore to the cylinders, and to prevent the aperture at the bottom of it from becoming clogged. A small stream of water also aids this process, and afterwards passing over the cylinders prevents them from becoming overheated. The latter are made of iron, and are case-hardened; they are not rigidly fixed in their place, so that if a piece of unusually hard material should get between them, the machinery shall not be brought to a standstill or become deranged; but the cylinders will yield place just sufficiently to allow such refractory piece to pass through. If the rock in which the ore is deposited be of a very hard nature, the use of stamps is generally resorted to, in place of the grinding process. The stuff is usually reduced by the crushing mills to a sufficient fineness to pass through a sieve containing nine holes to the square inch, which, when done by water-power, will not cost more than about 2½d. per ton.

After the ore has thus been crushed or ground, the washing takes place, which is performed by passing a stream of water through the ore, in the same way as the tin ores are separated from the earthy ingredients, a description of which will be found in Article XVI. In some foreign countries, especially in such as the Harz district, where the ores are so valuable on account of the silver contained in them, this operation is carried to a very high state of perfection, and the most improved forms of frames are employed; the ores too are there crushed much finer than is usual at English works, or is even thought desirable by our smelters. The very considerable specific gravity of pure galena, 7·6, enables the washers to separate not only the earthy portions, but also most of the metallic substances which may be associated with it: argentiferous ores require greater care in the washing, as the sulphide of silver is of less specific gravity than that of lead.

MINERS IN THE HARZ MOUNTAINS.

The ore being now ready for the smelter, the most ready mode of ascertaining the quantity of metal contained in it is to make the assay in an iron pot instead of an earthen crucible, the metal of the pot assisting in the separation of the sulphur from the ore. The sides of the pot should be about half an inch thick, and the bottom rather thicker still; it should be hammered out of a solid piece of iron, so as to have a smooth interior surface without any seams. Preparatory to charging it, the pot should be put in the furnace and heated to dull redness. It should then be removed from the fire for a moment, and filled with a mixture of ore and flux, the constituents and proportions of which will depend a good deal on the richness or otherwise of the ore to be assayed. Some recommend a mixture consisting of $\frac{4}{11}$ of ore, a similar quantity of carbonate of soda, $\frac{2}{11}$ of pearlash, and $\frac{1}{11}$ of bitartrate of potash, upon the top of which a little borax should be sprinkled. If a rich sample is being operated upon the mixture may consist of equal parts of ore and carbonate of soda, with a tenth part of argol; but for poorer samples, the carbonate of lead should be reduced by about one-third, and its weight replaced by borax. The pot must then be covered down, replaced in the furnace, and heated up to a full red. While at its full heat, the pot is removed from the fire, and the charge poured into an iron mould which has been rubbed over with plumbago and warmed; on cooling, a button of lead will be found at the bottom. The weight of this will give, by calculation, the per-centage of metal in the ore.

BUILDERS' QUANTITIES AND MEASUREMENTS.—XII.

BY E. WYNDHAM TARN, M.A.

In our last two papers on this subject we gave the measurement of dimensions of joiner's work and ironmonger's fittings throughout a small house consisting of a ground floor, first floor, and second floor: in the present paper we proceed to give the abstract of these dimensions. In the first part of our abstract, which appears in its entirety on this page, all the *superficial* work, or work of which superficial measurement is required, is brought together—namely, the floors, sashes and frames, doors, shutters, stairs, etc.; then measurements of skirtings, friezes, dresser-top, etc., which are regulated by the thickness of the deal of which they are made; and lastly, the various fittings which from their conspicuous position, or for appearance' sake, require to be made of mahogany. Following this we next take all the various parts of the fittings in deal and mahogany that are measured by the *run* without reference to length, breadth, or thickness; then we collect together all fittings measured by numbers; and lastly, the ironmongery and fixings. It will be manifest even on the most cursory inspection that the preparation of an abstract of dimensions is a piece of work which requires great care and attention, and as an item may readily be omitted where so many demand consideration, it is almost needless to remark that the work should be checked carefully. For the sake of practice, the student should take the dimensions given under each branch of the building trade in turn, prepare abstracts from them, and then compare those of his own making with the abstracts that we have furnished.

SEATS OF INDUSTRY.—XXVIII.

LIVERPOOL (*continued*).

BY WILLIAM WATT WEBSTER.

THE docks of Liverpool are the most extensive and convenient in the United Kingdom, and have been both an important cause and an important effect of its commercial prosperity. Mention has already been made of the first dock constructed at the port, in the beginning of the eighteenth century; but previous to that date efforts had been made to improve the navigation

of the Mersey, and the efficiency of the harbour of Liverpool. In 1694 Thomas Patten, of Warrington, widened the river, and made it navigable from Runcorn to Warrington. The old dock, which occupied an area of less than three and a-half acres, soon proved too small for the wants of the town, and was subsequently filled up; the new custom-house being built on its site.

In 1734 the Salthouse Dock was commenced, but it was only opened in 1753; and in 1761 an Act was obtained for building George's Dock, which was completed in 1771. Authority was obtained in 1784 for building two other docks, the King's and the Queen's; the former was opened in 1788, and the latter in 1796. The Prince's Dock, one of the largest on the Mersey, being 500 yards in length, and covering an area of nearly twelve acres, was completed in 1821. Since that date several enormous docks have been constructed; among others the Huskisson, which covers an area of 15 acres, 993 square yards; and the Brunswick, which has an area of above twelve acres; while the old docks have been improved and extended. Two new docks were finished in 1867. Liverpool now possesses about fifty docks and basins, extending along the margin of the river for about five miles; having nearly seventeen miles of quay space, and covering a total area of upwards of 700 acres, exclusive of the docks of Birkenhead on the opposite bank of the Mersey, which are four in number, including Wellesley Pool, which is considered the finest dock in the world. The docks of Liverpool were principally erected under the superintendence of Jesse Hartley, Esq., and are justly regarded as one of the great engineering triumphs of the century. Many of these docks are surrounded by spacious warehouses; those enclosing the Albert Dock, for instance, having cost £358,000, while the dock itself cost £141,000. An admirable feature of the Liverpool harbour consists in its two large floating landing-stages, one of which is 1,002 feet in length, 82 feet in width, and 4,500 tons in weight.

LIVERPOOL FROM THE MERSEY.

The completion of the Liverpool and Manchester Railway, which was opened in September, 1830, and cost £876,000—more than double the estimate laid before Parliament—marks an important stage in the progress of Liverpool. By an agreement entered into between the Bridgwater Canal Company and the Leeds and Liverpool Canal Company, the former acquired exclusive possession of the traffic between Liverpool and Manchester, although it was unable to forward the goods entrusted to it with the promptitude the trade required. Mr. Huskisson complained in the House of Commons that "cotton was sometimes detained a fortnight in Liverpool, while the Manchester manufacturers were obliged to suspend their labours; and goods manufactured at Manchester could not be transmitted in time, in consequence of the tardy conveyance." To remedy this grievance, an enterprising Liverpool merchant, named Mr. Sanders, in 1820 started a project for laying down a tramroad between the two towns, and he was soon joined by other merchants who were not interested in maintaining the monopoly of the canals. This scheme resulted in the Liverpool and Manchester Railway, which, however, had to contend against strong prejudice and powerful vested interests. Among the merchants who gave evidence before a Committee of the House of Commons in favour of the railway, in 1825, two deserve a place in this paper, because they exercised a potent influence on the trade and general well-being of Liverpool. One of these merchants was John Gladstone, the father of the present Prime Minister of England; and the other was William Brown, the founder of the Liverpool Free Library; of whom Cobden said in 1844, that he "held in his hands one-sixth part of the trade between this country and the United States." From the evidence of Mr. Gladstone we learn that

upwards of 10,000 vessels, with cargoes weighing in all 1,180,914 tons, entered the port of Liverpool in 1824; and that the dock dues, which amounted to £9,200 in 1787, when he settled in the town, had by 1824 increased to fifteen times that amount. The entire value of the goods received and shipped by Mr. Brown about this period amounted sometimes to £1,000,000 a year. There were then four lines of ships, sixteen in all, trading regularly between Liverpool and New York; and two lines, comprising eight ships, going to and from Philadelphia. The average value of the cargoes of these vessels was calculated at £50,000, but the goods they carried were in some instances worth three times that amount of money.

At the present time no less than four-fifths of the trade between the United States and Great Britain is carried on through Liverpool, as well as a large portion of the trade with South America and the West Indies; it also possesses a considerable share of the trade with the East Indies and China, although in the latter department Liverpool is surpassed by London. In 1864 the total number of vessels that entered the port amounted to 4,045, of which 2,898, with an aggregate of 1,372,203 tons burden, were British; and 1,147, representing a total burden of 498,292 tons, were foreign. From British colonies there arrived at the port in that year 1,127 British and 106 foreign vessels; while from foreign countries there came 1,771 British and 1,041 foreign vessels. The total value of the exports from Liverpool in 1864 was £72,748,031. In 1866 there belonged to the port 2,998 vessels, of which 2,569, of an aggregate burden of 1,326,317 tons, were sailing ships; and 429 were steamers, with an aggregate burden of 205,664 tons. The exports of the produce and manufactures of the United Kingdom from Liverpool, during that year, represented a total value of £87,486,497, against £41,449,797 from London; and 12,622 vessels, with an aggregate burden of 4,749,428 tons, entered the port. The importation of cattle and pigs into Great Britain from Ireland, which in 1866 amounted to upwards of £8,000,000, is carried on to a great extent through Liverpool.

For many years Liverpool has been the principal point of departure for emigrants from Great Britain and Ireland, and it is now the greatest port of emigration in the world. Large bodies of emigrants from Germany, and other parts of the Continent, find it cheaper to set sail from Liverpool for their various destinations, than from any port in their own countries. Steamers of large size, unrivalled speed, and with excellent accommodation for passengers, leave the harbour almost daily for New York, and other ports of the United States; and a magnificent fleet of steam-vessels, of unexampled magnitude, are engaged in trade with New York, Boston, Halifax, Rio de Janeiro, Buenos Ayres, Lima, Lisbon, Oporto, and the Mediterranean.

The manufactures of Liverpool consist chiefly of ship and boat building, cable and anchor casting; the construction of marine engines; and other branches of industry connected with the sea. Shipbuilding has declined during recent years, and Liverpool is now inferior in this respect to Sunderland, and to her great transatlantic rival, New York. The manufacture of soap is more extensively carried on in Liverpool than in any other town in the kingdom, and it is also one of the chief centres of the manufacture of chronometers, watches, and watch movements, of which latter large quantities are annually exported. In and near the town there are large distilleries of tar, turpentine, and whiskey; extensive rice and flour mills, saw mills, sugar refineries, cigar factories, roperies, and glass and alkali works.

Liverpool has nearly doubled its population every twenty years since the beginning of the present century. In 1861 its population numbered 443,938, and in 1871 it contained 493,346 inhabitants. Up to a recent date Liverpool consisted of narrow, irregular, ill-paved streets, lined with dull heavy-looking houses, and was regarded as one of the most unhealthy towns in England; but within the last forty or fifty years, and especially since the passing of the Local Sanitary Act of 1846, great improvements have been effected; and there are now few towns in Great Britain with wider, more handsome, and better-cleaned streets, and more substantial and sumptuous houses. In 1846 the water-supply, which before that date had been in the hands of private companies, who derived it from wells sunk into the red stone, was transferred to the Corporation at a cost of £554,807; and in the same year the latter obtained an Act authorising new works for the conveyance of water from a distance of twenty-six miles, which were opened in 1856, and cost £700,000. A new charter was granted to Liverpool by William III. in 1695, which was confirmed with a few emendations and additions by George II. and George III.; and by this charter the town was governed down to the passing of the Municipal Reform Act in 1835. By that measure the town was divided into sixteen wards, and placed under the government of a mayor, fifteen other aldermen, and forty-eight councillors. The parliamentary borough was enlarged by the Boundary Act, so as to include the out-townships of Everton, Kirkdale, West Derby, and Toxteth Park.

The principal public buildings in Liverpool are the Town Hall, St. George's Hall, the Exchange, and the Revenue Buildings. The Town Hall, founded in 1749, is an elegant Grecian structure; a handsome dome, supported by Corinthian pillars, and surrounded by an open gallery, rises from the centre of the building. The Exchange Buildings, which form three sides of the square enclosed by the Town Hall, were begun in 1803, and completed in 1809, at a cost of £110,840. In the centre of the square, a bronze statue of Nelson, designed by Wyatt, and executed by Sir R. Westmacott, was erected in 1813, at a cost of £9,000. The Revenue Buildings cover an area of 6,700 square yards, and comprise the office of the Inland Revenue, the office of the Commissioners of the Docks, and the Post Office. St. George's Hall is a sumptuous building in the Corinthian style; one portion of it is set aside for the Assize Courts, and the other for a concert-room, which is capable of accommodating an audience of 1,200.

There are about 150 churches and chapels in Liverpool; a third being connected with the Establishment, about 14 being Roman Catholic, 21 Presbyterian, 15 Independent, 16 Wesleyan, 2 Jewish, 1 German, and 1 Greek. Liverpool is provided with an unusual number of charitable and benevolent institutions, the most prominent being the Royal Infirmary, the Northern and Southern Hospitals, the Industrial Schools, and the Blue Coat Orphans' School. Among the principal educational, literary, and scientific institutions in the town, besides the Free Library and Museum, already incidentally mentioned, we may note the Botanic and Zoological Gardens, the Observatory, for which a new building was erected at Bidston in 1865, the Collegiate Institution, Queen's College, the Medical Institution, the Royal Institution, the Mechanics' Institution, the Society of the Fine Arts, the Academy of Fine Arts, the Egyptian Museum, and the Exchange, Lyceum, and Athenæum News-rooms and Libraries. Liverpool has several good theatres and concert-rooms, and in addition to the Botanic Gardens it has another fine park at Toxteth. Mrs. Hemans, William Roscoe, and Dr. Currie, the biographer of Burns, are among the most celebrated natives of the town.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXX.—TYCHO BRAHE.

BY JAMES GRANT.

THIS celebrated astronomer was born on the 14th of December, 1546, during the reign of Gustavus I. of Sweden, at Knudstrop, in the county of Schonen, near Helsingborg. When seven years old he was taught Latin; and for five years studied under private tutors. On the death of his father—an event which occurred when Tycho was very young—he was adopted by his uncle George Brahe, who, in 1559, sent him to study rhetoric at Copenhagen. The great eclipse of the sun, which occurred on the 21st of August in the following year, seems to have greatly impressed his mind, as it happened at the precise time astronomers had foretold it; hence, he began to consider astronomy as something divine, and purchasing the tables of Stadius, by studying them he rapidly gained some idea of the planetary system.

In 1562 young Brahe was sent by his uncle to Leipzig to study law, and there, by his acquirements, he manifested indications of wonderful talent. His natural inclinations, however, were not legal; he disliked the dry study of law, and preferred that of the heavenly bodies, and to the latter he applied himself so assiduously, that notwithstanding the injunctions of his uncle or the care of his tutor, to keep him close at the studies for which he had come to Leipzig, he attained a great knowledge of astro-

nomy. With what he could save from his pocket-money he purchased every book he could meet with on that subject, and read them with attention and enthusiasm, procuring ultimately, in cases that puzzled him, the assistance of his private tutor, Bartholomew Schultens. After a time, having procured a small celestial globe, he took opportunities, when Schultens was in bed, and when the weather was clear, to examine the constellations in the heavens, to learn their names from the globe, and their motions from observation.

Returning to Denmark in 1571, his studies and assiduity won him the favour of his maternal uncle, Steno Billes, who, being a lover of learning, gave him a convenient place at his castle of Herritzvad, near Knudstrop, for the erection of a building wherein to continue his observations and have a laboratory. Brahe built another observatory at Wandsbeck near Hamburg, when residing with the Count Rantzau. This edifice is still standing, and a bust of him is placed in one of the upper rooms. But it was at Knudstrop that, in 1572, he discovered a new star in the constellation Cassiopeia. Soon after this, having married a pretty peasant girl far beneath his rank, a quarrel ensued between him and his relations, and it was of a nature so violent that the king, then Frederick II., had to interpose his authority ere a reconciliation could be effected.

By command of the latter, in the following year he began to lecture at Copenhagen on the planetary system; and in 1575 he began his travels, and passing through Germany proceeded as far as Venice, where Luigi Mocenigo, under whom the famous battle of Lepanto was won, reigned as Doge.

Aware that he was coldly viewed by his relations in consequence of his marriage, he resolved to settle at Basle in Switzerland with his wife and children; but King Frederick, loth to lose a man so capable of doing honour alike to Denmark and to Sweden, promised, with a discriminating generosity that did him honour, to bestow upon him for life the island of Huen, in the Sound, between Copenhagen and Landscrona, and usually called by seamen, in those days, the Scarlet Isle. It was very fertile, and is seven miles in circumference. Frederick did more, for, however intolerant in religious matters, he was ever bountiful to the learned: he bestowed upon Tycho Brahe a pension of 2,000 crowns out of his treasury, a fee in Norway, and a canonry in the Cathedral of Roskilde which brought him a thousand more.

In the course of four years Brahe had built in the centre of his island the handsome castle of Uraniburg, which had many splendid apartments; and therein he had an observatory and all his books, mathematical and astronomical instruments. Adjoining it he erected a mill for making paper, a printing house, and laboratories for chemical investigations; but his favourite place for studying the stars was at Stellenburg, an edifice which he erected westward of the castle expressly for the purpose of an observatory. The rest of the isle he laid out in gardens, with fish-ponds, and in every way made it one of the most charming places in Denmark.

There Brahe resided for twenty years, pursuing his astronomical observations with remarkable industry. In these he was usually assisted by ten or twelve intelligent students, whom his generosity inspired him to provide for and keep about him, and whom he instructed in mathematics and astronomy.

In 1589 he received a visit from James VI. of Scotland, who was accompanied by his Lord Chancellor and many Scottish nobles. The king had recently been married at Upsala to the Princess Anne of Denmark, and though the limit of his stay in that country was to have been only twenty days, it extended to six months. James made Brahe many noble presents, and wrote some Latin verses in his praise; and the Scottish Chancellor (afterwards Lord Thirlstone), who had some pretensions to literature in his time, became intimate with him, and spent much of his time at Huen during the winter of 1589.

Brahe's tranquillity, his domestic happiness, and his studies, were all now fated to be destroyed. Soon after the death of his royal patron Frederick, he fell a victim to the envy and malignity of the ministry; they aspersed him to Christian IV., who in 1596 stripped him of his pension, his fee in Norway, and his canonry. He was then compelled to quit his favourite isle, which was bestowed upon a mistress of the king, and she, in a spirit of mere wantonness, is recorded to have destroyed all his works and buildings.

With his reduced household Brahe now took up his residence in Copenhagen, and with some of his instruments continued his astronomical observations and chemical experiments, until the same malevolence that drove him from Huen procured from Christian IV. an edict to discontinue even these.

Compelled now to leave Copenhagen, the unfortunate Brahe conceived the idea of seeking an introduction to Rodolph II., Emperor of Germany, who was fond of mathematics, mechanics, and chemical experiments—an amiable monarch, who, according to Voltaire, knew everything but the art of government. To pave the way for an interview, Brahe published his carefully-prepared "Astronomiæ instauratæ Mechanica," illustrated with plates, and dedicated it to the Emperor, who thereupon invited him to Prague. Thither Brahe repaired, and was received with the utmost honour by Rodolph, who assigned him a magnificent house, with a pension of 3,000 crowns, and the promise of a permanent fee for himself and his sons. With the latter and his students—among whom was the celebrated Kepler—he settled, in the latter end of 1598, in the Bohemian capital, where he built an observatory, the site of which is now occupied by the mansion of a noble family.

Tycho Brahe had the vulgar weakness, incident to his age, of giving credit to judicial astrology; but this superstition did not render him the less an astronomer, or the less able in mechanics. "His fate," says Voltaire, "was the same with other great men; he was persecuted in his own country after the death of the king his protector; but he found a noble patron in the Emperor Rodolph, who made him ample amends for all his losses, and for the injustice of courtiers."

The famous astronomical tables of Brahe and Kepler bear the emperor's name, being called the Rodolphine Tables, just as those which were made in Spain by two learned Arabs in the twelfth century bore the name of king Alphonso. Brahe did not long enjoy the new ease and affluence which surrounded him, as he died at Prague on the 4th of October, 1601, in his fifty-fifth year.

The apparatus of Brahe was purchased by the Emperor for 20,000 crowns; it remained, however, useless and concealed till the troubles of Bohemia ensued, when the army of the Elector Palatine plundered the city, and in a spirit of barbarism broke his instruments to pieces, and applied the brass and other metals to uses for which they never were designed. His great celestial globe of polished brass was, however, happily preserved and deposited with the Jesuits at Naysia in Silesia, from whence it was afterwards taken, in the year 1633, and placed in the hall of the Royal Academy at Copenhagen.

The family of the great astronomer is still in existence, and has been considered one of the oldest and noblest in Sweden. The present possessor of their great and antique château of Skugkloster, which was built in 1630 by Gustavus Wrangel, one of the most celebrated generals of the Thirty Years' War, is a lineal descendant of Tycho Brahe, and likewise of Count Brahe, who led the centre of the Swedish army at the battle of Lützen, in 1632. The château came to the Brahe family by marriage with that of Wrangel, and there is carefully preserved a portrait of the astronomer, and of the beautiful Ebba Brahe, to whom Gustavus Adolphus was so tenderly attached, and whom he would have made Queen of Sweden, but for the schemes of his mother, who married her by fraud or force to Count Jacques de la Gardie.

SHIP-BUILDING.—XIII.

BY W. H. WHITE,

Fellow of the Royal School of Naval Architecture, and Member of the Institution of Naval Architects.

THE SKINS OF IRON SHIPS (*continued*).

The plates forming the skin of an iron ship are secured to each other and to the frames by means of numerous closely-spaced rivets. These fastenings are made of superior qualities of iron, and are formed (as shown in Fig. 41) by means of rivet-making machines, some of which are most ingeniously constructed. The holes through which they pass are generally punched in the plates and frame angle-irons, and in the outer plates they are afterwards enlarged conically, or "countersunk," as shown in Figs. 39 and 40. The rivets are heated before being put in place, and when driven through from the inside a heavy hammer or "dolly" is held against the

head, while workmen outside beat down the point into the countersunk hole; to make good work, the rivet when cool should fill the hole. In cooling it is sure to contract somewhat, and a common rule for ensuring a good fit afterwards is to form the countersink as illustrated on the upper rivet in Fig. 39. The centre, A, of the hole on the inner surface of the plating is joined with the sides of the hole near the common surface, and these dotted lines produced form the sides of the countersink. This rule is, however, often departed from. When "knocked down," the point of the rivet is sometimes made slightly convex beyond the surface of the plate, as in Fig. 39; and in other cases is made flush, as in Fig. 40. Different builders have their own practice on such unimportant matters.

Punching the rivet-holes has been much objected to, on the ground that the plates are weakened thereby, and that it is difficult to ensure the exact correspondence of the holes in overlapping plates and frames. Efficiency in the fastenings obviously depends greatly upon such correspondence being obtained, so that the rivets may pass fairly through the holes; and with care it can be obtained, even when the holes are punched. The other objection to punching, its weakening effect, is not so easily removed, and it has led to the suggestion of drilling instead of punching. As the application of drilling machinery to iron ship-building has not yet been carried far, the much greater cheapness and rapidity of work rendered possible by punching has enabled that operation to keep its place. Should drilling machines be improved, however, so as to enable them to be used economically, it is probable that they will, to a great extent, displace punching, at least in the larger ship-yards; and if steel comes into general use this change is all the more likely to take place, as that material appears to suffer much more from punching than iron does. It is a good plan with steel, if the holes are punched, to anneal the plates afterwards, as the injury done by punching is then greatly lessened.

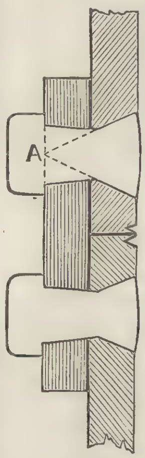

Fig. 39.

Punched holes are not exactly cylindrical like drilled holes, but are a little larger at the side which is most distant from the punch when it is made to press upon the plate, so that the holes are slightly conical, as shown in Figs. 39 and 40; and in making rivets a conical enlargement is formed under the heads to fit them (as in Fig. 41). On this account care ought always to be taken to punch the holes *from the faying surfaces* of plates; that is to say, from the outer surface of the laps of inside strakes, and the *inner* surface of the laps of outside strakes. When this precaution is taken, and the rivets are put in, their sections within the limits of the two plates resemble two truncated cones with a common smaller end. Hence, if by any corrosive action, or other cause, the rivet-heads should be worn away, the rivets would still hold the plates firmly together; whereas if the holes in the inner plates were punched from the inside surface, the rivets would have no holding power independently of the heads. There are many other matters of practical interest in connection with riveting, to which we hope to refer in another paper; but we must now proceed to describe the ordinary methods of arranging the fastenings in the edges and butts.

It may fairly be assumed that the in-and-out plan of plating need only be considered in this connection; and we shall then have to deal with lap-joints for the edges and with flush-joints at the butts. The edges are either "single" or "double" fastened. Single fastening is illustrated in Fig. 42, and is so simple as to require no explanation. Double fastening may be either "zigzag" as in Fig. 43, or "chain" as in Fig. 44. The latter arrangement is the more recent, and is now more frequently used, its chief advantages probably being the uniformity of spacing and the clearness from the butts which it permits in the edge-rivets. On the zigzag plan it will be noticed that a rivet comes directly in the butt, and that long spaces occur in one of the rows of rivets where the frames cross the plates; although this is sometimes obviated by placing two edge-rivets in each frame, it is more usual to follow the arrangement of Fig. 43. In the iron-clad ships of the navy, double chain riveting is always employed for the edges of the bottom plates. In merchant ships a similar plan is usually followed for at least the thicker plating; but when plates of $\frac{1}{2}$-inch or $\frac{3}{8}$-inch in thickness are employed, single-edge fastening is thought sufficient. And there can be little doubt that so far as the strength of the edge-connection alone is concerned, single riveting would answer every purpose; the use of a double row of rivets adding, of course, to the strength, but being rendered advantageous rather by its effectual "closing" of the lap-joint. Thick plates, being much less flexible than thinner plates, of course require more edge-fastening in order to secure the close contact so desirable in water-tight joints. This latter consideration practically regulates the spacing of the rivets in the edges, the "pitch" of which—or their distance from centre to centre—should lie between $3\frac{1}{2}$ and $4\frac{1}{2}$ times their diameter if the joint is to be made properly tight. The breadths of laps required are for single riveting from $3\frac{1}{4}$ to $3\frac{1}{2}$ diameters, and for double riveting from $5\frac{1}{2}$ to 6 diameters of the rivets. To caulk a lap-joint (such as in Fig. 40), it is first necessary to notch the edge of the plate with a suitable tool, and to drive the "burr" thus formed close against the inner plate. This simple operation is found to answer every requirement.

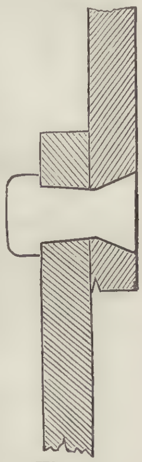

Fig. 40.

The plates are fastened to the frames by rivets spaced from 7 to 9 diameters apart from centre to centre, except in wake of transverse water-tight bulkheads, where the pitch is made about one-half as great, and other special methods are adopted, which will be explained hereafter. The edge-rivets in wake of the frames have to pass through three thicknesses, and more than usual care is required in order to secure good holes for them. On this account it is usual to leave the holes in the frames in way of the laps or "lands" of the plating, unpunched until the plates are fixed, and then to drill them, or else to "bore" them out with a sort of portable punching machine. All the other rivet-holes would be punched in the frame angle-irons before they are put in place, and they should be punched before the frame angle-irons are bent, in order to make thoroughly good work.

Turning now to the fastenings of the butts, we meet with much greater variety and difficulty. At present our remarks will be confined to a description of the principal plans that have been used, and in a future paper we shall attempt to show what are the true principles on which all arrangements of butt-fastenings should be based. Figs. 42—47 illustrate the chief methods adopted, and in each of them the vertical line drawn midway between the frames shows the butt of the plating, the boundaries of the internal butt-strap being shown in dotted lines. In each case also a sectional view is given showing the relative positions of the butted plates, the butt-strap, and the adjacent strakes of plating.

Fig. 42 shows a single-riveted butt of an outer or raised strake; the butt-strap proper being fitted between the edges of the adjacent sunk strakes, and two short supplementary straps, or fish-plates, being fitted over the joints of the strap and the sunk strakes. So far as the arrangement of the riveting is concerned, it will suffice to say that builders are scarcely ever content with single-butt fastenings, and that Lloyd's Rules only permit their use for the thin side plating of poops, forecastles, bulwarks, etc. Single riveting has, however, been used in very many cases, and Mr. Scott Russell has employed it in vessels built on the longitudinal system. It can only give sufficient strength against tensile strains, however, when associated with a good frame-space and a shift of butts giving a large number of passing strakes between consecutive butts; and even when this is the case a practical difficulty is raised on the ground that the butt is not efficiently closed and supported when single riveting only is employed. Respecting the other features of the plan, the use of fish-plates and a butt-strap, it must be stated that they were based upon the belief that it was necessary to strap the butt for the whole breadth of the strake, and that the fish-plates, besides doing this, helped to make the butt water-tight.

Fig. 41.

Another attempt in this direction is illustrated by the section

in Fig. 43, where the strap is actually forged in such a manner as to overlay the whole breadth of the butted plate. This was obviously a very expensive plan, and, as well as the preceding one, was not at all necessary, for every purpose is now found to be served by simply fitting the straps to the outside strakes between the edges of the inside or sunken strakes, as shown in the section in Fig. 44. With inside strakes it is, of course, easy to make the straps extend across the full breadth of the butted plates, and this is commonly done as shown in the sections of Figs. 45—47.

Reverting to Fig. 43, we have an example of a "double zigzag" butt-fastening, such as was formerly very generally employed, but has now given place, to a great extent, to "double chain" riveting like that shown in Fig. 44. Chain riveting is considered to be rather stronger than zigzag, and is now much from the butt. Sometimes, and more commonly, only the outer row of rivets on each side of the butt is thus treated. In either case the object of the plan is either to distribute the fastenings well, or to secure the butt with a greater number of rivets than could be worked in if double chain riveting were used. The spacing of the rows of rivets nearest the butt must, of course, be as close as before—*i.e.*, from $3\frac{1}{2}$ to $4\frac{1}{2}$ diameters—in order to allow of the butt being caulked.

The operation of caulking a butt-joint is illustrated in Fig. 39. Notches have to be cut with suitable tools in the abutting edges of each of the plates, and the burr so formed is carefully beaten into the joint to make it water-tight. Considerable advantages are gained by having the butts flush-jointed, both as regards the resistance offered to the ship's passage through the water, and the development of the strength of the plating. The

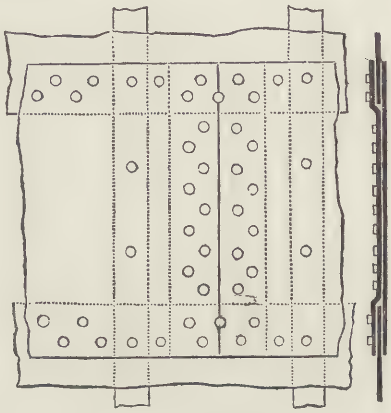

Fig. 43.

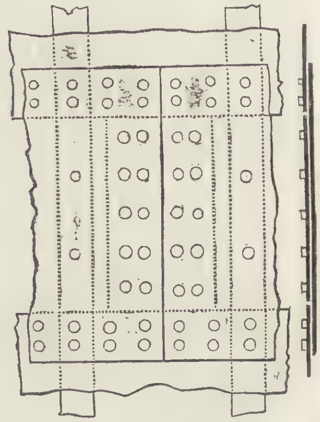

Fig. 44.

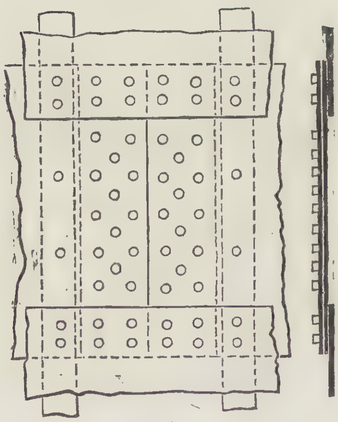

Fig. 45.

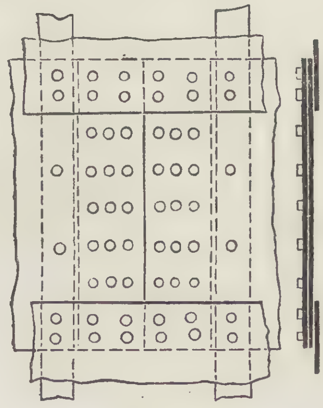

Fig. 46.

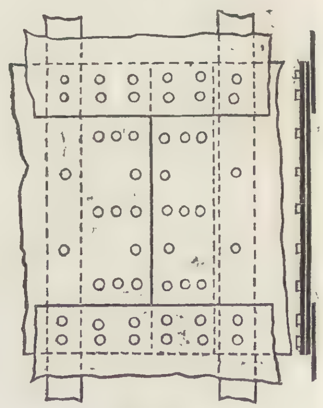

Fig. 47.

used in merchant ships, while it is exclusively employed in the ships of the Royal Navy. In fact, the general arrangement of fastenings in the bottom plating of the latter would be fairly illustrated by Fig. 44.

An example of a treble zigzag riveted butt is shown in Fig. 45, and one of treble chain riveting in Fig. 46. The former is but rarely used; and the latter, although it has been strongly advocated by some high authorities, has not been much employed. Sheer-strakes, middle-line keel-plates, and a few other longitudinal pieces, are almost the only cases in which treble chain riveting is adopted; but one or two builders have even gone so far as to use quadruple chain riveting in securing the butts of the sheer-strakes in vessels of unusual length. This seems quite unnecessary, however, and double chain riveting, associated with a good shift of butts, can be made to answer all essential requirements in fastening the butts of the outside plating. In Fig. 47 a plan not often used is illustrated, and will be seen to differ from that in Fig. 46, in having the alternate rivets left out in the two rows on each side most distant necessity for fitting the butt-joints closely was not formerly recognised by iron ship-builders, but now it is generally admitted; and either by planing or chipping the desired object is attained in well-built iron ships.

Butt-straps are usually of about the same thickness as the plates they connect, in some cases being $\frac{1}{16}$ of an inch thicker, in others $\frac{1}{16}$ thinner, and in others again of equal thickness with the plates. The fibre of the iron in the straps should always run in the same direction as that in the plates; so that the straps should be cut off the ends of plates. Their breadths vary with the character of the fastenings. For single riveting the total breadth of butt-strap would be from $6\frac{1}{2}$ to 7 times the diameter of the rivets, for double riveting from 11 to 12 times, and for treble riveting from 17 to 18 times. In both edge and butt fastenings it is a rule to have at least a space as great as the diameter of the rivets between the edge of the plate or strap and the row of holes nearest to it; and when there are two or more rows of rivets, the practice is to allow a distance varying from $1\frac{1}{4}$ to $1\frac{1}{2}$ times diameter between adjacent rows.

FISH CULTURE.—IX.

By Greville Fennell.

DISTINCTIVE CHARACTERISTICS OF SALMONIDÆ, ETC.

Yarrell tells us with truth that of the species of *Salmonidæ* existing in this country the characters and distinctions admit of considerable detail. Too much reliance has been placed upon colour, without resorting sufficiently to those external indications founded on organic structure which may with greater certainty be depended upon.

In the scale of the relative value of parts affording characters for distinction, the organs of digestion, respiration, and motion are admitted by systematic authors to hold high rank; and in the hope to induce sportsmen to become zoologists—so far, at least, as to enable them to determine the various species they may meet with by a reference to those external characters which are the most important—the specific distinctions in the genus *Salmo* will be illustrated by referring to the number and situation of the teeth, the form of the different parts of the gill-covers, and the size, form, and relative situation of the fins.

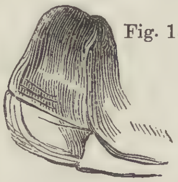

Fig. 18.

Fig. 16.

Fig. 17.

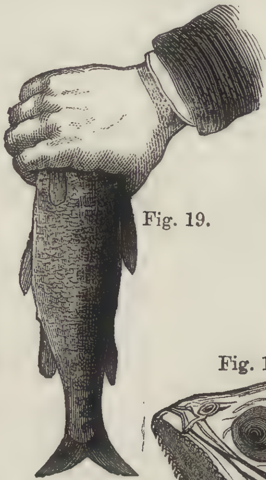

Fig. 19.

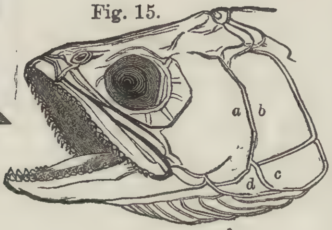
Fig. 14.

Figs. 14 and 15 here introduced represent a front view of the mouth and a side view of the head of the common trout. In the first of these illustrations (Fig. 14) *a* marks the situation of the rows of teeth that are fixed on the central bone of the roof of the mouth, called the vomer; *b*, *b* refer to the teeth on the right and left palatine bones, and the row of teeth outside each palatine bone on the upper jaw are those of the superior maxillary bones; *c* refers to the row of hooked teeth on each side of the tongue, outside of which are the lower jawbones. The trout is chosen, as showing the most complete series of teeth among the *Salmonidæ*; and the value of the arrangement, as instruments for seizure and prehension, arises from the interposition of the different rows, the four lines of teeth on the lower surface alternating, when the mouth is closed, with the five rows on the upper surface, those on the vomer shutting in between the two rows on the tongue, etc.

Fig. 15.



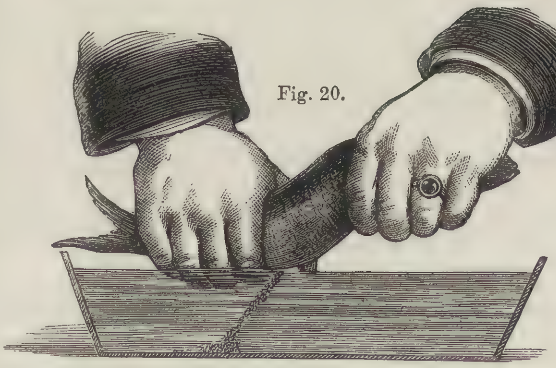


Fig. 20.

Fig. 15 represents, in outline, a side view of the head, of which *a* is the pre-operculum, *b* the operculum, *c* the sub-operculum, *d* the inter-operculum, *e* the branchiostegous rays; the four last parts together forming the movable gill-covers. The different fins are sufficiently indicated by being coupled, when referred to, with the name of the part of the body of the fish to which they are attached.

The external appearance of the adult salmon during the summer months, when it is caught in the estuaries of our large rivers, is too well known to require much description. The upper part of the head and back is dark bluish-black; the sides lighter; the belly silvery white; the dorsal, pectoral, and caudal fins dusky black; the ventral fin white on the outer side, tinged more or less with dusky on the inner surface; the anal fin white; the small soft fleshy fin on the back, without rays, called the adipose fat fin, or the second dorsal fin, is of the same colour nearly as the part of the back from which it emanates. There are mostly a few dark spots dispersed over that part of the body which is above the lateral line, and the females usually exhibit a greater number of these spots than the males.

These colours, differing but little, are, however, in a great degree common at the same period of the year to the three species that are the most numerous, as well as the most valuable, namely, the true salmon, the bull trout, and the sea or salmon trout, which are also further distinguished from the other species of the genus *Salmo* by their seasonal habit of moving from the pure fresh water to the brackish water, and thence to the sea, and back to the fresh water again at particular periods of the year. Further specific distinctions are therefore necessary, and those that will be pointed out as existing constantly in these species will, it is hoped, enable observers to identify not only each of these, but also the other species of the genus at any age or season.

The three illustrations on the left hand—viz., Figs. 16, 17, and 18—represent the form of the different parts of the gill-cover in the three species we have just named. Of these Fig. 16 is that of the salmon, Fig. 17 is the gill-cover of the bull trout, and Fig. 18 is the gill-cover of the sea or salmon trout. The differences are immediately apparent when thus brought into comparison.

In the salmon the posterior free edge of the gill-cover, as shown in Fig. 16, forms part of a circle; the lower margin of the sub-operculum is a line directed obliquely upwards and backwards; the line of the union of the sub-operculum with the operculum is also oblique, and parallel with the lower margin of the sub-operculum; the inter-operculum is narrow vertically, and its union with the operculum is considerably above the line of the junction between the sub-operculum and the operculum. The teeth of the salmon are short, stout, pointed and recurved. As stated in the generic characters, they occupy five situations at the top of the mouth—that is, a line of teeth on each side of the upper jaw, a line on each palatine bone, with a few only on the vomer between the palatine bone; the teeth on the vomer seldom exceeding two in number, sometimes only one, and that placed at the most anterior part. There are teeth extending along the vomer, as in the salmon trout, and more particularly so in some of those trout that do not migrate.

The inner surface of the pectoral fin is in part dusky; the tail being very much forked when young; but the central caudal rays growing up, the tail is much less forked the second year, and by the fourth year it has become nearly or quite square at the end.

It may be remarked here that, looking at the form of the three gill-covers, it will be obvious that a line drawn from the front teeth of the upper jaw to the longest backward projecting portion of the gill-cover in either species will occupy a different situation in respect to the eye; that the line will fall nearest the centre of the eye in the first, that of the salmon, and farther below it in the second, that of the bull trout.

The importance of these distinctions will be readily granted by the British reader, but far more so by the colonist, as it is now an ascertained fact that in Tasmania the flattering notion had long existed that salmon introduced from English ova were plentiful in their due season in the Derwent. This delusion has, however, recently been dispelled, the supposed salmon having been proved, after the above tests, to be trout, although trout of a very fine character. In order in future to obviate an error of this nature, Mr. Youell, to whom so much is due for the introduction of *Salmonidæ* in the Tasmanian river Derwent, and from thence to many other rivers, has caused casts to be made of the true salmon and trout, which, having been coloured from and to the life by the celebrated fish-painter, Mr. H. Leonidas Rolfe, have been forwarded to these colonies for general reference. Those, however, who would study similar casts, and much more of the greatest value, should pay a visit to the Fish Department of Mr. Frank Buckland at the Kensington Museum; and, if on a Saturday, that gentleman will cheerfully and lucidly explain a variety of circumstances in the history of fish culture which, if they do not induce the listener to follow out the pursuit in practice, will add no little to his wonder and admiration of the works of God.

Figs. 19 and 20 show the method of handling a trout of 1 to 3 lb. weight, and extracting the ova from a fish of from 3 to 5 lb. weight. We have already detailed the necessary process of manipulating a salmon of a much larger size.

We may observe that roach and dace are always heavier and fatter in those waters in which the well-known external parasite of the pike abounds. Upon one occasion our fisherman, Harry Christal, was fishing most fruitlessly for roach in the Colne at West Drayton, with the customary baits of gentles, worms, and paste, when by accident he impaled upon his hook one of these parasites, with which he was induced to fish, and caught in a short time three roach with that one specimen so accidentally captured. Hence the feasible suggestion that the entomologist and the botanist shall assist pisciculture by ascertaining the kinds of living creatures and plants on which fish thrive most, and by pointing out how they may be introduced into localities where naturally they are not found. The bottom of Loch Leven is in some places covered with a peculiar weed, sheltering various insects, chiefly crustaceæ, and small snails of various sorts; the lake also abounds in the more minute entomostracæ. Large quantities of both are found in the stomachs of the trout. This fact induced Mr. D. Esdaile ("The Rural Dean"), when consulted as to stocking a certain water with this prized trout, insisting upon the ova being accompanied by a quantity of the weeds and small stones to which the favourite food of the fish would adhere. In this respect Mr. Esdaile exhibited a proper discretion; not so another would-be benefactor to a stream in Hampshire, who brought up at some expense many bushels of the small snail of the lakes, which, while they lasted, fed the fish, but which themselves had not a chance of propagation for the want of the plant upon which they fed and propagated.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXXI.—MATTHEW BOULTON, F.R.S.

BY JAMES GRANT.

Matthew Boulton, whose happy improvements in mechanics rendered many important services to his country, and whose name is intimately connected with that of James Watt and the progress of the steam-engine, was the son of Matthew Boulton, by Christian, daughter of Mr. Peers, of Chester, and was born at Birmingham on the 3rd of September, 1728. He was principally educated at the private grammar school of the Rev. Mr. Ansted, who officiated at St. John's Chapel, Deritend, and was taught drawing by Worledge, and mathematics by Cooper. When he attained manhood, we are told that "he was above the middle stature and well built; he was exceedingly disposed to encourage modest merit, and was fascinating in his manner and conversation."

In his native town, Birmingham—then consisting of little more than thirty streets, though celebrated for the manufacture of leather seven hundred years ago, and for that of coarse iron articles previous to the Revolution—he established himself as a manufacturer, and invented and brought to great perfection, about the year 1745, inlaid steel buckles, buttons, watch-chains, etc. Of these great quantities were exported to France, where they were purchased "with avidity by the English, as the offspring of *French ingenuity*."

His manufactory at Birmingham soon became inadequate to his extensive improvements and many experiments; and in the year 1762 he took a lease of Soho, near Handsworth, in the county of Stafford. Two miles distant from the city, it was at that time a barren heath, with a little eminence on the bleak summit of which stood one solitary hut, the abode of a warrener. By the year 1765, Mr. Boulton had converted this place into the site of his superb manufactory, at the expense of £9,000; and in the year 1794 he purchased the fee-simple of Soho, and much of the adjacent land.

Inspired by patriotic ambition and a desire to encourage home art and manufacture, he established at Soho a seminary for draughtsmen and modellers, seeking men who were talented, and whom he rewarded liberally. This soon led to his establishing successfully an extensive manufactory for ornaments in what is called *ormolu;* and these ornaments not only found their way into the royal apartments at Windsor and St. James's, but to those of all persons of rank and taste in most parts of Europe.

On discovering that the mill which he had erected fell infinitely short, as a force, even with the aid of several horses, of that which he required to complete the great works he had in view, he had recourse in 1767 to the steam-engine, which was yet in its infancy, and did not at first answer the expectations that had been formed of it; and yet, if we are to believe Dr. Darwin and Aikin, the idea of such a power is much older than the days of the Marquis of Worcester or of James Watt, as the former asserts that Hiero of Alexandria, who flourished a hundred years *before Christ*, had "an application of the force of steam to produce a rotative motion by the reaction of steam issuing from a sphere mounted upon an axis, through two small tubes, bent into tangents, and issuing from the opposite sides of the equatorial diameter of the sphere—the sphere being supplied with steam by a pipe communicating with a pan of boiling water, and entering at one of its poles;" while the latter in the first volume of his *Athenæum*, under the title of "Omnia," asserts that Pope Sylvester II. had clocks and organs which were worked by steam about the end of the tenth century; and M. Delescluze about thirty years ago made a discovery among the MSS. of Leonardo da Vinci, that carries a knowledge of the steam-engine back to the fifteenth century, in the design for a *steam-gun* called an architonnerre, or "an invention of Archimedes."

In 1769 James Watt, of Glasgow, as related in his memoir, had obtained a patent for improvements in the steam-engine, which induced Mr. Boulton to invite him to Soho, and also to settle there, to which he consented. In 1775 Parliament granted a prolongation of the patent for twenty-five years to the Messrs. Boulton and Watt, who, on becoming partners, established at Soho an extensive manufactory for these engines, from whence they were sent to the greatest mines, manufactories, and other works in England; and among the various applications of steam, that for coining was of considerable importance, as one engine, managed by a few boys of from twelve to fourteen years, worked a number of coining machines with greater success and exactness, than could be done by the same number of able-bodied artizans, without endangering their fingers, as the machine itself laid the blanks upon the die, perfectly concentral with it, and when struck displaced one pair to replace it by another. The coining mill, which was constructed in 1788, was greatly improved, and by the end of the century was adapted to work eight machines, each of which was capable of striking from 60 to 100 coins, of the guinea size, per minute, or equal to between 30,000 and 40,000 per hour. If such a coining mill had been erected in the Royal Mint, says Shaw in

his "History of Staffordshire," it would in cases of emergency be able to coin all the bullion in the Bank of England, without the necessity, which then existed, of putting Spanish dollars and other foreign coin in circulation. At the Soho mill, the same blow which struck the face and reverse, also formed the edge, whether milled, plain, or with an inscription, as in the case of crown-pieces.

"The whole of this magnificent and expensive apparatus (says Dr. Darwin) moves with such superior excellence and cheapness of workmanship, as well as with works of such powerful machinery, as must totally prevent clandestine imitations, and in consequence (as coiners were then hanged) save many lives from the hand of the executioner. If a civic crown was given in Rome for preserving the life of one citizen, Mr. Boulton should be crowned with a garland of oak."

In 1773 the ingenious method of copying pictures in oil-colours by a mechanical process had been invented at the Soho works, under the patronage of the proprietors; and, like oleography, was brought to such perfection as to make its productions be taken in some instances for the originals. The art was brought to perfection under the management of Mr. F. Eginton, who was also celebrated as a painter on glass; as stated in our paper on James Watt (Vol. II., page 139), the art of sun-painting by daguerreotype was not unknown to Messrs. Boulton and Watt.

The former, in 1788, struck with the coining machine a gold piece of the old guinea size, as a pattern, the letters of which were indented instead of being in relief, while the head and other devices were protected from wear by a flat border; and from the perfect rotundity of form, etc., with the aid of a steel gauge, it could with ease and certainty, by its specific gravity, be distinguished from any base metal. And previous to Messrs. Boulton and Watt's engagement to supply Government with copper coins, in order to bring their apparatus to greater perfection, they had exercised it in coining silver for Sierra Leone and the African Company, and copper for Bermuda and the East India Company.

Many of the beautiful medals presented, about that time, to distinguished officers in both services, were from time to time struck at the Soho works.

On the accession of the Russian Emperor Paul I., Mr. Boulton presented him with some of the most interesting articles of their manufacture, and in return, received—from that unfortunate monarch, who perished by violence—a letter of thanks and approbation, together with a splendid collection of medals, specimens of all the modern money of Russia, and of many minerals from Siberia. Among the medals was a massive golden one, bearing the head of Paul. This piece, the beauty of which is said to have been unrivalled, was struck from a die engraved for the then Empress, who from her youth had taken a great delight in the arts, particularly that of engraving on steel.

With a view to still further improving and facilitating the construction of steam-engines, Boulton and Watt, in conjunction with their sons, established a foundry at Smethwick, a village in Staffordshire, three miles from Birmingham, and intersected by the canal. There the powerful agent, which had already done so much, was employed to reproduce and multiply itself; and the engines, which were there fabricated with wonderful regularity, neatness, and expedition, were forwarded to all parts of the kingdom by the Birmingham Canal, which, by means of a wet dock, communicated with the foundry.

Thus, in a national point of view, the undertakings of Matthew Boulton were in an eminent degree highly valuable and important. By collecting around him draughtsmen and artists of various descriptions, rival talents were stimulated or called into existence, and successive competition multiplied to an extent greatly beneficial to the public; while that which before had been a barren heath was covered with objects of industry, with population and plenty. The Soho works alone covered many acres, and by the time the patent expired, and Watt withdrew from them, with an ample fortune, they afforded employment for more than 6,000 persons.

Prior to this the firm had become involved in a quarrel with the famous inventor of the patent lock, Joseph Bramah, whose irritation broke out fiercely in the evidence given by him in the case of Boulton and Watt *versus* Hornblower and Maberly, which was tried in December, 1796; and on being silenced by the judge, Bramah revenged himself in a pamphlet entitled "A Letter to the Right Hon. Sir James Eyre, Lord Chief Justice of the Common Pleas," etc.

In 1809 the apparatus for *first* supplying the city of Glasgow with gas—then a wonder of the age—was prepared by Boulton and Watt, and fitted at Anderston, a suburb one mile distant from the city cross; and the whole, we are told in a print of the time, "constitutes a very pleasing exhibition. Two iron retorts of a semi-cylindrical form, each capable of containing one cwt. of coal, yield at every charge 750 cubic feet of gas, which, after being washed so as to deprive it of any disagreeable smell, is conducted into a large cubical plate-iron gasometer, of a capacity equal to 1,120 feet. The gas evolved by the regular process of carbonisation, during the day, is herein stored up for use. From this magazine, which floats in a water cistern, a main-pipe issues, which afterwards branches into innumerable ramifications, some of them extending several hundred feet under ground; thence to emerge, diffusing over a multitude of apartments a kind of artificial day, so vivid is the illumination. The flame, however, though exceedingly bright, is very soft and steady, and free from that dazzling glare which has been so greatly complained of in the otherwise beautiful light of the argand lamps." Such was the simple account of this new mode of illumination, which brought the peasantry in from the Campsie Hills and the Renfrew villages, to throng the streets, and gaze at as a new marvel, and which even Sir Walter Scott had ridiculed as a wild idea of lighting cities with smoke!

"No trouble attends this beautiful illumination," adds the memoir read before the Philosophical Society of Glasgow in 1810; "the occasional attendance of one man in the gas-house to charge the retorts and mend the fire being all that is necessary; *and no trimming or snuffing are required.*"

No expense had been spared to render his own works handsome and uniform in architecture, as well as neat and commodious; and the taste with which Mr. Boulton adorned the gardens and laid out the pleasure-grounds, rendered his residence at Soho both pleasant and picturesque; and there he died in the year 1809. He was not only a member of the Royal Societies of London and Edinburgh, but likewise of that which bears the title of the Free and Economical at St. Petersburg, and of many other foreign scientific institutions.

"To comment upon the private character of a gentleman in Mr. Boulton's situation (says the *Scots Magazine*, for the year subsequent to his death) would be a useless task: we shall therefore only observe that, as his great and expanded mind formed and brought to perfection the wonderful works he produced, so he felt no greater felicity than that of diffusing happiness around him. For a long time previous to his decease he had been confined to his room by illness, and his dissolution daily expected. His memory will ever remain dear to the British nation, whose glory was advanced in proportion to his own fame. While we commemorate those great men who have sought their country's honour in the fields of war, we ought not to omit paying a just tribute to those who have promoted arts, industry, and commerce, and diffused plenty and comfort throughout the realm, by cultivating science and applying it to the arts of peace."

Playfair, in speaking of Mr. Boulton, describes him as "a man of address, delighting in society, active, and mixing with people of all ranks with great freedom and without ceremony." James Watt also spoke of his partner in the highest terms, ascribing to his friendly encouragement, his partiality for scientific improvements, and his ready application of them to the purposes of art, his intimate knowledge of business and manufactures, his extended views and liberal spirit, most of the success that attended his own exertions.

THE LATHE.—IX.

By Henry Northcott.

SLIDE-REST APPLIED TO SIMPLE LATHE—SMALL FOOT-LATHE.

Fig. 28 shows the application of another form of the slide-rest to a simple lathe. This slide-rest has a surface-slide next the lathe-bed, and the slide and centre line of bed are kept at right angles, so that with the driving head-stock in its usual position, the motion of the surface-slide will always tend to produce a plane surface upon the face-plate of the lathe.

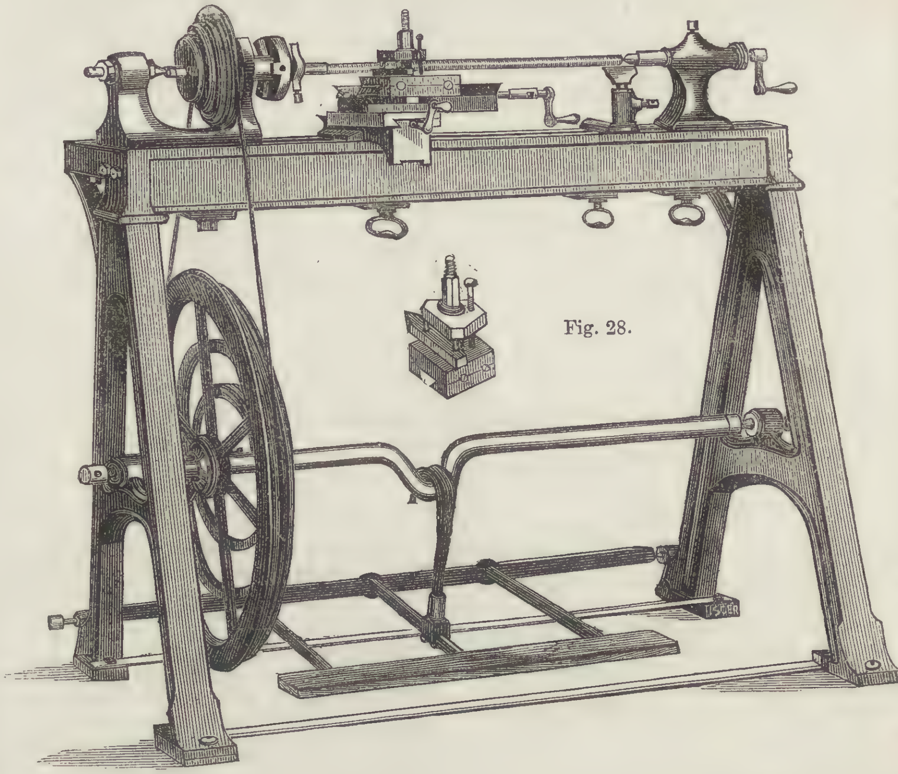

Fig. 28.

The traverse-slide is placed upon the surface-slide with the usual angular motion between the two. The traverse-slide, it will be observed, has a long motion, and this is a very desirable feature in all slide-rests applied to hand-lathes, as a good length of cut can be taken with one setting of the slide-rest; whereas if the slide be short, as is too generally the case, it becomes necessary, when turning up a long shaft, to frequently move the slide-rest along the lathe-bed into a new position. In slide-lathes or lathes in which the rest itself is moved along the lathe-bed to form the traverse-slide, it is quite unnecessary to have a long traverse-slide upon the rest; and, indeed, a long slide would be rather an incumbrance than otherwise. It must not be forgotten, in constructing or choosing a slide-rest, that the longer a slide projects out over the supporting-slide or lathe-bed, the stiffer and stronger it must be to resist a given depth of cut. The present example errs probably on the safe side in respect of weight of metal, but it is better to have too much metal in a slide than too little. A slide-rest, and, indeed, the whole of a lathe, has not only to be strong enough to resist fracture from the strains to which they are subjected, but every part ought to be strong enough to withstand these strains without springing or yielding in the slightest degree. This necessitates a great deal of metal, and unless the designer be very careful in placing it by correctly proportioning every part, lathes and most machine tools are caused to look unnecessarily heavy and clumsy. If the tool, from any cause, does not keep firmly in contact with its cut, the effect is most unsatisfactory and annoying. A most disagreeable noise is generally produced, and the surface of the work is found to be very rough and uneven. But want of metal is not the only cause of unsteadiness in a slide-rest. No quantity of iron will produce a good slide-rest unless the fit of the various sliding parts be everywhere close, and the workmanship of every part accurate. A great deal also depends upon the position of the tool with respect to the rest and to its cut, and as much upon the shape and condition of the cutting-edge of the tool, especially if the slide-rest be rather weak or unsteady. A good tool-holder also, as before mentioned, is very necessary; and, in the rest at Fig. 28 the holder is of this quality. It is of the triangular plate variety, as in a previous example, but the working out is much more mechanical. There is the central bolt which is very strong, and is furnished wit

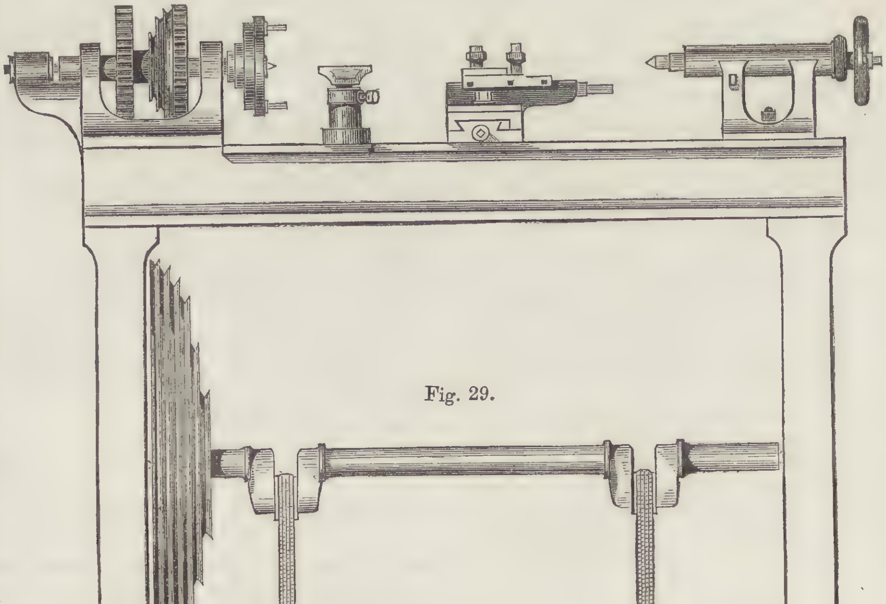

Fig. 29.

a well-fitting screw-nut. The length of the nut is unusually great as compared with the diameter, as the threads are subjected to a considerable amount of pressure and wear. The triangular plate has only one other screw through it, and this acts as a support to the third angle of the plate, and is adjustable to different thicknesses of tool, as in the previous example. At the two other corners of the plate are two knobs or projections made of hard steel, whose function it is to bear upon the tool which is placed underneath them. The two points are tightened down upon the tool by turning the nut upon the central spindle, and the tool is by this means firmly and securely held to its cut in any required position upon the tool-plate, as the triangular plate may be shifted anywhere around the central bolt. Altogether, this may be considered a fair specimen of the slide-

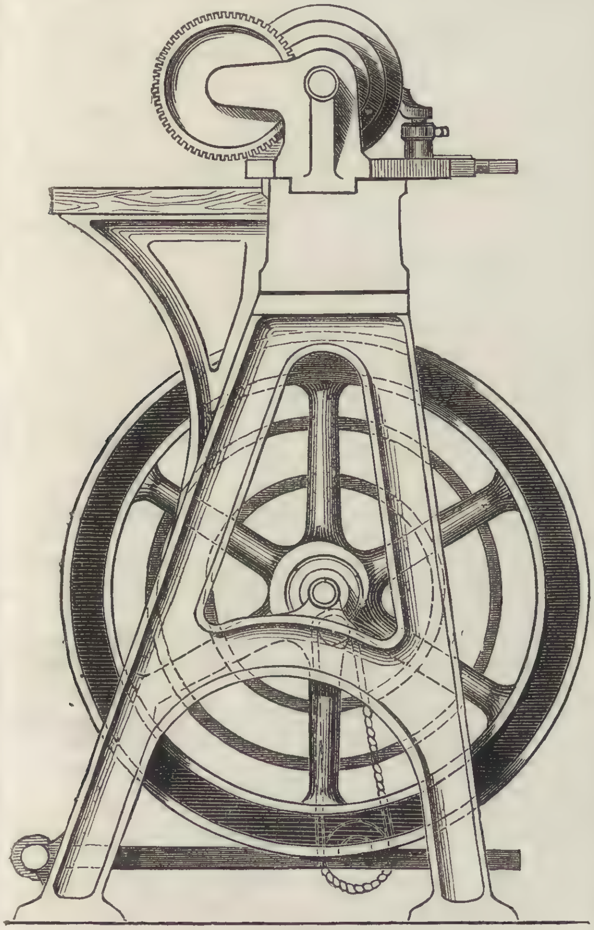

Fig. 30.

rest as usually applied to a hand-lathe. The illustration was engraved from a photograph taken from a lathe made by Mr. Munro, of Lambeth.

Fig. 29 is a front elevation, and Fig. 30 an end elevation of a small foot-lathe for hand-turning, but with slide-rest attached, as made by Sir Joseph Whitworth and Co., of Manchester. The lathe is driven by a treadle through two cranks, and the treadle and cranks are connected by two chains instead of the usual links. The chains pass over the crank-pins and around pulleys attached to the treadle-lever, as will be seen by the illustrations. The chains have a slow rolling movement when the treadle is in motion, and the friction is somewhat lessened by their use. Sometimes leather belts are used instead of chains; the former give perhaps a little more elasticity and a somewhat pleasanter motion when treading, but it would be difficult to say that one mode of connection has any substantial advantage over the other.

The crank-shaft is hung between centres, and the grooved cone-pulley has a set of four grooves for the fast speed and two slow-speed grooves in addition. The cone-pulley is made very heavy, so as to act as a fly-wheel, and carry the crank around against a heavy cut. The double gearing is of the usual kind, in which the wheels are slid into and out of contact with each other. The end pressure caused by screwing up the centres against work between them, and in other ways, is taken by a back-centre shown at the extreme left hand of the head-stock, and this, when practicable, is no doubt the best arrangement, as the thrust is direct, and the back-centre is easily adjusted to take off any pressure from the bearing-collars. In some cases, such as when change-wheels have to be placed upon the end of the lathe-spindle, the position of this back support becomes somewhat inconvenient, and it is sometimes expedient to receive the end thrust or back pressure upon the collars of the spindle-bearing. But in these cases the friction is certainly greater than when a proper back-centre is employed, as in the present example.

The spindle-nose carries a double or Clement's driver, and this looks rather heavy for the lathe-spindle. It may be questioned whether an ordinary driving-plate with a single arm would not do quite as well as the one shown in place, besides being considerably lighter. Both the hand tool-rest and the slide-rest are shown in position on the lathe-bed. The former is of the usual variety, as will be seen from the illustration. The slide-rest is an excellent one, and it would be difficult to find any fault either with its arrangement, proportions, or workmanship. The drawings will sufficiently explain its construction.

The screw head-stock has the internal screw and socket, the action of which has been already shown, and a sectional drawing of it given.

A bracket projects from each of the standards carrying the lathe-bed, and upon the two is placed a wooden shelf, which is very convenient for receiving the various tools, etc., that happen to be in use, and keeping them within easy reach of the operator.

Altogether, this lathe is an excellent example of a light hand-tool lathe, and the slide-rest is especially good; and in bringing our description of it to a close, it is needless to say that the workmanship of every part is first-rate.

BUILDERS' QUANTITIES AND MEASUREMENTS.—XIII.

BY E. WYNDHAM TARN, M.A.

PLASTERING.

The work of the plasterer belongs both to the outside and the inside of buildings. When any part of the outside of a building is covered with a coating of cement or stucco, this is executed by the plasterer. The internal work of the plasterer consists in covering the walls, ceilings, and partitions with a facing of plaster, adding ornaments, mouldings, cornices, etc., as may be required. Plaster or cement floors are also executed by this workman, and also the pugging on the sound-boarding which the carpenter has laid between the joists. White-washing or lime colouring to ceilings or walls belongs also to this trade.

For outside work or stucco there are a variety of different materials used, as well as modes of applying them. Rough casting, which is plaster sprinkled over with lime and small stones; rendering with blue lias lime mixed with sand; rendering with Roman or Portland cement, either neat or gauged with sand, plain or jointed to imitate stone. In measuring cement work, take all the surface that is coated with stucco in superficial feet, bringing into yards in the abstract; deduct all openings, state how many coats are used, and the proportion of sand to cement. Facias, pilasters, reveals, etc., are taken by the foot superficial; all mouldings are taken the girt by the running length, and the area in superficial feet entered in the bill. Arris edges, beads, quirks, $4\frac{1}{2}$ in. reveals, etc., are taken by the foot-run. All mitres, blocks, brackets, consoles, pateras, ornaments, etc., are numbered. Dubbing-out with tiles, in order to get an extra thickness or projection, is measured by the foot superficial, unless for a narrow string-course, when it is taken

by the run. The colouring of cement work, if not done with oil paint, is taken with the plasterer's work, by the superficial yard.

Stucco upon walls that are circular on plan is measured one and a-half times the girt by the height, and the area added to the plain work.

Panelled work is usually measured by taking the round of the panel as square arris, or moulding, describing the girt of the moulding.

No allowance is made for the scaffolding used in executing the stucco to outside walls of new buildings; but if it is done to old walls the scaffolding must be charged, when erected for the purpose of doing the work. In rendering old walls, the joints are raked out, and the walls axed, which is stated in the measurement, the work being taken as before by the superficial yard.

Cement floors are measured by the superficial yard, describing the proportions of sand and cement; but small works, such as hearths, coating cisterns, etc., are taken by the foot superficial.

In measuring the internal plastering to walls, take the round of the room by the height from floor to ceiling, if there are neither skirting grounds nor cornice, but if both, then by the height from the top of the grounds to half way up the cornice; this will be brought into superficial yards and described, rendering one coat, render and set if two coats, render float and set if three coats. Take the run of quirks to beaded angle-staffs. If, however, any part of the walls of the room is formed by a quarter partition, it must be measured separately from the brick or stone walls, and taken as lath and plaster—one, two, or three coats, as the case may be; and the same is the case if the walls are battened out for the plastering.

The ceilings are measured the length by the width from wall to wall if there is no cornice, and brought into superficial yards, as lath render one, two, or three coats. When there is a cornice, deduct its width once in each dimension, or take the area half-way across the cornice. Take the girt of the cornice by the length, and bring into superficial feet; number the mitres, ornaments, pateras, centre flowers, etc.; take the run of all continuous enrichments, and describe their girt. For very lofty rooms an extra price is charged for the use of scaffolding.

Friezes, soffits, raised or sunk panels are taken by the foot superficial, running the moulding or arris of the panels, and numbering the mitres.

Coves to cornices are measured separately from the moulding, the length by the girt, and brought into superficial feet.

Various cements are used for the internal finishings, the walls being either first rendered with common plaster, or with a rough coating of cement and sand, before the finishing coat is given. The measuring is similar to that above given for ordinary plaster, the quality of the cement work and number of coats being described. Skirting in cement, arrises, quirks to staff angle-beads, narrow mouldings, beads, enrichments, etc., are taken by the foot-run. Work in panels, pilasters, shafts, friezes, mouldings, cornices, etc., is measured by the foot superficial.

In measuring the plastering to walls that are circular on plan, take the height by one and a-half times the girt, and bring into superficial measurement, adding it to the straight work.

Whitening or colouring plasterer's work is measured by the superficial yard, describing the number of coats, and what tints are to be used. If cornices have to be in more than one tint they are taken separately, and also all enrichments that are picked out in colour. Old work, that has to be re-whitened or coloured, is described as wash, stop, claircolle, and whiten or colour, by the superficial yard.

Pugging, which is composed of coarse stuff and chopped hay, laid upon the sound-boarding between the joists of a floor, is measured by the square of 100 superficial feet, taken over the whole floor, without deducting the thickness of the timbers.

In entering plasterer's work in the dimension book, the surveyor uses various abbreviations. Thus, "R." stands for render; "R. S.," for render set; "R. F. S.," for render, float, and set; "L. P.," for lath and plaster; "L. P. S.," for lath, plaster, and set; "L. P. F. S.," for lath, plaster, float, and set; "W. S. C. W.," for wash, stop, claircolle, and whiten; "L. W.," for lime whiten; and so forth.

We shall now give a specimen of the entries of plasterer's work in the dimension book, which may serve to illustrate the foregoing rules:—

EXTERNALLY—PORTLAND CEMENT.

	25 6		Plain face on brick, Pd. cement with 3 parts washed sand, jointed.
	22 0	561 0	
4)	6 6		Deduct.
	3 0	78 0	
		483 0	
2)	10 3		Pilasters, ditto, ditto.
	1 4	27 4	
2)	22 0	44 0	Arris edges, ditto.
4)	16 6	66 0	4½ in. reveals, ditto.
4)	17 6	70 0	Architrave moulding, 3 in. girt, ditto.
	25 6		Dubbing-out with plain tiles.
	1 6	38 3	
	25 6	25 6	Chamfered edge.
	25 6		Moulded string.
	1 3	31 11	
2)	2 0		Ditto caps and bases.
	1 6	6 0	
		37 11	

No. 4 mitres to mouldg., 15 in. girt. 10 brackets, 12″ × 6″.
„ 8 mitres to mouldg., 3 in. girt.

	22 0		R. and rough cast on brick.
	18 0	396 0	

INTERNALLY.

2)	15 0		Pugging of coarse stuff and chopped hay, 1½ in. thick.
	12 6	375 0	
8)	4 0		R. with Portd. cement and 3 of sand to hearths.
	1 6	48 0	
	15 0		Ditto, ditto, to floors.
	10 6	157 6	
		205 6	
	52 0	52 0	Square skirtg. 7 in. wide, in Pd. cement.

PLASTERING.

	56 6		R. and S. to brick wall.
	10 0	565 0	
	10 0		Add.
	1 6	15 0	
		580 0	
3)	6 6		Ddct.

		511 9	
4)	10 6	42 0	Quirk.
2)	15 0 12 6	375 0	L. P. F. and S. to ceiling.
	24 0 3 0	72 0	Add soffit of stairs.
		447 0	
	24 0	24 0	Quirk.
2)	54 0 1 6	162. 0	Cornice.
	54 0	54 0	Enrichment, 6 in. w.

No. 12 mitres to 18 in. cornice.
,, 2 centre flowers, 3 ft. diamr.

3)	15 0 12 6	562 6	S. C. and W. to ceilings.
	45 0 3 0	135 0	Add soffit of stairs.
		697 6	
	54 0 1 6	81 0	S. C. and distemper 2 tints to cornice.

PARIAN CEMENT.

	56 6 10 0	565 0	Trowelled for painting.
	10 0 1 6	15 0	Add.
		580 0	
3)	6 6 3 6	68 3	Ddct.
		511 9	
4)	10 6	42 0	Quirk.
	45 0	45 0	Skirting 9 in. high, moldg. 3 in. gt.

No. 6 mitres to skirting.

2)	7 0 1 6	21 0	Pilasters.
	2 0 1 6	6 0	Plain moldg.

We have now given a specimen of entries of plasterer's work in the dimension book, first taking all parts which are to be worked in Portland cement, externally and internally; then the plasterings applied to the walls, ceilings, etc.; and, lastly, the finer work that is done in Parian cement. We have now to prepare an abstract of these dimensions, which will be found below. In this the work in cement and the work in plaster are taken separately. In the former the work in Portland cement with the addition of three parts sand is distinguished from the work in Parian cement, and is taken according to the mode of measurement by superficial area, run, or number. The work in the finer cement is also taken in the same way, but in this case it has been found more convenient to arrange the different kinds of measurement under one another instead of side by side. This has also been done with the rough casting and pugging, which is taken by superficial measurement. The same course is also adopted in dealing with the plastering, which is also arranged according to superficial area, run, and number.

ABSTRACT.

Portland Cement, with Three Parts Sand.			Parian Cement.	Plastering.

PRINCIPLES OF DESIGN.—XXX.

BY CHRISTOPHER DRESSER, PH.D., F.L.S., ETC.

STAINED GLASS.

FROM early times it has been customary to colour glass. To the ancient Egyptians a method of forming glass of various tints was known, and by producing a mass of glass consisting of variously coloured pieces vitreously united, and cutting this into slices, they, in a costly and laborious manner, produced a sort of stained glass which might have been employed for the sides of lanterns or other purposes. The Greeks were acquainted with a similar process, and bowls formed in this manner by them are common in our museums.

Soon after the re-discovery of glass in our own country, methods of colouring it were sought out, and beautiful cathedral windows were formed, which, soon after the discovery of the art of producing coloured windows, were of such beauty, and were so thoroughly fitted to answer the end of their creation, that little or no improvement upon these early works has even yet been made, and much of the decorative glass which we now produce is far inferior to these early works both as regards design, colour, and mode of treatment.

A window must fulfil two purposes—it must keep out rain, wind, and cold, and must admit light; having fulfilled these ends, it may be beautiful.

If a window commands a lovely view let it, if possible, be formed of but few sheets (if not very large, of one sheet) of plate glass; for the works of God are more worthy of contemplation, with their ever-changing beauty, than the works of man; but if the window commands only a mass of bricks and mortar inartistically arranged, let it, if possible, be formed of coloured glass having beauty of design manifested by the arrangement of its parts. A window should never appear as a picture with parts treated in light and shade. The foreshortening of the parts, and all perspective treatments, are best avoided. I do not say that the human figure, the lower animals and plants, must not be delineated upon window glass, for, on the contrary, they may be so treated as not only to be beautiful, but also to be a consistent decoration of glass; but this I do say, that many stained windows are utterly spoiled through the window being treated as a picture, and not as a protection from the weather and as a source of light.

Fig. 143.—DESIGN FOR A WINDOW IN STAINED GLASS.

If pictorially treated subjects are employed upon window glass, they should be treated very simply, and drawn in bold outline without shading, and the parts should be separated from each other by varying their colours. Thus, the flesh of a figure may be formed of glass having a pink tone; the robe of glass which is green, purple, or any other colour; the flower of white glass; the leaves of green glass; and the sky background of blue glass. All the parts will thus be distinguished from each other by colour, and the distinction of part from part will be further enhanced by the strong black outline which bounds the parts and furnishes the drawing of the picture.

Strong colours should rarely be used in windows, as they retard the admission of light. Light is essential to our well-being; our health of body depends in a large measure upon the amount of light which falls upon the skin. Those wonderful chemical changes, in the absence of which there can be no life, in part, at least, depend upon the exposure of our bodies to light; let our windows, then, admit these life-giving rays. It must also be remembered that if light is not freely admitted to an apartment the colours of all the objects which it contains, and of its own decorations if it has any, are sacrificed, for in the absence of light there is no colour.

It is not necessary, in order to the production of a beautiful window, that much strong colour be used; tints of creamy yellow, pale amber, light tints of tertiary blue, blue-grey, olive, russet, and other sombre or delicate hues, if enlivened with small portions of ruby or other full colours, produce the most charming effects, and by their use we have consistent windows.

A good domestic window is often produced by armorial bearings in colour being placed on geometrically arranged tesseræ of slightly tinted glass. In some cases such an arrangement as this is highly desirable, for the room may thus get the benefit which a bit of colour will sometimes afford, and at the same

time a pleasant view may be had through the uncoloured portion of the window. As an illustration of this class of window, we extract one from the catalogue of those excellent artists in stained glass, Messrs. Heaton, Butler, and Bayne, of Garrick Street (Fig. 145)

No architectural constructive feature should be introduced into a window—thus, an elaborate architectural canopy overshadowing a figure is not at all desirable. If a figure is formed of a perishable material, and stands on the outside of a building, it is well that it be protected from the rain by a canopy; but such a contrivance when introduced over a figure drawn on a flat window is absurd, being useless. Let us always consider what we have to do before we commence the formation of any ornamental article, and then seek to do it in the most simple, consistent, and beautiful manner.

More than once in the course of these papers I have protested in strong terms against pretence in art and art-decoration—the desire to make things appear to be made of better material or more costly substances than what they have in reality been wrought from; that leads most men to paint and varnish a plain free-stone mantelpiece in imitation of some expensive marble, or to make doors and window-shutters, skirting and panelling that the carpenter has fashioned out of red or yellow deal, assume the appearance of oak, or maple, or satinwood, by the deceptive skill of the grainer. In no case can the imitation ever approach a fair resemblance to the reality it is proposed to imitate. The coarse, rough grain of the soft free-stone, which is incapable of receiving a polish, or rather of being polished until it becomes as smooth, and even, and lustrous as good glass, can never be made by successive coatings of paint and varnish to afford a satisfactory resemblance to the marble that it is supposed to represent, however carefully the cunning hand of the painter may have imitated the veins, and spots, and curious diversities of colour with which Nature has variegated the surface of the substance that he is endeavouring to copy. Nor, again, can a coarse-grained, soft wood, however skilled may be the hand that manipulates it, be treated so as to resemble the texture and smoothness of hard, close-grained wood, which from its very nature is capable of receiving the high polish that the softer material can never take if treated by the same process. And what is applicable to the treatment of wood and stone is applicable also to the treatment of glass: for as a free-stone mantelpiece or deal door, however suitable and pleasing to the eye either may be when simply painted in the one case and varnished in the other to preserve the surface from the deteriorating influences of dirt of any kind, can never be made by the exercise of the highest skill to present the appearance of marble or oak; so glass, by the application of colour rendered transparent by varnish, can never be brought to resemble glass stained or painted by the legitimate method, either in delicacy of tint, or depth, and richness, and brilliancy of deeper colour. The greater part of the imitative stained glass, or "diaphanie," as it is styled, fails not only in colour, but in design; and in this indeed it may perhaps be said to be chiefly faulty. The designs for the most part which are printed on paper in colours err principally in being too elaborate, and in representing figures and scenery which are not in character or keeping with the designs that are usually represented in painted glass. If confined to simple diaper work, or borderings and heraldic emblems, as shown in Figs. 144 and 145, or patterns similar to that shown in Fig. 143, the artistic effect produced would be more satisfactory, although it can never equal genuine stained glass in depth of colour or purity of tone. But there is no necessity for any one who is averse to doing so to resort to imitation even in a means of decoration apparently so far beyond the reach of most of us as painted glass. The material, in the first place, is cheap, and the mode of procedure has been described in some of the papers that appear in this work under the general title of "Practical Application of the Fine Arts." It may be urged by many that a want of skill or an inability to draw may present an obstacle to success. It may do so for a time; but a will to succeed at last, aided by patience and perseverance, will ultimately overcome all obstacles.

Fig. 144.—WINDOW-BORDER IN STAINED GLASS.

SOLDIERING.—V.

BY A STAFF OFFICER.

ARMAMENT: CAVALRY.

WHILST immense improvements have been gradually introduced into the equipment of other arms of the service, hardly anything has occurred to render the action of cavalry on a battle-field more effective than it was formerly. Now, as formerly, the power of cavalry in actual attack depends on the extent to which the velocity and weight of the horse is brought into play. It follows at once that the weapons which are most suitable in attack, are those which give fullest effect to these. Little improvement has been introduced into the hand-to-hand weapons of war—the sword and the lance. On the other hand, since men on horseback can only use fire-arms with less, not with more efficiency than men on foot, improvements in them tend scarcely to increase the power of cavalry.

The result, however, is not to render the action of cavalry less important, but to change its character. There are still cases, as the fight at Rezonville in the last war has taught us, in which even now vast masses of cavalry may, by devoted courage, so hamper and delay the action of an enemy as to save an army. But the cavalry is almost inevitably destroyed. A general has still sometimes to call upon his horsemen to make the sacrifice, but it is like asking men to lead a forlorn hope. Victory may result. Few of those who have prepared for it will live to see it. The great problem, however, under ordinary circumstances, is how to get with the least sacrifice the greatest amount of value out of an arm which a very brief consideration of the facts will show to be even more essential than formerly to the safety and success of an army.

The tremendous power of modern weapons has rendered the element of *time* one of even more absolutely vital consequence than it was formerly. For within a given time, a properly prepared army may inflict upon an army unprepared a disaster far more complete and final than was ever possible formerly. Hence to obtain the fullest information at the earliest possible moment has become not merely an *important* matter, but one of altogether paramount importance. Now time is the very element in which cavalry has always had the advantage over all other arms of the service.

Nor is that all. The suddenness of the effects of modern fire-arms has produced a tendency to as sudden discouragement even among the best of troops. Gravelotte supplies us with a notable instance of it, even among those who had been victorious in every fight. Such panics, if troops are fit to fight under modern conditions at all, pass away almost as rapidly as they occur. If an enemy observe them, and taking advantage of the favourable moment act upon it, victory is in his hands; if he allows the chance once to pass away, his hope of its returning is small. Now, here again time being the element of all importance, cavalry is the arm to be used. Moreover, the effect of cavalry has always been essentially moral. Nothing impresses the imagination so much as the apparent power of clouds of horsemen pouring down upon the seemingly devoted heads of the pigmy-looking foot-soldiers who are crouching in the ground to take aim at them. It needs only that the infantry man now-a-days should be calm, and should realise the efficiency of his weapon, in order to render the attack, powerful as it is in appearance, impotent in practice. But men in panic are not calm, do not reason. Hence cavalry thrown at the right moment upon discouraged and somewhat disordered infantry, ought to render it impossible for them again to take part in the action then going on.

Furthermore, since an army once beaten is greatly discouraged, great opportunities are sure to present themselves after a battle, and towards its close. What I spoke of in the last paragraph are rather incidents in the course of an action. Whole armies are rarely so disorganised at once by a single panic, that they may be freely assailed in the way there spoken of whilst a battle is in full vigour. A brigade or a battalion, under exceptionably severe stress of fighting, exposes itself to such assaults, it may be at a very early stage of the fight. These incidents, whenever they occur, must be taken advantage of. But after a lost battle, or towards the end of the day when it is becoming clear that the battle will be lost, the whole of the beaten army, without being panic-struck, tends to yield to a sense of despondency. Troops that have been comparatively little engaged feel this almost as much as those that have been hotly pressed, provided the fresher troops have been able to realise the extent of the disaster, and unless they are exceptionally war-tried men. Here again, therefore, immense opportunities, now as formerly, present themselves to the arm which strikes most rapidly, and which most impresses the imagination. The effect produced by cavalry acting in this way is in reality *far greater* than formerly; for while men cowed by disaster are not much more deadly enemies if they have breech-loaders in their hands than if they had the Brown Besses of the Peninsula, let them once recover themselves, and each man represents a far greater power to be overcome than in the old time. It is, therefore, more important than ever to strike whilst the task is relatively easy. On the other hand, a much smaller body of infantry, if it retain order and remain uncowed by disaster, will now be able to repel the incursions of pursuing cavalry.

Once more, since cavalry will be used on both sides, and when one body of horsemen is thrown in to take advantage of panic or disorder, another will be launched to save the assailed infantry from disaster, it becomes of the utmost importance to have in hand a body of horsemen so armed and equipped as to be able to overcome any whom the enemy may bring into the field.

I have pointed out as I proceeded through the above enumeration of the chief purposes for which cavalry is required, how far the conditions apply at the present moment; but the distinctions between the different classes of cavalry to meet these necessities have sprung up in the past, and have in the main differed little, except perhaps in the relative degrees of their importance, from those which we now possess, or indeed now require.

The first broad distinction in the classes of cavalry employed is that between "heavy" and "light:" the former, intended to consist of such powerful men and horses, that it shall be able to ride down all opposition, and to be so equipped as to be victorious in onsets of cavalry against cavalry; the latter, intended to develop to the full all qualities of rapidity and prompt action. We have also what are known as "medium" cavalry, intended to do much the same work as the light, but to be also a supporting body for them in the shock of battle.

The light cavalry is especially designed to fulfil all those duties of gathering information, watching round the outskirts of an army, foraging, striking short rapid blows against disorganised troops, to which I have already alluded as of so much importance, and which were popularly attributed to the Prussian Uhlans or lancers during the recent campaign. In Prussia, however, the Uhlans are medium, not light cavalry, and for many of the duties of this kind they are the least fitted of all, except the very heavy cavalry. During the late war it became important to throw as large bodies of cavalry as could be gathered together round the advancing armies, and hence as in open country lancers were very effective, and little actual fighting was required, they, as well as others, were pushed forward far in advance of the army. The lance has been rightly called the queen of cavalry weapons, for it is the one which gives to the horseman the fullest play in those respects in which he has advantage over the man on foot. Its effect is produced by the actual forward dash of horse and horseman; the very nature of the blow which it delivers protects its holder. For the horseman, even the sword is most effective when it is used as a rapier, not when it is raised to strike a blow. For the rapier thrust gains force from the horse's impulsion; the sword cut gains nothing from that cause, and in the delivery lays open the swordsman: hence the advantage of a weapon which, depending solely on its thrust, has for it the longest possible reach. The lance is, however, far more valuable for large bodies of horsemen acting together, than for mere scattered advanced parties; it is awkward and fatiguing for very light work. For these purposes the hussar is the prince of horsemen. The armament of hussars with us is the sword and breech-loading carbine, with no defensive armour. The lancer has sword and pistol besides his lance, with no defensive armour.

But whether for outpost duty—that is, for the watch and ward over an army, and collecting information—or for the battle-field, light cavalry of whatever kind require to be supported. Experience in the past has been fully corroborated by recent evi-

dence, as to the fact that the support which they require is of two distinct kinds. For battle fighting, where cavalry attack will be met by cavalry counter-attack, the best of all support is that furnished by powerful cuirassed regiments, equipped with armour genuinely defensive against cavalry weapons, who by sheer weight and impetus, as has been proved again and again, can, if properly handled, be almost certain to ride down the best of light horsemen. The light horsemen may catch them at a fault; but when the two fairly meet, the lightly equipped soldier specially prepared for other work has hardly a chance against his powerful and well-protected enemy. On the other hand, these cuirassed regiments require to be kept in reserve specially for these duties; to employ them in the harrying light work of a campaign is to destroy them. For this purpose another kind of support requires to be furnished. The name " dragoon " has become a most indefinite one with us, implying little else than a heavy cavalry soldier. In its origin, in its earlier use, as understood by Napoleon and during the American War of Independence, it had a very different meaning. The latest experience of the war of 1870 convinced all who passed through it that the old dragoon must be revived. His essential character was that of a mounted rifleman: his pride to be so effective on foot that the enemy were certain to mistake him for the best of infantry soldiers, and to believe that the solid infantry of the army, and therefore the guns were arriving, so that it was time to abandon any weakly held outpost. Rossel has recorded how often villages which otherwise would have been hotly contested for hours, have fallen at once before such trained dragoons, because of the false impression they created that greater force was at hand. But to gain this the dragoon must be in all respects equipped and trained as an infantry soldier; taught to ride well, only that his transference from point to point may be as rapid as possible. His drill must be identical not with that of cavalry but with that of infantry when he is on foot; every part of his equipment must tend to make him put confidence not in the force of his horse in a charge, but in the efficiency of his weapon when he is dismounted: such ought to be the real characteristics of this most invaluable of soldiers. We do not at present, except in the Hampshire Yeomanry, possess a specimen of him; his creation has been invariably advised by all who have considered the question how to bring the gain of time which the horse offers into such combination with our all-efficient fire-arms as shall enable us to seize positions by virtue of the horse's rapidity, and to hold them by virtue of the power of the new arms. The difficulty that has always stood in the way is the dread lest we should only create bad infantry and bad cavalry: we are sure to produce that result as long as the only test we apply as to efficiency is that of parade. Dragoons will constantly tend more and more to be mere heavy cavalry; but in proportion as our training in peace time becomes more and more a study of analogous duties in war, in that proportion will an appreciation of the importance of the mounted rifleman or dragoon be extended. Men will take a pride in belonging to a body which has more opportunities for dealing startling blows that tell throughout a whole campaign than, in proportion to numbers, any other part of an army whatever. During the fighting in the Le Mans campaign the Prussian cavalry, to save the weary infantry, took duty all round the resting army. Many were the fights which occurred in that enclosed England-like country between the Prussian dismounted horsemen and the French levies; the result was that before long all became convinced that as such duties must often now fall to the lot of cavalry, it was essential to place in their hands a good far-reaching fire-arm. Hitherto the Prussians had had a most legitimate fear lest if the fire-arm were made too good, the cavalry should begin to trust to it when mounted rather than to the impulse of the charge. The result would inevitably be that the horseman, using his fire-arm under circumstances of less advantage than the foot-soldier, would be beaten in every encounter. But the days are past when we could afford to deprive ourselves of an important advantage, lest our men should make a wrong use of it. We must meet the difficulty by superior training, not by defective armament. This, however, we shall have to consider later. At present it is sufficient once more to press the fact that whatever fire-arms may be given to cavalry, they are essentially either for use on foot, in exceptional instances for cavalry encounters, or for isolated foraging. For the assault of broken infantry and all such purposes the less they are used the better. The only distinction in our service among the heavy cavalry is, that the household cavalry are armed with cuirass, steel helmet, sword, pistol, and breech-loading carbines. The " Heavies " are armed with brass helmets, swords, and breech-loading carbines. The Scots Greys alone are equipped so as to look like mounted guardsmen. It may be safely predicted that one of the earliest results of the first war we are engaged in will be the creation of a corps of mounted riflemen. Unfortunately, creations of corps during war time are not easy now-a-days.

EQUIPMENT: CLOTHING.

We pass now to the consideration of those other matters of equipment scarcely less necessary to be noted even than armament itself. First of all, clothing; and, secondly, the few essentials which require to be carried on the persons of the foot-soldiers, and on the horses and carriages of the cavalry and artillery.

As to clothing: some means of distinguishing between the civil population and those engaged in fighting was felt to be needed as soon as war began to be conducted in a civilised manner. The importance, for the sake of the civil populations themselves, of insisting that none shall fight who do not wear the uniform of one of the armies engaged, has been pointed out again and again by those historians who have most carefully examined the question. Nevertheless, it almost always happens that during a period of war patriotic and personal excitement drives the peasantry of an invaded country into acts of individual hostility against the enemy. The duty of the government of a country so invaded is to publish at once the clearest possible information to the people of the invaded districts, telling them by what sacrifices they can best aid the general effort to repel the invaders. The aid which true patriotism would offer is an entire submission to directions so issued. The great difficulty usually lies in this, that the mass of a large population does not realise what an invasion is till the hostile armies have shown themselves and committed acts asserting the right of the strong. Then furious wrath produces terrible acts, followed by more terrible reprisals. Hard as it may seem, it has been powerfully argued that the wisest and most humane course, where a whole population has not been able to fly before an enemy, and where the war is one between civilised nations, is to leave none but women and children, the aged and infirm, in the villages through which the invasion passes, and to sweep the whole virile population of those provinces into the service of the army. The population thus left should offer no resistance whatever to the enemy. No modern general dares to allow atrocities to be committed where no resistance has been offered. His difficulties will be too seriously increased by any such conduct. But what is for him an inconvenience, is for the peasantry decimation, if not destruction; for, preach as we may, no army will allow itself to be quietly murdered off one by one by men whom it has had in its power, and has spared on the understanding that as they do not wear the uniform which proclaims their hostility they will not act overtly against it.

The Prussians, economical as they are, meet the difficulty by having *his suit of uniform ready*, and his appointed place assigned to almost every man in the whole country who is capable of actively aiding their own army in any capacity. It is no doubt not necessary for us to take the precautions which are indispensable to nations unprotected by our strip of blue water, but the illustration is sufficient to show how very important a national question uniform may become. To the army it is the outward sign of its unity and of its common duty. If, therefore, the proposition from which I have started is true—that the question to be considered in each matter is how the spirit you desire can best be developed—it is scarcely possible to doubt that men should be taught to have a great respect for their uniform.

As all things which are necessary and good in themselves have a disagreeable part, so this is apt to present itself often to outsiders under a very unpleasing aspect. Foolish men in every profession and calling do not see the difference between a happy confidence that the work they have chosen is for them the best of all work, and a contempt for the work on which others are engaged. Foolish men outside every profession and calling mistake the pride which the best men will always have in their own business for personal egotism

and conceit. The two react much on one another, and hence it very often happens that it is regarded as a special offence of the army against the nation, that men are taught to hold up their heads proudly, and to walk along "as if everything they saw belonged to them." It is a misfortune that such mistakes as to the meaning of pride in a calling should be made on both sides. It is, no doubt, a misfortune that we are not in the millennium; when we are, it may be presumed that armies will cease to exist. But in the meantime, those who wish to have an army effective must be content to endure the sight of a certain amount of so-called "military swagger." If it is not accompanied by a certain special readiness to assist others, and to fit into awkward positions, it may be safely assumed that the man is the worse soldier on that account. To take a single instance, try whether those Life-Guardsmen who in front of the Horse-Guards offices seem to be each taking up the space of three men as they pace up and down, are when you speak to them more or less ready than the clerks in the War Office to lend you all the assistance in their power for getting the information you require.

It immediately follows from this principle of cultivating as far as possible the soldier's respect for his uniform, that his dress should be such as will tend to make him take a pride in it. A man dressed in sackloth and ashes may feel that his dress is exactly the one that he ought to wear, but it would be a contradiction in terms to say that he would take a pride in it; his object is to learn to take pride in nothing. I have often heard men say that you ought to make soldiers' clothing handsome, because handsome uniform is the bait with which to catch recruits. I do not think that is either a true or an honest way of looking at the matter. If it were a deceptive bait, I should say you did yourself more harm than good, since it is more essential to an army than to any other body to be joined by those only who heartily wish to belong to it. Moreover, as a matter of fact, those regiments which find it easiest to get good recruits, though they are largely assisted by their uniform in doing so, are certainly not those which are most gaudily dressed. The Rifle Brigade, for instance, is perhaps the most serviceably dressed of line regiments, but it is not the most showily got up. What I believe the fact to be is, that there is a certain contagiousness in any genuine feeling of pride in a good regiment; that that contagiousness is the best possible agency for recruiting; that the pride itself is to some extent fostered by a liking for their own uniform among the men of a corps, affected no doubt partly by what their civilian friends think of it.

The other matters which concern the clothing of soldiers are chiefly such as common sense would suggest; that it shall be judiciously modified according to the climate in which it is to be used; that it shall be as convenient and as durable as it can be made. There is only one point in which the conditions of a soldier's work introduce a matter of special importance; he should be able to carry certain changes of clothing with him if possible, and hence it is very advisable that his garments should be as light as other conditions will permit. Practically this is a matter so difficult to reconcile with cheapness and other requisites that it may be said to be wholly ignored.

OPTICAL INSTRUMENTS.—XXI.

BY SAMUEL HIGHLEY, F.G.S., ETC.

ARTIFICIAL SOURCES OF LIGHT (*continued*).

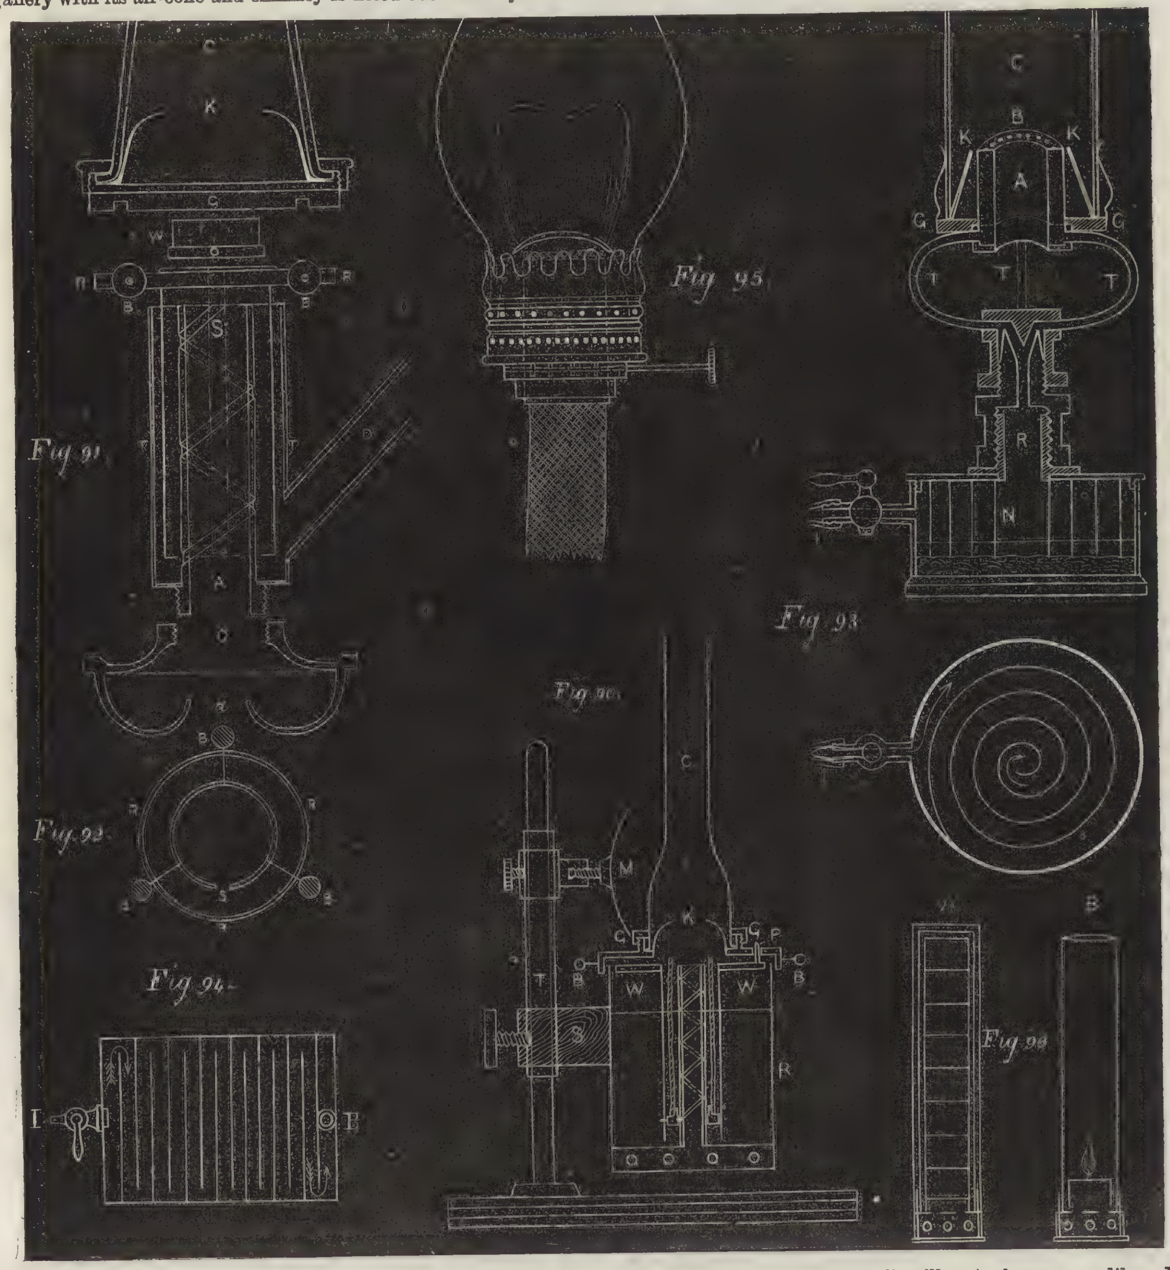
Paraffine Wax Burner.—Solid paraffine, together with the recently introduced "ozokerit," is extensively used for the manufacture of candles. For such purpose, the most purified samples possessing a high melting-point are those most suitable, *hardness* being the quality most essential for candle-making. The crude sample, having the lowest melting-point, may be burnt in a suitable argand lamp, if reduced to a melted condition, and presents some advantages to those who object to the oily nature and odour of paraffine oil and petroleum, as paraffine wax is clean to the touch and perfectly odourless, while it burns with a pure white light that is alike intense and dense in the flame, and is *perfectly free* from danger, for, if spilt or overturned, it immediately solidifies, and may then be peeled off anything it settles on. The drawback to its use is that a mass of it takes a long time to melt, which is inconvenient. The lamp suitable for burning melted paraffine wax is shown in Fig. 90. It consists of a cylindrical reservoir, R, of stout brass, $3\frac{1}{4}$ inches high and $2\frac{3}{4}$ inches diameter, with a thick brass central air-tube, the stoutness of material being necessary to keep the mass of paraffine liquid when once thoroughly melted by the heat conveyed from the flame through the metal-work to the centre of the reservoir.

The wick is fitted to a little ring of brass, from which projects a pin that runs in a serpentine groove cut on the inner side of the air-tube, and drops into a slot cut in a tube, W, placed outside the wick concentric with the air-tube. From the top of this slotted tube a broad flange extends to the outer cylinder of the reservoir, by which the wick-tube is kept in place, and acts as a guide when it is rotated by a stout pin, P, riveted on the upper side of the guide-flange. By this pin the wick can be wound down to the bottom of the reservoir, and the wick can then be cut off even with the top of the central air-tube. Over the top of the cylinder a brass cap fits that carries an oxygenating cone, K, and a screw-gallery, G, that supports the chimney, C. In this cap a hole is cut that fits over the pin, P, so that when it is rotated on the cylinder by means of three ebony balls, B, fixed to its circumference, it likewise rotates the flange connected with the wick-tube, and allows of the wick being raised or depressed to the proper height for perfect combustion. If the height of the chimney has been properly adjusted to this kind of lamp, a short bright flame should be obtained that is perfectly free from smoke; should it smoke, a longer chimney is required. Should the flame be thin, the chimney is too long; if drawn in, the chimney is too long or too much contracted. In this arrangement the wick is somewhat disposed to char. It would be a great improvement if wicks could be made of asbestos. In spirit-lamps I have found that a wick may be made of fine wire (platinum is preferable, though the most expensive) fitted very tight into the wick-holder, when the spirit may be sucked to the summit through the interspaces by capillary attraction; but such an arrangement is not suited for non-mobile liquids, like vegetable oils or melted wax, that moreover tend to clog any such contrivance.

The wax may be melted by cutting it into shreds before filling the reservoir, from which the wick and other parts have been removed, and placing the lamp on the hob, or in an oven; but the better plan is to raise the lamp on the supporting-rod by the adjusting-tube, T, and placing beneath the central air-tube a small flat capped spirit-lamp. The adjusting-tube is attached to the reservoir by a block of wood, S, that serves as a convenient handle when the lamp is hot. The mirror, M, is arranged and adjusted on the sliding tube, T, in the manner previously described.

Animal Oil Lamps.—The lamp most usually supplied with the ordinary phantasmagoria lantern of the shops is a fountain argand, with a flat reservoir, shown in Fig. 91, as in this case the illuminating material may be placed inside the body of the lantern with advantage, the oil being improved by warmth. The best illuminating material is good camphorised sperm oil. Two ounces of camphor should be moistened with a little alcohol, then pounded in a mortar, and to the magma thus produced, a pint of oil added, and stirred till dissolved. The argand burner must be so connected with the reservoir that the point of constant level is about $1\frac{1}{4}$ inches below the top of the wick. The chimney, C, somewhat conical in shape, is fixed to the metal gallery, G, by a brass screw-cap that overlaps a lip on the lower end of the chimney. The gallery also carries the air-cone, K, and in its external ring three slots are cut that drop over three pins terminating in ebony balls, B, B, that spring from the wick-regulator, R R. The wick is placed perpendicularly on a brass "wick-holder," W, from which projects a pin that fits a slot, S, in the "wick-adjuster," R, and also a serpentine groove cut on the inner side of the air-tube, A, of the wick-tube, T T. The wick-adjuster, R, is a tube that drops into the wick-tube, T T, outside the wick, and from the top of this tube springs a flange perforated so as to intercept as little air as possible from passing to the cone, K, as shown in the lower section (Fig. 92). On the slot, S, in the adjuster, R, being placed opposite the upper end of the serpentine groove in the air-tube, A, the pin in the wick-holder will fit into both, and the brass wick-holder will then drop into place between the two, but not in any other position. On rotating the flange from right to left the wick is worked to the bottom of the

wick-tube, T, in which position it must be carefully cut off even with the top of the tube by a pair of sharp "shield-scissors," specially constructed for trimming lamps. On rotating the flange of the adjuster from left to right the wick is raised, and when about one-eighth of an inch above the tube it is in the best position for the brightest, smokeless flame, when the gallery with its air-cone and chimney is fitted over the adjuster. filling the lamp, when both corks must be removed. After time has been allowed for the wick to get thoroughly soaked with oil, it should be lighted, allowed to burn for a few minutes, then blown out and re-trimmed with that exactitude that is essential to secure an even, smokeless, bright flame, and this can be better accomplished after the wick has been slightly charred. If the wick be soaked in strong vinegar, and then thoroughly dried before use, it will not char so readily. It need hardly be said that the metal-work must be kept clean, and lamp-glasses and reflectors thoroughly polished before use. The best reflectors are made of suitable thin concave glasses that have been silvered by Liebig's or Petitjean's process, by a deposit of pure metallic silver (not the ordinary mercurialised tinfoil silvering) on the convex side, protected by an electro deposit of copper. Such reflectors are far more brilliant than the ordinary plated reflectors; they cannot tarnish, and only require wiping with a soft wash-leather to make them ready for use, instead of having to clean them with moistened rouge



The oil is carried from the flat reservoir by the delivery-tube, D, which opens into the wick-tube. An oil-cup, O, for receiving any overflow from the wick, screws on to the air-tube, A, its centre being perforated at a to encourage a free up-draught; the upper surface of this cup is also perforated to admit air to the central tube of the burner. A burette oil-can is a neat and clean contrivance for filling lamps—that is to say, a can from the bottom of which springs a narrow tube that is curved into a long spout on a line just below the neck. One of a pint capacity may be used as a store-bottle, in which case both neck and spout must be corked till required for

worked over with the pad of the thumb, and polish with a leather buff. Such mirrors must be guarded by a metal concave shield of a deeper curve than the back of the reflector, and be perforated to admit air for the purpose of keeping it cool.

Argand Gas Burners.—Until recently "Leslie's burner" held pre-eminence for light-giving qualities. This consisted of a series of small conical iron tubes converging from a broad connecting base in a conical form to a narrower centre. The chimney was arranged with an air-cone, so as to cause an up-draught between the several tubes and upon the flame. The drawback to this form of burner was the liability for the small tubes to become clogged by the corroding action of the gas. The most perfect gas argand at present attainable is the "London burner," a recent patent. It is well known that if house-gas be passed through the vapour of benzole, as recommended by the late Mr. Mansfield, who fell a victim to his experiments, the illuminating power is greatly increased; but the London burner gives a light very nearly equal to naphthalised gas, while the flame is short, cylindrical, steady, very bright and white, but, unless naphthalised, lacking in density. This burner is shown in section in Fig. 93. N, the napthaliser on which it is mounted, serves as a stand; I being the inlet-tap, and R the gas-regulator, a very essential part of this burner, through which it passes by three small curved tubes, T, T, T, to the argand burner, B, which is made of steatite, to render the exit-holes incorrodible, A being the central air-way. Outside the burner is a thin white metal air-cone, K K, supported by a gallery, G G, that also carries the glass chimney, C. The regulator consists of a solid conical point that descends from the top of the brass cap from which the three gas-tubes, T, T, T, spring, which fits into a hollow conical tube, or counter-fitting, that screws up into the cap, so that the flow of gas can be entirely cut off or admitted to full extent, being, in fact, a conical stop-cock that can be regulated to the veriest nicety by rotating the gallery, G G, to the left or to the right, the lower part being firmly screwed to the naphthaliser, N, or directly on to a gas-bracket or other supply-pipe. This regulator must be adjusted till the flame forms a perfectly bright cylinder about 1½ inches high, for if allowed to flare up the chimney the best result is not attained. Any stop-cock attached to the ordinary gas supply must be turned full on as the regulator takes its place, and there must be no check on the supply externally. This burner is made in three sizes: the smallest is suitable for microscopic lamps; the second I prefer to the larger model for magic-lantern work, as it gives a denser flame. The naphthaliser, N, is shown in section beneath. It consists of a cylindrical box, to the lid of which is soldered in a spiral coil a band of zinc nearly the depth of the box, that "beds" in a thick felt pad laid on the bottom, and terminates in the centre just beneath the hollow socket on which the burner is screwed. Benzole is poured in through this opening till the felt pad is well saturated, so that it may keep the spiral passage filled with benzole vapour. The gas passes in by the tap, I, and in its course to the central opening, R, becomes impregnated with the vapour, or, as it is termed, "naphthalised." Another form of "naphthaliser," used for photographic self-registering meteorological apparatus, is shown in Fig. 94. Its arrangement for making the gas pass over a long course of benzole vapour within a small compass is self-evident. The gas enters at I, and passes out at B. It is better to fill the passages with sponge-cuttings, as offering a larger surface from which the vapour can be given off. In winter, this arrangement may be supported over a water-bath heated by a small gas-jet, so as to ensure the vapour being given off during cold weather at a uniform temperature.

Flat Wicked Burners are very serviceable for microscopic illumination, especially if the thin edge, instead of the broad side, of the wick be turned towards the mirror, when fine markings are to be brought out.

A section of one of Dietz's flat-wick burners is shown in Fig. 95. As air is not passed through the centre of the flame, it is projected on to the flat wick by a slot cut in the large air-cone that stands above both wick and the lower part of flame.

Heavy Hydro-carbon Oil Burners are not much employed for scientific purposes; but there is one form of burner, patented by Holmes, that I think might be modified in form and made serviceable for microscopic illumination, as it gives a small but very bright jet of light. A small metal tube is closed at the upper end, pierced with a few minute holes, and packed with coarse lamp cotton. When the wick is saturated with heavy hydro-carbon oil, the end of the metal tube is warmed with a spirit-flame for a few seconds till the oil is vaporised and issues from the holes in the form of gas, when it ignites. The tube is then placed in the reservoir of the lamp, and the little jets continue to burn. Neither lamp-glass nor globe is necessary for this form of burner.

Fish-tail and Bat's-wing Burners.—These well-known forms of gas-jets are useful where glass chimneys would prove in the way, and where the equally compact lime-light burner would be regarded as too elaborate. Two fish-tails placed close behind each other produce an intense light. To prevent flicker through floor-draughts, these jets may be placed within a shallow three-sided box with the front side closed with a plate of glass, air being admitted from beneath by a series of well-distributed holes bored in a block of wood that serves to form the base of the arrangement.

Candles.—Sperm candles are employed as the standard of comparison with other lights; thus we say such a burner equals so many standard candles (six to the pound). Candles are made with single and double wicks implanted in tallow, "palm," "composite," stearine, wax, spermaceti, paraffine, ozokerit, etc. A Palmer's candle in its spring-tube to keep the flame at a constant point is a convenient arrangement for the travelling microscopist, especially if the tube be fitted in an adjusting clamp that can be fixed to the edge of a table, to allow of the point of light being raised or depressed. Night-lights are of great use to the travelling photographer, especially if made with paraffine wax, as a number can be packed in a cylindrical pasteboard case, that can be placed inside a yellow chimney, the whole being enclosed in a tin guard-tube (as shown in Fig. 96A), the lid of the same serving as a cup for the light and a gallery for the chimney when arranged for developing dry plates, etc., as shown in Fig. 96B.

Other Sources of Light.—In concluding the series of articles on "Sources of Light," in which I have endeavoured to describe the best type of each class of illuminating apparatus, it is only right to notice some that I have had no personal experience in, or that may be regarded as little known inventions; thus there is the "Bourbouze burner," which is thus described:—

"The Bourbouze lamp is the name of a new French invention, which gives, it is stated, as much light as the oxy-hydrogen or Drummond lamp, but is very much less costly. The combustible is coal-gas intimately mixed with air. The mixture enters a tube, and then passes through a metallic plate pierced with a great number of small holes, so that the gas is divided into an infinite number of small jets. These play upon a tissue of platinum wire, and it is not until the gas has passed through this tissue that it is lighted. Under the influence of the heat produced, the platinum soon becomes white hot, and it is then impossible to look at it with the naked eye. The gaseous mixture is forced through the system by a slight pressure; about one cubic metre of gas is consumed per hour."

Similar in arrangement is the apparatus of Mr. Hogg, of Edinburgh, which is constructed in the following manner:—"Two tubes are employed on the Bunsen lamp principle, one of which is of smaller diameter than the other, and the said smaller tube is placed within the larger tube. One tube is placed in communication with condensed gas, or air, or with both, such gas or air being compressed by a pump or other suitable apparatus for compressing or condensing air, or gas, or aëriform or gaseous fluid. This pump or apparatus may be of ordinary construction, and may be worked by hand, steam, or other power. The other tube is placed in communication with ordinary arrangements for the supply of atmospheric air or gas thereto. The gas or the air, or both, may be supplied at any determined pressure, or it or they may be condensed or compressed (before reaching the tube or tubes) in a pump or apparatus for the purpose of ordinary construction. The mixture of gas and air is passed through a perforated plate of platina or other suitable material, or a tissue of platina wire gauze, or other suitable wire gauze, by which it is divided into numerous small jets. The mixture of gas and air is obtained thus—that is to say, one of those agents is conducted through the smaller tube and discharged through the opening thereof into the larger tube, into which also the other agent is admitted. The tubes thus act as a sort of blow-pipe. The aëriform or gaseous mixture passes through the larger tube to a piece or surface of fine

platina. Pierced plate, or wire gauze, or woven platina wire, or other suitable metal, may be substituted for the platina. The minute jets pass through the interstices of the platina or other material, and are ignited. The metal soon becomes incandescent, the supply of air being duly regulated, combustion is made perfect, flame disappears, and the platina or metal becomes a surface of intense light. Sometimes, instead of using a mixture of gas and air, compressed or condensed gas by itself and air at the ordinary pressure are used. Sometimes the gas and air may be heated before burning, to obtain a maximum effect."

An arrangement wherein atmospheric air under pressure is driven through a small tube coiled into a spiral and heated by a lamp, passes out at a blow-pipe nozzle through a spirit or house-gas flame on to a lime-ball in the manner of the oxy-calcium jet. Such an arrangement, if effective, would be economical, and save the trouble of making oxygen, while the size of the reservoir would be greatly reduced. I hear this spoken of promisingly, but as yet I fear it can only be regarded as an undeveloped source of light.

TECHNICAL DRAWING.—LXX.

DRAWING FOR BRICKLAYERS (*continued*).

COMMON DOUBLE FLEMISH BOND.

DOUBLE Flemish bond implies that this bond appears on both sides of a wall. In double Flemish bond it is the custom in some parts to use alternate stretching courses on both sides of the wall—that is, courses in which false headers or bats are combined with stretchers. Thus two rows of fissures or un-

Fig.580.

broken joints, each 9 inches in length, and at intervals of 4 inches apart, are produced, one near the face and the other near the back of the wall, each being at the distance of half a brick from the adjacent surface of the wall.

Fig. 580 is the plan of one course of a portion of a two-brick wall, built according to double Flemish bond.

"Hence," says Sir Charles Pasley, "on comparing these two arrangements, it will be evident that both sides of a wall are weak in a common double Flemish bond, whilst in the common single Flemish bond one side of the wall only is defective. The common double Flemish bond is therefore a very imperfect arrangement, which never ought to be used at all, and, to the best of my knowledge, is never used in the walls of a building by any skilful bricklayer. On comparing together the various kinds of brickwork, it appears to me that the common English bond is by far the simplest and strongest, and that it ought therefore to be always used in preference to Flemish bond, which is sure to leave one side of the wall weak, and to a certain degree liable to split by longitudinal fracture."

English bond is not only much stronger in itself than Flemish bond, but it has the great advantage, which the other does not possess, of being able to alternate occasionally in a substantial manner with one or more diagonal courses of brickwork in walls of two bricks in thickness and upwards. This useful arrangement we will now proceed to explain.

DIAGONAL BOND.

In thick walls, but more especially in foundations, a third kind of bond, called diagonal bond, is sometimes used. This consists in laying certain of the courses of bricks at right angles to each other, and oblique to the surface of the wall, with which they form at every part an angle of about 45°*

In adopting this arrangement, intermixed with English bond, the diagonal bricks in those courses do not extend so far as the face or back of the wall, where a line of common heading or stretching bricks is laid in the usual manner: thus the wall, when finished, has all the appearance of common English bond.

A two-brick wall is the thinnest in which diagonal courses can be used combined with English bond, and in this case only with the stretching courses. Figs. 581, 582, and 583 represent this arrangement, in which are introduced, first, a heading course of common English bond (Fig. 581); secondly, a diagonal course between the stretchers (Fig. 582); after this, a second heading

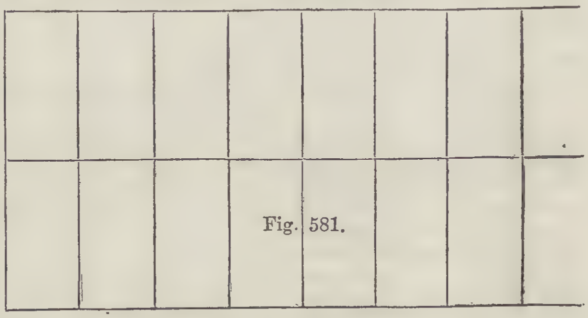


Fig. 581.

course, and then another diagonal course between the second set of stretchers (Fig. 583) at right angles to the former.

The triangular spaces at the extremities of the diagonal bricks between them and the common headers or stretchers at the external surface of the wall must be filled in with bats or fragments cut to the same form.

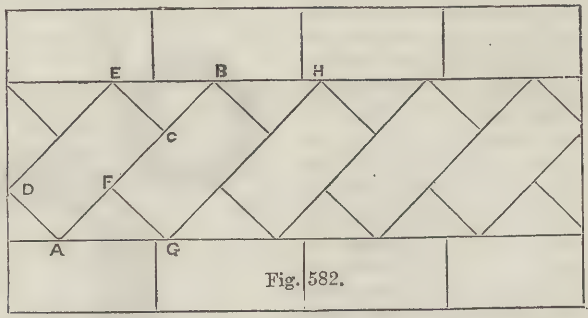

Fig. 582.

Sometimes the bricklayer, instead of using all fragments, will cut the end of a whole brick obliquely, so as to meet the outer row of headers or stretchers, in which the diagonal bricks are enclosed. But this precaution seems scarcely necessary if the interstices arising from the former method be well filled up with solid pieces, instead of being simply stuffed with mortar.

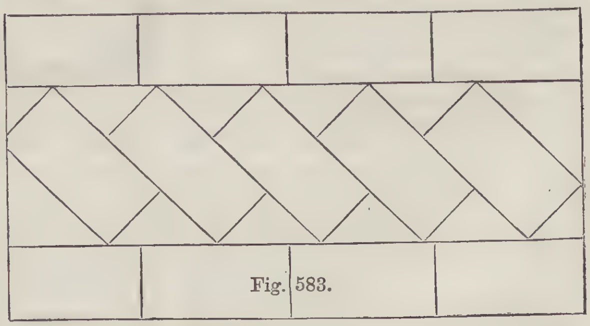

Fig. 583.

Although Figs. 582 and 583 appear very simple, some little care is necessary in drawing them. It must be borne in mind that the bricks, though placed obliquely, are *not altered in their rectangular form*—a fact which students often overlook. The following method is therefore given.

Having drawn the parallel lines representing the total thickness of the wall, and having drawn lines within these at distances equal to the lines of headers or stretchers which are to

* One diagonal brick laid at an angle of 46° 24′ with the face of the wall occupies the space of one header in the thickness. The bricklayer finds the proper angle by trial. The angle of 45° is therefore only approximate, and is here used for convenience in drawing.

form the faces of the wall, draw a line at any point, as A, at 45° to the line of the wall—viz., A B (this will, of course, be done by means of the set-square of 45° worked against the T-square); reverse the set-square, and from A draw A D. The space between these two lines will then be the right angle D A B. Now on A B set off A C equal to the length of a brick, and from A mark off on A D the width of a brick. From C and D draw lines parallel to A B and A D, which meeting in E will complete the rectangle representing the brick, the point E, if the work be correctly done, falling on the line bounding the space to contain the diagonal course.

From B set off B F equal to A C, and from F draw F G; from G draw G H, and in this way the work will proceed.

The use of diagonal courses consists in producing a more powerful bond than the lap of a quarter brick only, which is all that the common English or Flemish bonds are capable of yielding; and there is no possible way of laying the diagonal bricks wrongly, for if they be intermingled with common English bond, according to the rule given, one, two, three, or more whole bricks laid diagonally will just fill up the core of the wall, in proportion to its thickness; and all the successive courses of those bricks will break joint properly, whether in reference to each other, or to the common courses of English bond, above or below them. This may easily be proved by building a wall, as above described, with the model bricks.

The student will observe that in thus combining the diagonal courses with English bond, the same effect will be produced by throwing in the courses of diagonal bond singly, instead of using two in succession. For example, after one course of English bond, might come one diagonal course, then another course of English bond, after which might follow the second course of diagonal bond. But whichever arrangement be adopted, the successive diagonal courses ought to be laid in contrary directions.

Diagonal courses laid as here described are sometimes called "herring-bone bond." This term is more correctly applied to the method by which the direction of the diagonal bricks in the core are reversed in the same course. Diagonal bond is further illustrated in "Building Construction" (Vol. I., p. 172).

FREEHAND DRAWING.

The example here given (Fig. 584) is a design for an ornamental floor-tile. The entire tile would be square. This portion, being half of the whole, consists of course of two squares, each square representing a quarter of the tile, which thus consists of four repeats of the same ornamental form. Having drawn the two squares, proceed to draw diagonals in each, corresponding with A B C D. Draw the centre lobe of the ornament, using A B as the centre line. The curves, turning in a continuous direction, bend outward, and are kept balanced by the line E F, parallel to the diagonal C D. The rest of the figure will be easily followed from the example, care being taken in the exact balancing of the sides.

As it is intended that the student should complete the tile, he should draw the whole square at starting, and divide it into quarters; the diagonals are then to be drawn in each of these smaller squares, and as any single part of the ornament has been sketched in one compartment, it should be repeated in each of the others respectively, until the whole is completed; by this means each line can be singly compared with the others, and thus the balancing of the forms will be facilitated.

When the whole outline has been carefully revised and "lined in," the design may be coloured: the ground may be black and the ornament Venetian red; or the ground may be blue and the ornament orange; or the ground may be crimson and the pattern green, or any such combination, according to the taste of the student. It must, however, be remarked that, since the floor-tile is intended to ornament a perfectly flat surface, no attempt at shading must be made, since shading has the effect of causing the form to appear to be raised, or to stand up from the surface; and it will easily be understood that anything approaching *raised* ornamentation would be out of place on a floor.

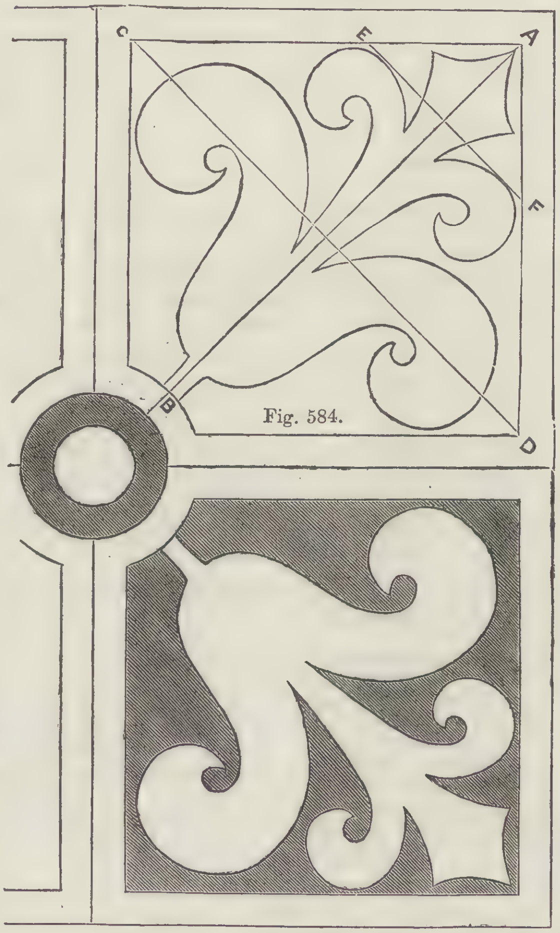

Fig. 584.

The colours used for colouring this and similar designs are not the usual cakes supplied in colour-boxes—though, of course, these would answer the purpose if others cannot be obtained—but, owing to the transparency of most cake colours, it is rather difficult to cover surfaces evenly; and in this example the spotty appearance thus caused is very disagreeable, whilst much time would be spent in "stippling" up the work.

The colours best adapted for this purpose are those called "body-colours." They are sold either in powder, or in some cases, in lump, by the artists' colourmen. These are ground up, first with water, and then with the addition of a little gum arabic, white of an egg, or weak size. Very good body colours may be obtained under the name of "moist colours," in metal tubes, which are found to answer the purpose very well. They are more expensive than the powder colours, but are more finely ground, and are mixed with gum, or other medium, requiring only the addition of water to be ready for use.

LINEAR DRAWING (*continued*).

BRICK ARCHES.

The general principles of arches having been elucidated in "Building Construction," it will be unnecessary here to repeat the lesson. We will, therefore, only remind the student of some technical terms used in relation to arches, such as the *piers* and *abutments*, which support them; also the *span* or width, and the *rise* or height of an arch. The *skewbacks*, or sides of the ring of brickwork, when the arch does not spring from a horizontal plane; the *haunches*, or lower segments of each side, as distinguished from what common bricklayers call the scheme part, or upper segment of the arch; the *intrados*, or whole interior, of the lower surface; the *extrados*, or whole exterior, or upper surface; the *crown*, or summit of an arch; the *voussoirs*, or arch-stones; and the *key*, or *keystone*.

The various kinds of arches—such as straight, segmental, stilted, Gothic, etc.—have also been described in the articles on "Building Construction."

The arches used in buildings of any importance are of two kinds—external and internal.

The former are executed with great care, and in an ornamental manner; the latter are done strongly, but roughly, being afterwards concealed from view by the inside finishing of rooms, etc.

CIVIL ENGINEERING.—XVIII.

BY E. G. BARTHOLOMEW, C.E., M.S.E.

LIGHTHOUSES (*continued*).

THE name of Smeaton will ever be associated with the Eddystone. It was upon these weather-beaten rocks, which had already borne two lighthouses, one of which was destroyed by water and one by fire, that the great engineer was to erect the monument which for nearly 120 years has nobly withstood the buffetings of the elements.

It is worthy of note that at the time Smeaton was recommended by the then President of the Royal Society, the Earl of Macclesfield, for the task of rebuilding the Eddystone Lighthouse, he was not an engineer either by profession or education. A philosophical instrument maker by trade, he confesses that when he commenced his designs he was a total stranger to such structures. He had, however, studied very carefully the character of the two previous lighthouses; and whilst he was prepared to retain all the good points in them which presented themselves to his judgment, he was ready to bring his great genius and large stock of common sense to improve upon their weak points, and altogether abandon their faulty ones.

What his views upon the matter were we shall best explain by quoting the drift of his own words. He says, "It appeared evident that had it not been for the courses of moorstone (in Rudyerd's structure) inlaid with the frame of the building, and acting like the ballast of a ship, it would long ago have been upset, notwithstanding all the branches of iron-work contrived to retain it; and that in reality the violent vibration which the late building was constantly subject to, had rendered its base or seat in some degree rounding, like the rockers of a cradle. It seemed, therefore, a primary point of importance to procure, if possible, an enlargement of the base.

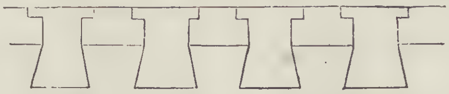

Fig. 39.

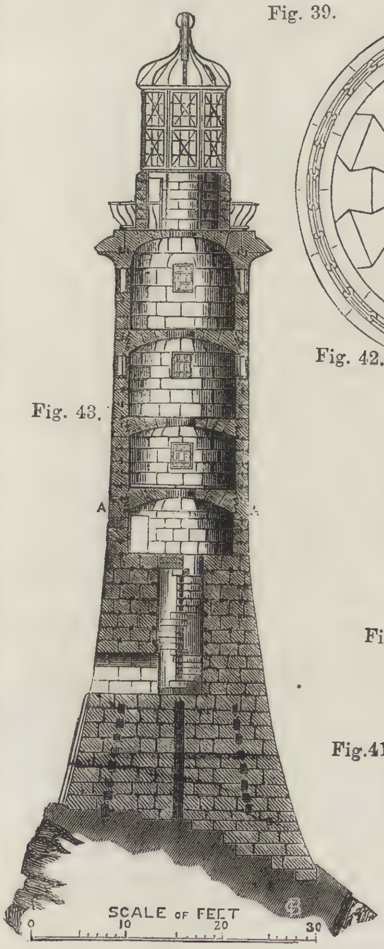

Fig. 43.

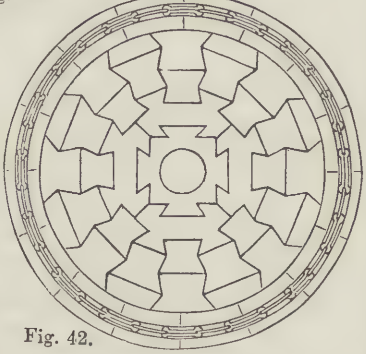

Fig. 42.

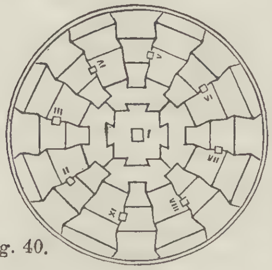

Fig. 40.

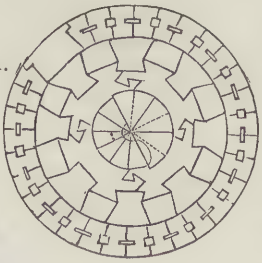

Fig. 41.

It also seemed desirable to adhere strictly to the conical form, or at least to a modification of the conical form." He observes, in reference to the true cone, "The necessary consequence would be, that the diameter of every part being proportionally increased by an enlargement of the base, the action of the sea would be greater upon the building in the same proportion; although as the strength increases in proportion to the increased weight of the materials, the total absolute strength to resist the action of the sea would be greater by a proportional enlargement of every part, *but would require a greater quantity of materials.* On the other hand, if we could enlarge the base, and at the same time rather diminish than increase the size of the waist and upper works, as large an amount of strength and stiffness would arise from a larger base, accompanied with a less resistance to the acting power, as if a similar conical figure had been preserved, whilst at the same time *a less quantity of material* would be employed." A stone edifice having been determined upon, the engineer, following up the mode of reasoning stated, decided upon giving his structure the waist of a large spreading oak. He made a model in wood, having a small degree of tapering, and then fitted it to the oblique surface of another block—the surface of the Eddystone being sloping—and found that by arranging the several curves, they could be firmly united to form an efficient foundation. The model having given satisfaction, the works were ordered to be commenced forthwith.

Before proceeding further with an account of the construction of Smeaton's lighthouse, we wish to direct the attention of our readers to the paragraphs we have italicised. It will be observed how careful the engineer was to avoid the unnecessary employment of material, and by what a happy train of reasoning he arrived at the method of doing so. Well would it be if, upon every occasion, the engineer sufficiently studied the design he has to carry out, and the work he has to do, as that just so much material as is necessary should be employed, and no more. It is an absolute fact that there are many engineering operations which are actually *weakened*, by the unnecessary employment of material. The work is burdened with weight, and the material which adds to the weight adds not the least atom of strength to the design; expense is unnecessarily incurred, and often the design is rendered clumsy and unsightly. We purpose referring more particularly to this important feature in engineering works, the useless employment of material, in a subsequent paper.

Having definitely decided upon the material to be employed, and the form to be given to the lighthouse, Smeaton's thoughts were next directed to the best method for uniting his stone blocks. He had, after careful inquiries in the neighbourhood, decided upon using moorstone for the basement and lower portion of the building, and Portland stone for the upper portion. Accordingly, he contracted for 240 tons of the former, at 25s. per ton roughed out, and 4d. per foot superficial for working the beds. This price, however, did not include the cost of conveyance to the rock, but only to the yard at Plymouth. The moorstone is taken out of the quarry by splitting it with a number of wedges driven into notches or grooves cut in the surface about 4 inches apart, more or less, according to the size and strength of the block. The holes are sunk with the point of a pick. The mode of quarrying the Portland stone has been alluded to in our description of the Portland Breakwater. The manner of uniting the blocks deserves careful attention. At first Smeaton's thoughts were directed to iron cramps, but after mature thought this plan was rejected; then the idea of dovetailing, as employed in woodwork, occurred to him. He had seen something of the kind in a description by Belidor of the stone floor of the great sluice

at Cherbourg, where the tails of the upright headers are cut into dovetails, for their insertion into the mass of rough masonry below. (See Fig. 39.)

"From these beginnings," he says, "I was readily led to believe, that if the blocks themselves were, both inside and out, all formed into large dovetails, they might be managed so as mutually to lock one another together, being primarily engrafted into the rock; and in the round and entire courses above the top of the rock they might all proceed from, and be locked to, one large centre stone. It is obvious that by this method of dovetailing, while the slope of the rock was made good by cutting the steps formed by Mr. Rudyerd also into dovetails, it might be said that the foundation-stones of every course were engrafted into, or rather rooted into the rock; which would not only keep all the stones in one course together, but prevent the courses themselves, as one stone, from moving or sliding upon each other. But after losing hold of the rock by getting above it, then, though every stone in the same course would be bonded in the strongest manner with each other, and might be considered as a single stone, which would weigh a considerable number of tons, and would be further retained to the floor below by the cement, so that, when completed, the sea would have no action upon it but edgeways; yet as a force, if sufficiently great, might move it, notwithstanding its weight, and the small hold of the sea upon it, and break the cement, before time had given it that hardness which it might be expected to acquire afterwards, I had formed more expedients than one for fixing the courses to one another, so as absolutely to prevent their shifting." Such is Smeaton's description in his own words of the method he proposed to adopt in uniting the component pieces of his work, and the reason of his doing so. We shall see how well he carried out his purpose.

The mortar used was compounded of blue lias lime and puzzolana in equal quantities, prepared by beating it up in a strong wooden bucket with a wooden pestle. The lime, in quantities of a quarter of a peck at a time, was beaten first, and when formed with sea-water into a thin paste, the puzzolana was gradually added whilst the beating was continued.

The system of dovetailing determined upon, necessitated an immense amount of labour upon each individual block, and the accuracy required in fitting the pieces together rendered it desirable to arrange each course in a completed state, which could then be taken to pieces for transport to the rock. Application was made to the Mayor of Plymouth to permit the temporary use of one of the municipal buildings for the purpose of fitting the courses together, but it was refused; and a shed was hired for the occasion. The greatest care was requisite to prevent any confusion in the relative position of the stones. For this end, each stone was marked or numbered, and lines were drawn across the middle of each tending to the centre. The result of this precaution was that no difficulty or delay occurred in bedding the stones into their position upon their arrival at the rock. We subjoin plans of a few of the courses, showing the method of jointing adopted. Fig. 40 represents the first course, which was composed wholly of hewn stone. It is the seventh from the bottom course, which latter consisted only of four hewn stones, lying as it did at the bottom of the slope of the reef. The stones increased gradually in number in each course from the bottom until the seventh was reached, consisting of four, thirteen, twenty-five, twenty-three, twenty-six, and twenty-six stones each respectively. As one stone or more of each of these six bottom courses were engrafted in dovetail recesses cut into the solid rock, there could be no danger whatever arising from the horizontal force of the sea acting against them; but the seventh course rising entirely above the rock, a plan was adopted by the engineer for producing an artificial arrangement which should cause a similar effect. This plan was as follows:—In the centre of the sixth course, and in eight regular positions around this centre, holes were cut in the stone 12 inches square. The centre hole was 13 inches deep, and the remaining eight were 6 inches deep. Into these nine holes, blocks of hard marble from the Plymouth rocks, 12 inches square, were introduced, and securely fixed in their positions by mortar and wedges. Corresponding holes to these marble blocks were cut in the proper stones of the seventh course, as shown by the figures in Fig. 40; and the projecting ends of the blocks were introduced in them, and were thus most immovably fixed against any force acting horizontally.

In this manner seventeen more courses were carried up, the whole being solid, with the exception of the winding staircase and entrance doorway, which commenced on the fourteenth course from the bottom. A height of 27 feet above ordinary spring-tide high-water mark was thus attained, and at this point the hollow or habitable portion of the building commenced. In Fig. 41 we give a plan of the twenty-fourth course, in which the dovetailing arrangement of the exterior stones is shown. This system was adopted at this stage, because the building lacked the benefit of the interior stones to tie the several courses together. The diameter of the building immediately above the rock is 25 feet, but at the course shown in Fig. 41 it was reduced to 16 feet 8 inches, the rooms being 12 feet 4 inches in diameter, and the walls 13 inches thick. The walls were composed of single blocks of moorstone, sixteen in each course, cramped with iron, and joggled at each joint. The joggles are of sawn marble 8 inches long, 4 inches broad, and 3 inches thick.

At the twenty-eighth course the vaulted floor forming the ceiling to the upper store-room was introduced, and into this course was laid the first circular iron chain, which was lodged in a groove cut round the middle of the upper surface of the stones. The necessity for this chain, shown in Fig. 42, which represents the twenty-ninth course, marked A A in the section (Fig. 43), will be apparent from the nature of the construction of the floor resting upon this and the course above.

By reference to the section it will be seen that each floor rests upon two courses, and although arched it has not the benefit of sloping abutments to support it. Had each floor consisted of a single stone, there would have been no outward thrust to provide against; but being made in pieces, it had the same tendency to thrust the encompassing walls outwards, as the component stones of an arch; although, irrespective of the encompassing chain, the system of dovetailing which was also introduced in the floors tended to mitigate the evil of the lateral pressure.

Smeaton adopted the endless chain by a consideration of its value in the cupola of St. Paul's Cathedral, where it had been introduced by Sir Christopher Wren. Each of the floors is encompassed by two endless chains, the bars or links of which are $1\frac{1}{2}$-inch square, and the grooves receiving them are 4 inches deep and wide. After each chain was laid in the groove 11 cwt. of lead was run in.

The height of the main column containing forty-six courses is 70 feet, and its diameter at the top 15 feet. The lantern is formed almost entirely of copper. It consists of sixteen frames, with nine panes of glass in each. The lantern is 24 feet high, and the diameter 9 feet. The light was originally derived from a chandelier 6 feet 4 inches in diameter, to contain sixteen candles; and a smaller one within and above it, 3 feet 4 inches in diameter, to contain eight candles. In 1807, however, the chandeliers were removed, and a reflector-frame substituted, fitted with argand burners, and parabolic reflectors formed of copper, covered with highly polished silver.

Smeaton completed this elegant and substantial building in rather less than three and a quarter years.

We shall present to our readers the description of another lighthouse, as being an excellent specimen of marine engineering, the Bell Rock Lighthouse, erected by Mr. Robert Stevenson. The Bell Rock is situated in the German Ocean, eleven miles S.W. from the Redhead, in Forfarshire. The rock is a red sandstone, the surface being very rugged and full of cavities. The north-east end is the highest portion of the reef, and is partially left dry at low water of neap tides, but the lower level is only visible at springs. The spring tides here rise and fall 15 feet, and the neaps 9 feet.

In 1806 an Act of Parliament was passed to construct a lighthouse upon this rock, and it was decided by the Commissioners to adopt a design similar to the Eddystone. Owing, however, to the nearer coincidence of level between the Bell Rock and the mean level of the sea, as compared with the Eddystone, the operations were greatly more difficult at the outset. The commencement of operations was ushered in by mooring a vessel, fitted out as a light-ship, about one and a-half miles N.E. of the Bell Rock, to be employed as a tender during the first season's operations, to which the artificers retired

whilst the rock was covered with water. The distance of the nearest land from the rock being so great, and the set of the tide so strong, the advantage of a place of refuge at so short a distance is obvious. The light-ship was moored in twenty-two fathoms of water, her moorings consisting of a mushroom anchor weighing 33 cwt., and a heavy chain, to which she was attached by a hempen cable 14 inches in circumference; and at these moorings she rode without accident for four years. The method of lighting this light-ship was peculiar. The vessel had three masts, and each mast was fitted with a cylindrical lantern, the mast passing through its centre. Each lantern contained ten lamps, with as many silver-plated reflectors, arranged around the mast, so that on no side was the light obscured.

Early in 1807 stones were collected from the granite quarries of Rubeslaw, in Aberdeenshire, for the *outside casing* of the first 30 feet from the base, whilst sandstone for the interior or hearting of the solid portion, and for the upper portion of the building, was procured from Mylnefield quarry, near Dundee. The cornice and parapet wall of the light-room were prepared at Edinburgh, and the stones taken from Craigleith quarry. A piece of ground at Arbroath was leased for a work-yard, and here materials were laid down, and workmen collected; sheds also were constructed, and a barrack erected for the accommodation of about 100 artificers. Operations were commenced at the rock itself in August, 1807.

MAP AND PLAN DRAWING.—II.

By C. C. King.

SCALES — COMPENSATING INSTRUMENT — TRIANGULATION: BASE-LINE OF SURVEY, ETC.—SURVEYING CHAIN—LEVELLING—CONTOURING—DELINEATION OF MAPS AND PLANS.

So far, then, we have only obtained a single definite point on the actual surface to be surveyed, and the means of transferring it relatively to the paper on which the projected meridians and arcs of latitude are drawn. The results of the various steps which have now to be taken may either be immediately represented as they are taken, which would only occur in smaller surveys, or, when calculations and corrections have to be entered into, this may be deferred till the work is more advanced. Ultimately, however, the representation must be produced, and then the question of the scale to which the map is to be made has to be considered.

A scale is merely the relation that exists between any dimension on the true surface, and the same as represented on the map. The size of the map, therefore, entirely depends on the scale that is selected, and this is again determined as a rule by the size of the paper on which the map is to be drawn. Thus, if the extreme limits of the area are 1,000 miles laterally, and the size of the paper is about a foot square, the scale will have to be one of 1,000 miles to 10 inches, suppose, or 100 miles to the inch; by which it is inferred that every inch on the map corresponds to 100 miles of true measurement, and that if therefore the inch be divided into 100 equal parts, each one may be considered to show the relative value of one mile on our paper. This is the principle on which scales may be constructed, and practically are so on smaller sketches where the space available for drawing is the chief consideration; but there are numerous scales already prepared for convenience' sake on the ivory or wooden protractors and "scales" in every box of mathematical instruments to suit ordinary maps. Thus we usually find the inch divided into 20, 30, 35, 40, or 45 equal parts, representing so many different proportions of miles, yards, or feet to the inch, and numerous other subdivisions of the same unit, such as twelve parts to the inch, useful in a large scale where feet and inches alone are the principal dimensions. In English maps the "scale" is usually denoted as one of so many miles to the inch: thus in the Ordnance Survey we find one mile to the inch; but in Continental maps it is represented by a fraction, giving the ratio of the map to the actual area, as, for example, $\frac{1}{1000000}$ or $\frac{1}{63360}$. The latter fraction is but another method of defining one mile to an inch; for

The ratio of the map : the true area : : 1 : 63,360.
: : 1 inch : 63,360 inches.
: : 1 inch : 1 mile.

In either case, the scale is actually drawn on the map, a convenient length being taken which is divided into the required number of parts, and if it be large enough, the left-hand division is further marked off into a certain number of small ones, to admit of more minute measurement. Thus if the principal divisions show lengths of ten miles, the first will contain ten equal and smaller portions. Standard atlases generally contain two or three scales for different purposes, as, for example, those of geographical or Italian miles, of which there are 60 to a degree; French kilometres of 111·307 to a degree; German geographical miles of 15 to a degree; and lastly, the scale which is appended to every English map, the statute mile of 69·16 to a degree.

The scale then being determined, the survey can be proceeded with. The base-line has to be measured, and carefully aligned, so that its length and position may be marked on our skeleton map, as well as furnish one absolutely accurate side for the first triangle of the triangulation. For this purpose a theodolite, of large size usually, is fixed at one extremity of the base, and remains there during the whole of the operation, to prevent any lateral deviation from the straight line during the measurement. Rods are planted in the ground at intervals of from a half to three-quarters of a mile, and the inner edges of these are carefully aligned by means of the telescope of the instrument. The starting-point is marked by a block of stone carefully fixed and levelled, and having on its upper surface a metal plate containing a minute point carefully marked.

Various materials have been used for measurement, owing to the absolute necessity for exactitude, and the difficulty of regulating or calculating the alterations made by the expansion of the measuring bar at different times of the year or even at different times in the same day. Thus steel chains, glass, platinum, or deal rods made into rigid wands, have been employed in various instances, and the latter material was used in the re-examination of the Hounslow Heath base, first determined by steel chains in 1784; but in using any of these the temperature has to be noted as every chain is laid, for the expansion of the materials varies with the temperature, and there was at that time no arrangement for making the instrument itself correct its own inaccuracies from this cause.

A more perfect apparatus has been devised for modern surveys, which approaches as nearly as possible complete accuracy. It is a compensating instrument, the construction of which is based on the principle of the unequal expansion of metals. Two rods of iron and brass, about ten feet long, are welded together at their centres, and laquered so as to equalise the influence of the variations of temperature on them. At their extremities are attached two tongues of iron, fixed at right angles to the bars and projecting beyond them, and on their outer parts a minute point of platinum is inserted. The action of the expansion is as follows:—

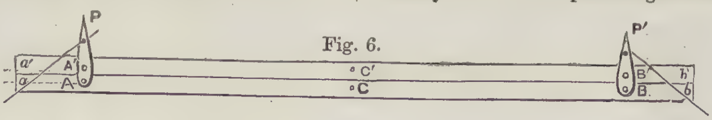

Fig. 6.

Let A B and A′ B′ (Fig. 6) be the two rods united at C C′, and let A P and B P′ be the metal tongues. Now A′ C′ and A C are equal to one another at a given temperature; but if the rods expand to the points a' a and b' b the position of the points P and P′ are unaltered. For assume the increase of temperature to be t, and the coefficient of expansion to be m; then

$$\text{A}a = \text{AC} \,.\, m \,.\, t\,;$$
$$\text{A}'a' = \text{A}'\text{C}' \,.\, m \,.\, t\,;$$
$$\therefore \quad \frac{\text{A}a}{\text{A}'a'} = \frac{m}{m'} = c\text{, a constant.}$$
$$\text{But} \quad \frac{\text{PA}}{\text{PA}'} = \frac{\text{A}a}{\text{A}'a'}\,;$$
$$\text{Therefore} \quad \frac{\text{PA}}{\text{PA}'} = \text{a constant.}$$

That is, A P is independent of the temperature t; and even though expansion occurs, the position of P, or P′ by similar reasoning, remains unaltered.

The distance P P′ is accurately adjusted in the construction of the instrument. These rods are then placed in boxes for the sake of preservation, the points or tongues projecting beyond them, and levels and telescopic sights are fixed to these outer casings both to align the successive bars and level them. They are carefully set up on small platforms resting on trestles, and aligned and levelled by means of "small motion" screws. Five of these instruments were used in the measurement of the Irish base, and after being brought into the alignment another instrument was employed to overcome the difficulty of bringing the points of any two bars in exact contact or juxtaposition. A powerful double microscope, fitted in a compensating frame, of similar character to that of the bars themselves, was placed between two bars. Spirit-levels were attached for adjustment and a telescope for alignment, and the two lenses of the instrument, which were exactly six inches apart, were furnished with micrometric screws, which enabled one of them to be focussed over the platinum point at the extremity of a bar. The microscopes being rigidly fixed to one another, so as to preserve their relative distance, the point of the adjacent bar was brought beneath the lens of the remaining microscope by means of the small motion screws provided to give the measuring rod a slight lateral motion. Thus five bars, giving a length of fifty-two feet, were laid at one time, and the rate of progression was about 250 feet per day. In order to transfer the extremity of the last measurement taken on each occasion to the ground, and enable the work to be carried on the following day, a microscope with a long focus was fixed mid-way between those above described, and a block of stone protected by an iron cover, in which there was a brass disc containing a small silver plate, was securely embedded in the earth, immediately below the focus of the central microscope of the frame. Extreme care was taken lest this should be disturbed, and it was therefore covered at night by a wooden cover and watch kept over it.

Thus the base-line of the survey is most carefully determined, and even if a sufficient length cannot be obtained by actual measurement the length can be extended, provided a considerable line has been measured, by a system of triangulation based on the portion already traced. The accompanying figure (Fig. 7) will explain this. The only thing to be noticed is that the points E, F, G, H, I, J, are clearly visible from the starting-point A, and are nearly at right angles to the points D, K, B, which have been carefully noted and fixed during the measurement. The various parts of the triangles are thus determined, until finally the measured base A B is extended by calculation to the point C (Fig. 7).

Before the base can be considered complete it is reduced to the horizontal plane, if there are any irregularities in the surface over which it has been conveyed, and finally to the level of the sea. This is necessary in accurate work, as the arc actually determined is greater than that which would be measured on the surface of the sea, to which all heights and dimensions are referred, on account of the sphericity of the earth.

Having completed the determination of the base-line, the more prominent or most central and convenient points are fixed for the greater triangulation. Powerful theodolites are used for this purpose, and care is taken that the triangles are as nearly equilateral as possible, so as to avoid the inaccuracy taking very acute angles would induce. The theodolite is simply a telescope fitted on a stand, and capable of receiving movement in a vertical plane, for which purpose it rests in a support, provided with a vertical graduated arc working on carefully adjusted points, and also partaking of a horizontal movement. This is arranged by having the upper telescope frame referred to fixed on a metal disc, having a vernier, which works smoothly and accurately on a lower one, which is graduated on its circumference from zero to 360°, and which admits of being levelled by means of vertical "plate" screws. Two spirit-levels at right angles to one another are fixed for this purpose on the upper plate, which is moreover bevelled or chamfered on the edge to form a sloping surface on which the angular measurements taken can be the more easily read.

The triangulation proceeds from the base-line in a series of gradually increasing triangles, and these are repeatedly taken, their means carefully calculated, and their reduction to the true surface completed by mathematical calculation. A very large theodolite is used for this portion of the survey, and as the distances between the points of the triangles were frequently very great, or, as in the case of the distance between London and Shooter's Hill, much obscured by the smoke of the City, an ingenious device was employed to enable these long sides of the triangles to be ascertained. A reflector is placed at one of the points, and constantly moved so as to reflect a ray of light in the known direction of the other extremity of the line. The observer there directing the telescope of the theodolite in the direction of the reflector, moves the instrument over a very small field by means of the "small motion" screws, until a ray of light is reflected into it; the telescope is then allowed to remain stationary until a second ray verifies the accuracy of the preceding observation. Great distances have been readily fixed, and points forty-five miles apart have been thus determined.

When the greater triangulation is completed, the minor points, those of less importance, are united by a series of smaller triangles, until we can finally mark down on the map the relative position of all the prominent natural and artificial features of the area, the whole of which, with the exception of the base-line, have been fixed by mathematically corrected trigonometrical calculation. The remainder of the work is done by absolute measurement with a chain, the small theodolite being still used for correction, and to determine the bearings of the points with regard to those of the greater triangles.

Fig. 8.

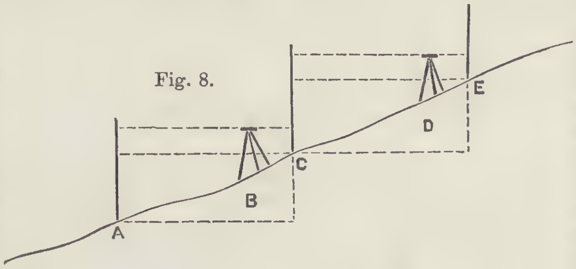

Fig. 7.

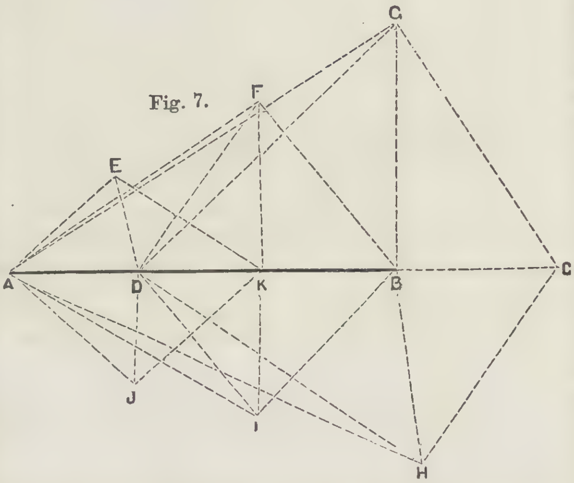

The surveying chain is a metal chain composed of iron wire links, one hundred in number, connected by oval rings, the extremities being terminated by swivels and open handles. It is divided into ten equal parts by pieces of brass which are loosely attached to the chain, and which are divided at their outer ends into as many projections as will indicate the number of links at these points from the ends of the chain. In using it it is carefully stretched straight, and the workman carrying the front end marks the point at which the extremity rested by a small metal rod or arrow of which he has ten, and the second surveyor, after advancing to the point and aligning his end of the chain with it, removes the arrow and carries it until the whole ten remain in his hand. This serves to correct the number of times the chain has been used in any measurement, as it would be at any time indicated by the number of arrows. Corrections have to be made for temperature and for sloping ground, and much skill is required, and frequent adjustment of the chain to a standard measure is essential to accurate work.

By these means the whole of the area treated as a plane sur-

face—that is, without reference to its differences of level—will be mapped. It now remains, therefore, to find the different altitudes of the various elevated portions, and to ascertain further the position and character of different levels taken throughout the country, and which serve to determine the shape of the physical features. The former are obtained by levelling, the latter by contouring.

Levelling means the method of ascertaining the altitudes of any points above the surface of the sea, which is called the "datum level." In England the datum level is that of the mean tide at Liverpool. It is conducted by means of a theodolite, either by taking the angles of elevation or depression from point to point, which necessitates much correction for the curvature of the earth and for refraction, or by the more correct and general method of using the instrument as a spirit-level. Other instruments, which, as their names denote, are merely telescopes capable of being accurately adjusted horizontally, such as the Y level and the "dumpy level," are frequently employed for the same purpose. It is usual to start from one of the "bench marks," that is, one of the points of the greater or lesser triangulation which has been carefully marked on a fixed stone or a building. A levelling rod, which is a telescopic bar made thus for portability, so as to obtain as long a rod as possible with but little inconvenience, and which is graduated in feet and inches, is placed perpendicularly on or close to this point A (Fig. 8), and the theodolite stationed in some convenient position, B, is levelled, the telescope directed on it, and the reading in feet and inches noted down. The rod being now removed to a position, C, higher up the slope, the reading is again taken without removing the theodolite, and the difference between the two observations manifestly shows the difference of level of the two stations fixed by the levelling staff. This, if continued, will ascertain the required altitudes, and is, roughly speaking, the principle of levelling, though there are many minor operations connected with it which serve to correct inaccuracies.

Contours are only shown in maps of very large areas, when an orographic map is alone required to show the relative heights of mountain chains. It would, unless a very large scale is used, tend to encumber the paper with too much detail; but as sections are frequently determined by it, and in some small surveys it is often employed to portray conveniently the shape of the physical features, it will be necessary to examine briefly the method of operation. If we imagine a line to be traced round the coast of a country at its datum level on the sea, a continuous curved line, marking the form of all the features, will be produced. If again we assume the sea to rise to a certain height, and then for a similar line or contour to be made, and so on at regular intervals, a series of curves, finally becoming closed curves more or less concentric, will be obtained, which will at each of these levels delineate completely all the hills and valleys, plateaus, and intricacies of every portion of the country. Contouring consists in tracing out and depicting these lines, and is performed practically by a levelling staff and small theodolite. The latter is stationed at a point whence a view over a large area can be embraced, and the staff is placed at a certain point, the altitude of which has been ascertained previously, and through which it is purposed to make the contour pass. The theodolite carefully levelled is directed on it, and the reading in feet and inches taken, after which the levelling staff is removed to a successive series of points, at each of which it is gradually moved up or down the slope, until the wires in the telescope of the theodolite or level again cut the same height on the staff as they did at the first operation. Manifestly the points on which the staff rested are therefore on the same level, and are marked with small pickets. The positions of these are determined by the chain, and by taking their relative bearings with the theodolite, and the small intervening spaces are sketched so as to complete the contoured line.

Thus the entire delineation of the area, its features, its towns or villages, the direction of its roads, if the map be a topographical one like the Ordnance Survey of the United Kingdom, have all been determined, and by the use of the scale can be transferred to our paper. Even in large atlases but a small portion of this information can be delineated for want of space, and the towns and cities and the river-lines, or mountain chains, can only be given. The amount of information that can be given by a large scale will be more fully referred to in considering the construction of a "plan;" but in the maps of countries such as France or Russia, depicted on scales suitable to ordinary atlases, there are but few noticeable points.

The sides of the map show the number of degrees in the parallels of latitude, for every five degrees generally, the arcs themselves being designated by the numerals, and the intermediate spaces being subdivided into the number of degrees lying between each arc. The top and bottom of the map show in a similar manner the degrees of longitude, and thus by marking the intersection of any of these co-ordinates, the latitude and longitude of given points may be found. Rivers are marked by a single irregular line if small, and by a double line if large, on maps of great dimensions; while the character of the cities is shown by the letters by which their names are expressed. Thus capitals or places of the first rank are marked in Roman characters; towns of the second rank in smaller type, but still vertical lettering; while places of less note are designated in small type with slanting or italic lettering: thus, **BERLIN**, SMOLENSK, *Salisbury*.

The mountain ranges are represented by fine lines, nearly parallel at first, commencing at the summits of the hills, where they are usually dark, and extending approximately to the plains, where they become lighter and more divergent. These lines are called *hachure* lines, and represent the course that would be taken by rills of water trickling from the summits to the plain. They are invariably used in the larger species of maps, as they interfere but little with the general clearness of the representation.

NOTABLE INVENTIONS AND INVENTORS.

XXVIII.—SIR ISAMBARD BRUNEL.

BY JOHN TIMBS.

THE lives of the two Brunels, father and son, were for more than half a century strikingly identified with the progress and the application of mechanical and engineering science.

The elder Brunel, Isambard Mark, was born in 1769, in Normandy, at Hacqueville, a few miles from Rouen. His parents, who were respectable agriculturists, had four children, of whom Isambard was the eldest. He was intended for the priesthood, but from his earliest boyhood showed a decided inclination for mechanical pursuits; and when at the college of Gisors he would steal away to the village carpenter's shop, and draw faces and plans, and learn to handle mechanical tools; and it is related that one day, seeing a new tool in a cutler's window, he pawned his hat to purchase it. He was next sent to the seminary of Nicaise, at Rouen, where he preferred the study of exact sciences, mathematics, mechanics, and navigation, to the classics. In his play-hours, he loved to watch the quay; and seeing some large iron castings landed from an English ship, he inquired whence they had been brought, and on being told from England, the boy exclaimed, "Ah, when I am a man, I will go and see the country where such grand machines are made." On his return home, though only twelve years of ago, he was already a proficient in turning, in the construction of models—ships, machines, and musical instruments—and is stated to have invented a nightcap-making machine, which is still used by the peasantry in that part of Normandy. He also made an octant, guided by the one belonging to his tutor, and by a treatise on navigation; and at the age of fifteen he took such interest in astronomy as to observe the stars, greatly to the astonishment of the villagers. All this precocity was little gratifying to his father, who would have preferred to see his son in the church or in some merchant's office.

Brunel next passed some time in the family of M. Carpentier, a friend of his father, at Rouen, and went through a regular course of lessons in drawing, perspective, and hydrography. Influenced, probably, by M. Carpentier, who had been a trading captain, Brunel enlisted as a sailor in 1786, from which date up to 1793 he made several voyages to the West Indies. He was remarked for the skill, intelligence, and good humour with which he discharged a seaman's duties. He used instruments of his own construction, and while making a pianoforte, when the ship once lay at Guadaloupe, he also made for himself a quadrant in ebony. His ship having been paid off in 1793, Brunel went to Paris, where he got embroiled in the fury of the Revolution; but he escaped to Rouen, and thence fled to the United States. At New York he joined a party of his countrymen

who were about to explore the shores of Lake Ontario to survey the lands of a French company. Brunel led the party of seven persons encamped in the woods, and found a charm in the adventurous work. In 1794 he was appointed, conjointly with one of his fellow-explorers, to survey the canal which now connects Lake Champlain with the river Hudson at Albany. With this work Brunel's career as an engineer may be said to have begun. He next sent in a design for the Houses of Congress, which, though acknowledged as the best, was rejected as too costly and magnificent for simple republicans. He afterwards acted professionally as an architect; and, among other works, built and fitted up the Park Theatre, New York, since burned down. He was appointed chief engineer for New York, and was there employed in the erection of the forts for the defence of the city, and in the establishment of an arsenal and foundry, where his ingenious contrivances for boring cannon and moving large masses of metal with facility showed how successfully he could bring new ideas to bear on the work immediately in progress.

Brunel left New York in January, 1799, and landed in Falmouth in March, where he met Miss Sophia Kingdom, with whom he had become acquainted when in the family of his friend Carpentier at Rouen. This acquaintance, and a desire to work among the scientific engineers of Europe, drew him to England. He married Miss Kingdom shortly after his arrival. He brought with him to England an autographic machine for copying maps, drawings, and written documents; a machine for twisting cotton thread and forming it into balls; and a machine for trimmings and borders for muslins, lawns, and cambrics.

In the accounts of Brunel's inventions, it is stated that the idea of making block pulleys for ships by machinery first occurred to Brunel while he was in New York; but the accuracy of this statement is denied, as we shall presently show. He was employed by Government to carry the plan into execution in the dockyard at Portsmouth. The contrivance comprises, so to speak, sixteen different machines, all driven by the same steam-power, seven of which cut and shape logs of elm or ash into the shells of blocks of any required size, while nine fashion stems of lignum-vitæ into pulleys or sheaves, and form the iron pin, which being inserted, the block is complete. Four men with this machine turn out as many blocks as fourscore did formerly, and at less cost. The supply has never failed, even in time of war, though 1,500 blocks are required in the rigging of a single ship of the line. This machinery, erected by Maudslay in 1804 at Portsmouth, though very complex, in twenty-five years required no repairs. It cost £46,000, and the saving per annum in time of war has been £25,000. A second set of machinery was executed in 1807 for the dockyard at Chatham. There is also a set of magnificent models of this invention in the possession of the Navy Board. The machines work in succession, so as to begin and finish off a two-sheaved block, four inches in length, in the most perfect manner. The entire details of this machinery would far exceed our limits; but the principal parts of which it is composed are clearly described in the first supplement to the *Penny Cyclopædia*.

As to the claim for the invention, when the models were exhibited at South Kensington in 1864, it led to the repetition of the statement that the machinery was invented by Brunel, to which a correspondent of the *Times* replied:—

"Sir Isambard Brunel did not invent, nor did he ever claim to have invented, the block machinery which he had a share in putting up at Portsmouth. The original invention, or series of inventions, was by two men, father and son, each named Walter Taylor, natives of Southampton.

"The beginning was rather more than a century ago" (this was written in 1864), "and was made by the father, who had been at sea, and had been practically impressed with the inefficiency of the blocks in use in his time. After a time they took out a patent for part of their inventions, and subsequently a second patent. These included friction-wheels and circular saws, both of which we owe to the Taylors. During the continuance of their patents, they, under contract, supplied the Government with blocks for the Navy, and for some years they were the only blocks used in the Royal Navy. When, towards the close of the last century, their patents expired, they wished to obtain an extension of them; but the Government objected, and decided for setting up the machinery for themselves.

"Mr. Walter Taylor, the son, who was then making his blocks at the Wood Mills, South Stoneham, near Southampton, generously offered to the Government every facility for the purpose. The Government employed two clever young men to set up the machinery, one of whom was Mr. (afterwards Sir) Isambard Brunel, and the other Lieutenant (afterwards General) Bentham, R.E. With the benefit of Mr. Taylor's explanations, these two young men examined his machinery, and then proceeded to set up machinery on the same principle at Portsmouth.

"Having the resources of Government to back them, they improved the details of the machinery, using for it steam-power instead of water-power, by which Mr. Taylor's mills were worked; but in every essential point the block machinery at Portsmouth is the invention of the Messrs. Taylor. General Bentham's share in the improvements has been forgotten as much as the Messrs. Taylor's original invention.

"Some years ago the specifications of the patents were printed in the *Builder*, and they will enable any one of a mechanical turn of mind, who wishes to ascertain how far Messrs. Brunel and Bentham were indebted to the Messrs. Taylor, to do so easily. The originality of the invention was more than once publicly claimed for the Messrs. Taylor during the lifetime of Sir I. Brunel, and the claim was never contested by him or General Bentham, although General Bentham's widow objected that too little credit had been assigned to her husband."

Mr. Brunel next built in Chatham dockyard the steam sawmill, subsequently improved for cutting veneers, by which double the usual number could be obtained. A popular writer sixty years since describes Brunel's workshops at Battersea, where the single action of a steam-engine of sixteen-horse, or eighty-men power, turned by means of bands four wheels fringed with fine saws, two of eighteen feet in diameter, and two of nine feet. Here mahogany and rosewood were sawed into veneers the sixteenth of an inch thick; the same power at once turning these tremendous saws and drawing their work from them. A large sheet of veneer, nine or ten feet long by two feet broad, was thus separated in about ten minutes. The large saws revolved sixty-five times in a minute; hence, $18 \times 3{\cdot}14 \times 65$ gives 3,672 feet, or two-thirds of a mile, in a minute; whereas, if a sawyer gives thirty strokes of three feet in a minute, it is but ninety feet, or only the fortieth part of the steady force of Brunel's saw.

Brunel next invented a machine for making seamless shoes for the army, which, in regard to subdivision of labour, resembled the manufacture of pins. Every step was effected by machinery; while, as each operation was performed by one hand, so each shoe passed through twenty-five hands, who completed from the hides as supplied by the currier a hundred pairs of well-finished shoes per day. As each man performed but one step in the process, which implied no knowledge of what was done by those who went before or followed him, so the persons employed were not shoemakers, but wounded soldiers, who were able to learn their respective duties in a few hours.

SHIP-BUILDING.—XIV.

BY W. H. WHITE,

Fellow of the Royal School of Naval Architecture, and Member of the Institution of Naval Architects.

THE SKINS OF IRON SHIPS (*concluded*).

THE durability of an iron ship is practically governed by that of the outside plating, which is the part of the structure most liable to deterioration from the oxidising or corrosive action of the sea-water outside, and of the bilge-water within the ship. It will be understood that in making this statement we exclude the wood-work of the decks, inside planking, etc., which may be worn out and replaced many times during the period of service for which the iron hull remains efficient, and no argument will be needed to show the importance of using every possible means to prevent diminution in the thickness of the skin-plates.

The anti-corrosive paint most commonly used on the outer surface of the plates is red-lead, and this is found to answer fairly when renewed at frequent intervals. Other paints and compositions are also employed, most of which are patented; but it is doubtful whether any of them will ever entirely take the place of the cheap red-lead paint. This is also largely used for the protection of the inside of the plating from the

upper part of the bilges to the top-sides, where the wash of the bilge-water is not likely to reach when the ship is rolling at sea. Within these limits further protection is required, and is supplied by a thick coating of cement or asphalte, fixed upon the plating, cement being preferred in most cases. Experience has shown that the corrosive action of the bilge-water—arising from the substances it holds in solution, which render it an active chemical agent, or from other causes, such as galvanic action—is most to be dreaded; and many instances might be referred to in which the rivet-heads and the inner surfaces of the plating have been rapidly corroded when left uncovered. Lloyd's rules require all iron merchant ships to be protected below the bilges by cement or asphalte; and they also point out the desirability of so arranging the protecting material as to facilitate the drainage of the bilge-water to the suction-pipes of the pumps. The latter is an important practical matter, as the lodgment of bilge-water in any part of the vessel should always be prevented. To allow the bilge-water to flow readily to the pumps, holes or "water-courses" are cut in the transverse framing, longitudinals, keelsons, etc., and the cement or asphalte is brought just up to the height of these holes. By these means, when well applied, the corrosion and wasting of the plates are practically prevented, cases being on record where the reduction in thickness has not exceeded one-sixteenth of an inch in fifteen or twenty years.

Fouling cannot be so well prevented as corrosion, although very many schemes for its prevention have been proposed and tried. To give some idea of the number of such schemes, it may be stated that between 1861 and 1866 over a hundred patents for anti-fouling compositions were taken out, and during the same interval other compositions were proposed, the preparation of which was kept secret. At present, after all these attempts, the only means of keeping iron ships thoroughly clean is to dock them frequently, to clean or scrape off the growth of marine plants and animals, and to re-coat the bottom with some composition. Fast merchant steamers, such as those of the Peninsular and Oriental Company, are docked and cleaned about once in every six months, in order that no considerable loss of speed may be caused by foulness. Ordinary merchant ships are docked and cleaned about once per annum, the bottoms being coated with red-lead and some protective composition. In the Royal Navy it is customary to dock iron-built ships at least once a year, and to re-coat the bottoms; but the troop-ships employed on active service are docked more frequently. By this means any serious loss of speed can be prevented, when the necessary accommodation is available; but docks are not to be found in all ports to which merchant-ships proceed, or they may not be of sufficient size to receive the ships. And even when this difficulty does not occur, there is the question of expense to be considered, one which is of no small importance. For example, on the Thames the cost of docking, cleaning, and re-coating an iron ship of 1,000 tons gross register tonnage would probably be from £60 to £80, and for larger vessels the expense would, of course, be greater. In distant foreign ports the charges would necessarily be higher; and it might so happen that the vessel had been so long afloat as to render docking a necessity even under these circumstances. But experience proves that the truest economy is to be found in incurring the expense of cleaning an iron ship's bottom, rather than in allowing it to remain foul, and so greatly reduce the speed. There are instances on record in which vessels have been so retarded by foulness as to lose one-third, or even one-half their speed as compared with their performances with clean bottoms; and on a voyage like that from China or Australia, such a loss would far more than counterbalance the expense of docking and cleaning, considerable though it be. One indirect result of this fact is found in the rapid increase in docking accommodation all over the world since iron ships have been in use. Graving or dry docks, floating docks, hydraulic lifts, hauling-up slips, and other plans, have been devised for affording the accommodation required, and there is now consequently a greater chance of preventing iron ships from becoming seriously foul even on distant voyages.

Repeated trials of anti-fouling compositions show that the best of them cannot be considered efficient after more than an average of nine or twelve months' service. These compositions, it should be noticed, are distinct from the anti-corrosive preparations previously referred to, and are put on upon the latter. In the merchant service red-lead is, as we have said, the anti-corrosive paint most generally employed, and it answers very well. In the Royal Navy, either this, or else Hay's anti-corrosive composition, is generally used beneath the anti-fouling preparations. To name the latter would be tedious; to attempt to describe them would be a most hopeless task. Some inventors have based their schemes upon the belief that the barnacles, and other marine animals which attach themselves to the bottoms, should be poisoned by the anti-fouling compositions; but these plans scarcely appear well-founded, seeing that such animals are said to suffer no inconvenience when subjected to the action of the most deadly poisons. Other inventors, deeply impressed with the advantages of copper sheathing as used on wood ships, have attempted to prevent fouling by using preparations containing copper in some form; but here again failure has taken place as regards the prevention of fouling, and the iron hull has sometimes suffered corrosion in consequence of galvanic action resulting from the use of the copper. Another class of proposals consists in the attachment of cement, or glass, or some other material not likely to have any injurious effect upon the iron, to the outer surface of the plating; but these plans have also been found wanting when tried. In short, without saying more respecting the characters of the proposed anti-fouling compositions, it may be stated broadly that up to the present time no sufficient remedy has been found for this serious fault of iron ships. Whether a completely successful anti-fouling preparation will yet be produced it is impossible to say; but if it should so happen, the inventor will undoubtedly confer a great benefit, and should reap a rich reward.

A few remarks respecting the inside planking or plating wrought upon the frames of iron ships must conclude this paper. The general term "ceiling" is applied to all the internal planking, which is commonly connected either to the reversed angle-irons by nut-and-screw bolts, or nailed to pieces of wood (termed "cants") secured to the sides of the frame angle-irons. Between decks in many, but not all cases, the ceiling planks are worked with close-joints, and so form an inner lining. In merchant ships it is also common to have the floors up to the height of the upper part of the bilges completely lined, or "ceiled" over. From this height upwards in the hold-space, the ceiling is sometimes close, and at others only partial, the latter arrangement being known as "batten-and-space" ceiling. Half-round bars of iron are sometimes employed instead of wood planks when the batten-and-space plan is followed. In all these arrangements, however, the main object is to form an inner skin of some kind in the hold, upon which the "dunnage" or the cargo may rest, and to lessen the probability of damage to the skin-plating. There is no idea of adding structural strength, nor is such an addition at all necessary in a well-built ship. One prime consideration to be borne in mind in fitting the ceiling is the provision of means for readily removing the planks in order to ascertain the condition of the skin-plates, and to renew the protecting materials upon them when necessary. Over the parts where the cement is fitted such inspection is especially required; and it is a common practice to fit the ceiling upon the floors of merchant ships in detached pieces, or "hatches" that can be readily lifted. But in other places facilities should be provided for making an inspection of the condition of the hull; and in arranging the structure of an iron ship an endeavour should be made to render access easy to every part, for the purpose of inspecting, cleaning, and painting.

It is only proper to note in passing how great a contrast exists between the facilities for thoroughly ascertaining the condition of an iron ship, and the opportunities afforded for surveying wood ships. When the ceiling is removed from an iron ship, and she is placed in a dry dock with a clear hold, both surfaces of the skin plates are fully exposed, and may be reached by the surveyor. If corrosion has taken place in the plates, or in the frames, it can be readily discovered; if it is at all considerable, the thickness of the worn parts can be at once ascertained by drilling; and in case of need those parts can be removed without much difficulty, and new plates or bars fitted. The heads and points of the rivets are also open to observation, and so the surveyor has complete means of ascertaining the condition of the various pieces and their fastenings. Turning to the wood ship, a very different state of things is met with. Supposing her to be docked, and to have her hold cleared, it is not

possible by the strictest examination of the inside and outside to obtain a complete knowledge of her real condition. To do this planks must be removed here and there; the planking and timbers must be "bored" in many places to ascertain whether the wood remains sound; fastenings must be driven out in different parts, as their condition cannot be predicated from the examination of the heads and points, because the middle parts of bolts often waste without any external sign of the decay; and many other devices must be had recourse to if the survey is made thorough. Should repairs become necessary they are often most difficult and expensive. A rotten timber, for instance, can only be replaced with considerable difficulty, and in doing the work it often happens that other defects not previously discovered come to light. In short, the actual state of the iron ship can be ascertained with much less trouble than that of the wood ship, and any repairs needed can be effected with greater ease. These are considerations which should have great weight in judging the relative merits of wood and iron ships, and they greatly influence the commercial success of the two classes of vessels.

Reference has already been made to the fact that many iron ships have inner water-tight skins, forming double bottoms which add both to their strength and safety. The plating of these inner skins is sometimes worked on the in-and-out plan (illustrated by *c*, Fig. 34, page 305), and at others is fitted flush upon the frames. Mr. Scott Russell has adopted the former method in the *Great Eastern*, and other vessels built on his longitudinal system; and an example of the latter will be found in the part section of an iron-clad ship shown by Fig. 23, page 224. When the plating is flush, short edge-strips are fitted between the continuous angle-irons, on the under-side of the plates, so that no liners are required. This method is found to answer very well in practice, and to make water-tight work. It need hardly be said that the butts of the plates in the inner skins are carefully shifted both with regard to each other, and with regard to the butts of the outside plating and longitudinal frames. Carelessness in this particular would obviously lead to a considerable loss of strength, as compared with that attained when proper precautions are taken. In the Government service the diagonal shift of butts (Fig. 36, page 305) is commonly used for the inner bottom, and both edges and butts are single-riveted. This mode of fastening has also been adopted for the inner skins of ships built by Mr. Scott Russell.

In order to make the double bottoms thoroughly efficient as a means of preventing serious damage when the outer plating is penetrated, it is desirable to subdivide the space by numerous water-tight partitions, and to supply water-tight tops. Both these necessities are met in the iron-clads, and have been previously illustrated. As a rule the double bottoms are made to extend up to a few feet above the water-line, and to end at a deck, but this is not always done.

Merchant ships are seldom built with double bottoms, but it is becoming very common to construct tanks for water-ballast in some part of such vessels, and thus what is virtually a "partial double bottom" is often formed. Various plans are followed in building these tanks, but the feature common to most of them is the provision of a water-tight inner skin worked either upon the floors themselves, or else upon longitudinal keelsons fitted upon the floors, this inner skin being by some means brought into water-tight connection with the outer plating of the bottom. With transverse framing it is not an easy matter to ensure this water-tight connection, and to obtain it the frames in wake of the tank are often cut off near the turn of the bilge in order to admit a longitudinal plate-frame which shall form the side boundary of the tank. This frame has angle-irons on both edges, and is riveted to both skins, the caulking of the two joints being readily performed. Another plan consists in scoring the inner skin out between the transverse frames near the bilges, and riveting its edge to the outside plating; but this involves considerable difficulty in securing water-tightness at the junctions of the inner plating and the frames. The economical value of water-ballast, however, is so great as to override these questions of practical difficulty and expense. Ships so built can, by the admission of water into the tanks when without cargo, be brought to the proper trim; and the water can be pumped out speedily when required. Time and money are thus saved to a very considerable extent, and it is no wonder that ship-builders provide this simple means of avoiding all necessity for using rubble-ballast, on the old plan. The use of water-ballast began, we believe, in the iron screw colliers trading from the Tyne, and it has already been the source of enormous savings. If ship-builders were, however, to push their reforms somewhat further, adopting improved methods of framing, and complete double bottoms, they might, without sacrificing any of these advantages, produce stronger and safer ships.

SANITARY ENGINEERING.—XXI.

HOUSE DRAINAGE.

Passing on from the subject of our last two papers, closets and traps—*i.e.*, the mechanical appliances for what we may call the internal sanitary engineering of a house as contrasted with the external—we now come to the provisions requisite for removing sewage and waste water of different descriptions in the most efficient manner; and here we have to deal with many incidental circumstances arising from locality, the facilities of the neighbourhood, and other different causes. The method of external drainage for a town house, which has nothing to deal with but its own water-supply and sewerage, and of a country mansion in a district where no general sewage system exists, must necessarily differ in detail, although some few broad general principles will apply in each case.

Thirty years ago no general system of drainage was in existence, and cesspools were in very constant and general use even in London, and to this day in many courts and back-ways they are still in existence, though when discovered by the sanitary inspectors they are speedily done away with, and the modern system of pipe-drainage compulsorily introduced, as required by the Sewers' Act. As a matter of antiquarian curiosity, it may be interesting to remark that in sinking for unusually deep foundations in the City and elsewhere, it sometimes happens that old cesspools are opened of which the lining or walls (steining is the technical name) was done with the horns of animals curiously bonded together, forming a receptacle for the solid soil, but allowing the liquid manure to soak and drain away into the surrounding ground; these are probably of very early date.

In the time of the Romans chalk was used for a similar purpose built up dry in irregular lumps, and within the last few years two cesspools were discovered in the excavation for the foundation of a new building on Ludgate Hill. The late practice was to use bricks laid dry without mortar in a similar way, and old disused cesspools of this class are often turning up. In all urban districts or metropolitan centres the cesspool system has long been abandoned, and the general system of sewage bears the burden of all inhabited houses within a given area; but in some suburban districts, and in all country situations where there is no adjacent river or brook to receive the sewage, or in point of fact to act as a sewer, the necessity of the case compels the adoption of the cesspool system, and of this, therefore, with the various modifications and the necessary hygienic details, we must give some account. To return, however, to our subject proper—the details of house drainage. Some years ago an idea was prevalent that pipes of three inches diameter of glazed stone-ware would be sufficient to convey the drainage of an ordinary dwelling-house; but experience has proved that, though theoretically large enough, the constant stoppages arising from adventitious causes—a rag, a piece of newspaper, a gradual accumulation of grease from kitchen waste—required such constant attention that these small sizes of pipes have been long ago abandoned, and we may state that the sizes now practically in use are six inches diameter for a small house, and nine or twelve inches for a large house or a mansion. Where there is a general system of sewerage, these pipes should be conducted to the common sewer in the street or road, as much fall as possible being obtained as is compatible with the level of the ground or the nature of the situation. Two inches in the length of ten feet may be taken as an absolute minimum, as in cases where this fall is not obtainable it is better to adopt some independent mechanical method of dealing with the sewage or drainage. As an instance of the way in which exceptional cases may arise, we may mention the case of the London and Westminster Bank in Lothbury. On making some recent addition to this building, owing to the exceptional nature of the ground, a bog situate on the exact line of the old Walbrook, it was necessary that the ground should

be excavated to a depth considerably below any of the adjacent sewers; there was no influx of drainage proper, but a considerable amount of subsoil water to be dealt with; a small well or sump was formed for its reception, and it is periodically removed by pumping into an adjoining sewer.

The glazed drain-pipes now universally in use are comparatively a modern invention. Into the detail of their manufacture we do not now propose to go, as that will form the subject of other series of papers in THE TECHNICAL EDUCATOR, but only to explain the precautions to be adopted in their use, and the various modifications of constructions of detail required for efficient house-drainage.

There are various descriptions of pipes manufactured from different materials in different districts, all equally efficient, but each possessing some peculiar characteristics. In Staffordshire they are burnt from a species of fire-clay, and are dark in colour, similar in material to what are called Staffordshire bricks; in London they are burnt from clay obtained from various parts of the country with a large admixture of broken pottery finely ground and sifted for the better kind of work; while in Kent, in the neighbourhood of Aylesford, the Gault clay is the principal ingredient, and a pipe of lightish colour and very tough consistency is the result. The same patterns, however, apply very much throughout, and it is with the detail of these that we have now to deal. When first introduced they were about 2 feet in length, the joint being made by a plain socket, as shown in the sketch above (Fig. 36).

It is evident that where long lengths of pipes are laid upon this system, the only method of opening them for examination was to break one or more of the pipes, and when the repair was made a patch with tiles and cement was the result, running risk first of leaking, and then of an obstruction of the inside of the pipe by the falling in of a portion of the material, or the running out of the cement while the joint was being made, which subsequently would harden into a permanent obstruction. To get over these difficulties various plans were introduced. Our next sketch shows a method in which the upper lip, as we may call it, of the socket is absent, which allows a single length to be removed and another dropped into its place: this presents some advantages (Fig. 37).

Fig. 36.

Fig. 45.

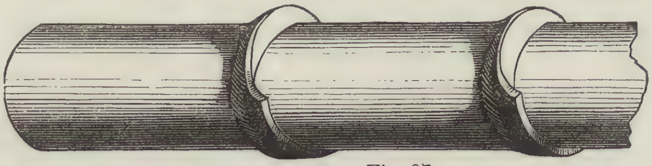

Fig. 37.

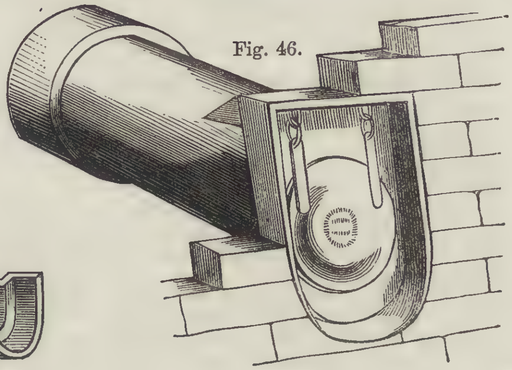

Fig. 46.

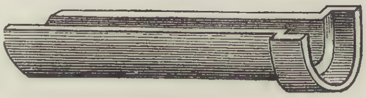

Fig. 38.

Fig. 44.

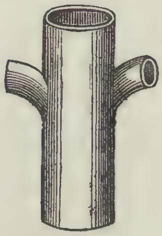

Fig. 43.

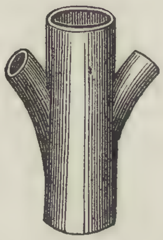

Fig. 42.

Fig. 40.

Fig. 41.

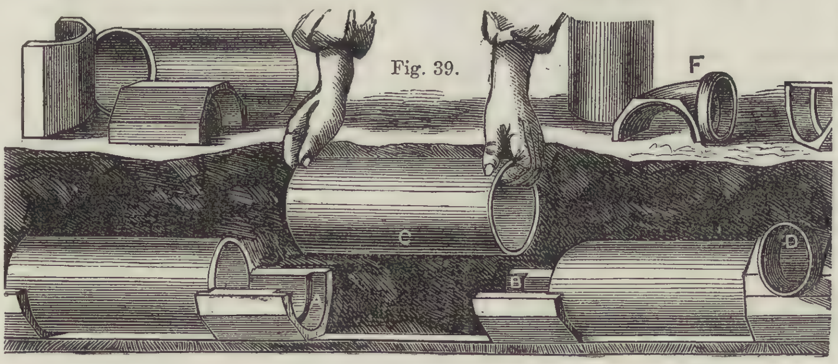

Fig. 39.

Another method is to manufacture the drain-pipe in two halves longitudinally, the upper half removable, the lower half remaining undisturbed while the drain is examined and cleared out. The sketch (Fig. 38) shows the construction.

Another more complicated but probably more efficient plan is shown below in Fig. 39, which also indicates the exact method of laying the pipes and the introduction of junctions.

There are various other inventions of similar character, but we have only instanced a sufficient number to show what facilities exist for ready access to a system of pipes for examination and cleaning.

In the erection of new buildings it is not desirable that the drain-pipes should be laid when the work is first commenced, for although the plan promises certain advantages in keeping the basements dry during the progress of the work, it is found in practice that the settlements which almost invariably take place in new work very often break the pipes where they pass through or under the walls; the subsidence or sinking of the ground from various causes sometimes produces the same result. It is therefore recommended that the carcase of the building should be first completed, and that the carrying out of the drainage should be deferred until the latest period at which it will not interfere with the floor-laying and finishing of the interior.

The junctions of pipes now claim our attention, and we give some illustrations of the "junctions," as they are called, which are made ready burnt for that purpose.

Figs. 40, 41 represent the junction *single* of a smaller pipe with a larger one at different angles, and we have to call attention to the point that the direction of the junction at its angle should always be the same as that of the fall or current of the

larger pipe, as if this is not attended to, and the entry is made in the contrary direction, obstruction will sooner or later result. We show in Figs. 42, 43, 44, 45 four different kinds of double junctions to which the same remarks apply. The ventilation of these drains is a very important matter now only beginning to occupy a leading share of public attention, as also the disinfection of the sewage gases arising in them; but with these points we shall deal at length in a subsequent paper. One point now remains to be alluded to—the entry of the drains into the sewer, where a sewer is in existence; this should always, if the level permits, be above what we may call the central axis, and for this reason, that if by accident the sewer should be flooded (and our late experience of metropolitan main drainage shows that even now such an event is far from uncommon, especially, as may we say, in the Farringdon Street district), all the lower end of the house-drain is filled by the back pressure of the water, and as long as the obstruction in the main-drain lasts becomes, as it has been called, an elongated cesspool; whereas if the entry is made well up towards the topmost level of the sewer, this difficulty is very materially obviated.

In many districts, metropolitan and otherwise, the sewers are waterlocked, as it is called, for twelve hours at least out of the twenty-four, and then some precaution like that indicated in Fig. 46 becomes most desirable—a stone-ware pipe provided at its junction to the sewer with a galvanised iron flap which closes as the tide rises. This is called a *tide-valve:* it opens the moment the tide falls at the slightest pressure of water from within; this prevents all back-water flowing up into the sewers or basement of the house, while it allows a facile exit for all the daily requirements at proper times of the tide.

Thus far we have dealt with the technical detail of "house drainage" in localities where a complete system of public sewers is in existence. We must now give some attention to localities where there is no such provision, and where, therefore, the introduction of a sump or cesspool becomes an absolute necessity; and here, taking the case of a large mansion or asylum situated in an isolated part of the country, we have various elements to consider. There is (1) the surface water; (2) the subsoil water; (3) the water-supply from well or otherwise; (4) the rainfall—various at different times of the year; (5) the sewage proper from closets, kitchens, stables, and elsewhere. The rain-water is sometimes separately dealt with and stored in a tank by itself. On sandy or gravelly soils not in a low district, the subsoil and surface-water may be left to take care of itself and make its way through the ground; but on heavy, low-lying clay lands this cannot be done, and therefore proper provision must be made for its disposal; and we may take this as a first axiom, that the cesspool, whatever its size—and for a large asylum it should be about as large as the dining-room—should be situated as far away from the inhabited portion of the buildings as possible, and should be made water-tight, providing at the same time ample means of ventilation from its upper levels; if this is not done, the sewage gases will find their way up the pipes, and, if these are not efficiently ventilated, into the living-rooms, with the certain result of general discomfort and unhealthiness, and in bad cases even of typhoid fever. If there is an available overflow, the waste sewage water may be advantageously distributed over the land; if not, mechanical means must be adopted to empty the receptacle at stated times.

In porous or open soils it may be advisable to have the pipes pervious, so as to allow the drainage water to percolate away through the surrounding land; and where, as in shingly soils adjoining the sea, the tide rises, no deleterious results will follow. But in retentive soils the result will be the saturation of the surrounding ground with sewage matter. In every case, however, local circumstances must dictate the course to be taken, and it is impossible to prescribe one uniform course for every locality.

Before the present generation these questions hardly arose, as the ordinary method of house-drainage was by the old-fashioned barrel-drain, as it was called, a simple tube of brickwork in mortar of various sizes from 9 inches upwards, built round a wooden centre which the workmen removed forward from length to length as the drain was built; while in some isolated districts common red pottery pipes were used mostly without sockets. In these cases the ventilation was provided for almost completely by the natural circumstances—the crevices existing in ordinary brickwork, and the butt-joints of the pipes, allowing a free escape for the sewer gases; while the larger size of the drains, never less than 9 inches for house purposes, left a very considerable air-space. Except, however, in cases of very rapid fall the amount of sewerage deposit in these old-fashioned drains was always considerable, and one important point to be attended to on entering upon a new property was to have the drains opened and cleaned out, a disagreeable and sometimes unhealthy process, which, however, it was absolutely necessary to repeat at intervals of a few years. Where a modern system of pipe-drainage is judiciously laid with proper points of access, the drains, if not entirely self-cleansing, as they may generally be made by the adoption of some of the systems of flushing described in our previous paper on "Economy of Water-supply," can be cleaned out and kept in a satisfactory state with comparatively little trouble or annoyance.

Since public attention has been so prominently directed to the subject, several new inventions have been introduced for the ventilation of house-drains, and of this subject we shall treat at some length in our next paper.

CAPITAL AND LABOUR.—I.

By J. E. Thorold Rogers, M.A., Tooke Professor of Economic Science.

THE SUBJECT IN GENERAL.

In the whole range of subjects with which political economy or social science has to deal, none is nearly so important as the relations which subsist between what are called capital and labour. At the present time the questions which arise on these relations are in the highest degree vast, difficult, and menacing. Attempts have been made from time to time to construct a society within society, in which an experiment can be made, for the purpose of substituting a new organisation for that with which we and our forefathers have been familiar since the earliest memories of civilised society. Such expedients, known by the general names of communism and socialism, have been advocated not only in France, Germany, and England, where the density of population, and the consequent pressure of poverty, lead to the ventilation of schemes for the reconstruction of society, but in the United States, where there is abundant space for all kinds of industry, and where, in consequence, those social problems which agitate an old and fully peopled country do not yet, and will not for a long time, be prominent enough to demand a solution.

Latterly, however, the movement has assumed proportions of far greater magnitude. Trade between nations, and the facilities of intercourse with which science has assisted trade, are making and will make the municipal boundaries which separate nations mere geographical expressions, which are easily passed. Modern communities are getting ideas from each other. A few years ago, the man who travelled over Europe was a mere exception. A few years ago the chief intercourse between nations were the diplomatic communications which governments instituted and maintained. Now the habit of travel is becoming general. It is rapidly influencing the artisan classes. Society, long immovable, is beginning to transfer itself from place to place. Nay, we are informed that labour has an organisation throughout the civilised world, which is rapidly being consolidated, which has its agents in every great town, and which, under the name of the International Society, is powerful already, and is likely to become more so. In all these attempts, partial and general, to change the foundations of society, there is a struggle between capital and labour, between profit and wages, between the employer and the workmen, between property and industry. I purpose in these papers to attempt an explanation of these several social forces.

Ask any economist, and he will tell you that capital is the accumulation of past labour, intended to move or assist labour, and that it is either a transient or a permanent assistance, the former requiring constant renovation, the latter being of an enduring character. Ask him what labour is, and he will tell you that it is the power which intelligence gives man over the properties of matter and life, by which muscular effort can make matter useful. It will be added that this power which the labourer is able to exercise over matter may be either the direct action of the man, or may be indirectly exhibited upon certain inorganic and organic powers; in other words, that the work-

man may be plying his own muscles, or may be guiding animal power, or be using steam, wind, or any other natural motion which man is able to control and direct for his own ends. In technical language economists speak of fixed and circulating capital, of muscular and nervous labour.

All these definitions and distinctions, however, are not fundamental, but only denote tendencies under which the same facts appear in different forms, or in which one of the circumstances which accompanies the fact is exhibited in different degrees of intensity. Thus the labour of a manager is said to be nervous, that of a workman muscular. But unintelligent effort is of no avail, even for the commonest acts, nor can the sharpest intelligence give effect to its thoughts, except by means of muscular effort. No labour appears to be more characteristic of the brain than the thoughts of a poet or musician are, but both these personages must at least exercise the mechanical function of writing or speaking.

Again, it is true that capital is the accumulation of past labour, embodied or condensed in material objects. With one exception—viz., land available for occupation or cultivation in densely-peopled countries—there is no object whatever, which possesses value, that has not obtained its value, by reason that labour has been expended on it. A sack of wheat, a bale of cotton, a barrel of wine, a wedge of gold, a house, a spinning-machine, possess whatever value the market assigns to them by reason that labour has been expended on their production. It signifies nothing, from this point of view, whether the article is movable or has been gifted with qualities which cannot be recovered or resumed in their original form. In every case, it is labour, and labour only, which confers on these objects those properties which economists recognise and comment on.

Unless we acknowledge this fact, we shall find it impossible to discern satisfactorily what are the relations of capital and labour, of the employer and the workman. If we acknowledge them, we shall, though not without some trouble, discover the key to these social questions, which, as I have already stated, are of such pressing and universal interest. For we shall discern that the production of labour is just as much an investment of labour, and therefore just as much an exhibition of capital, as any of these objects are to which reference has been made above. A man who brings up children, and renders them fit for those various forms of industry to which human capacity is fitted, is just as fully investing capital in them, as if he were building houses, or constructing machines, or collecting agricultural crops. It is only because his domestic relations to such children are the prominent features in their connection with him, that the position in which the education of labour stands to the general energies of society is misapprehended or ignored.

If we would see what is the significance of this production of labour to the general well-being of society, and observe how exactly it corresponds to any other investment of capital, we may consider an hypothesis, which could not happily become an actual fact, but may be contemplated as an abstract possibility, and has been, unfortunately, verified at one epoch in the history of civilisation. We can imagine that the transmission of that which an existing generation knows may be withheld from a growing generation, that the additions which are being made to the present stock of human knowledge or skill were arrested, and that what is known is not communicated. Such a state of things, it may be imagined, could occur suddenly. It has, as I have said, occurred gradually at one period in the history of mankind, for Europe in the tenth century of our era had lost nearly all the arts, and almost entirely the culture, which existed at the commencement of that era. The consequence of such a sudden cessation in the function of communicating the knowledge and skill of one generation to its successor, would be a rapid or gradual relapse into barbarism. Such a reverse would be of incomparably greater significance than any diminution in any other kind of wealth, and would be followed by infinitely more disastrous results. The maintenance and education of children is therefore a far more important investment of capital, a far more significant object of labour, than any other accumulation. It seems not to be so, only because under certain circumstances there are more men to work than there is work for them to do. To some extent this occurs in the case of other accumulations; for there may be more wealth accumulated than there are objects on which such accumulation can be advantageously employed. Quantities, however, of unemployed labour diminish the portion of general wealth which labourers can individually appropriate; quantities of unemployed wealth in other objects increase the power by which labour can be called into activity.

Capital, then, and labour available for industrial objects, and which is also in demand for industrial agencies, are only two forms of the same fact; both are accumulations of labour. There is no labourer who does not possess in himself an investment of capital; there is no capitalist who does not represent an active industry, if he be an employer of labour, and superintends the labour which he employs. The struggle which arises from time to time between the employer and the labourer, is a struggle between two forms of the same fact, between two forms of labour, each of which is seeking to appropriate more of that common produce which is shared between the labourers on the one hand and the employers on the other. In social science there is no struggle between diverse forces, rivalry existing only in similar forces. Hence if the function performed by the capitalist and that fulfilled by the labourer are united in the same person, not only is the quarrel necessarily at an end, but the maximum of productiveness is attainable at the minimum of cost or loss. In the course of these papers we shall see what are the phenomena of that state in which this harmony is effected. Until it is effected there is no means by which an adjudication can be made on these rival interests, except it be that of the barbarous expedient of strike and lock-out, or the temporary settlement of arbitration.

POSITION OF THE QUESTION IN ENGLAND.

In foreign countries, especially in France and Germany, the relations of labour and capital have been debated from that point of view which contemplates the reconstruction of society. These two countries have been the homes of those socialist or communist movements which aim at altering human life and action from its very foundations. These projects are futile, for civilisation, imperfectly as it may have been realised, is a true growth which cannot be made different from what it has become by means of any external influence. It is true that the advocacy of these expedients has made men restless, discontented, turbulent, and sometimes violent, but no success has ever followed on the efforts which have been made after such fundamental changes.

There is a reason, however, why these projects have been developed in these countries. In both the unity of the nation has been effected only after great toil, and by a government which has been almost despotic. Now, in such a state of society, the right of individual action or of combination is very sparingly accorded. The policy of a government in such a country tends always towards doing as much as it can, and of discouraging independent action on the part of its subjects. The administration is centralised, as people say. Hence the people learn to depend on government to give them a start, and refer to government when they are at a loss or in a difficulty. Now it is only a step from this state of mind to that other in which government does not merely regulate action, but takes upon itself the business of originating action. Under these circumstances a people begins to believe that government is a power which can and ought to confer great benefits on the people, which can assist them in a thousand ways, which can finally not only correct what is wrong in the laws or customs of society, but can do what is expedient, right, and charitable. But if the government can do so much good, why not, it is argued, undertake the development of that benevolent scheme which, in the dreams of some enthusiast, will remove all that is evil from the world, and produce all the good? Human life is full of misery and poverty: it is the business of those who govern human affairs to find a remedy for these disorders.

PRACTICAL APPLICATION OF THE FINE ARTS.—XII.

THE ART OF MOSAIC (*continued*).

By P. H. Delamotte, Professor of Drawing, King's College, London.

We give in the present paper some representations of mosaics, that have been, or are being executed by Simpson and Son of London. We had hoped to give these in colours, but as this

could not be accomplished, we must do the best we can with the woodcuts. In speaking of woodcuts, however, we may here remark, that in many of those given in previous numbers, among which we may reckon all those from Cirencester, the exact number and shape of the tesseræ have been preserved, the original pavements having been traced, and the tracing diminished by photography to the required size of the woodcut. But in spite of this, coloured illustrations would give far more clearly the style of work produced by English workmen in the present day.

We may be permitted to refer here to a life-size mosaic of Hogarth, intended for the South Kensington Museum. The likeness is naturally taken from the well-known portraits of the great father of the essentially English school of painting. We are glad, independently of the value of the mosaic, thus to point out a portrait of a man to whom English art owes so much. We look upon it that to Hogarth, even if he was not a painter of the highest class, nor a man of transcendent talent, English art, and so the whole range of national art, owes a deep debt of gratitude. By his determined protest against the trammels of foreign taste; by the violation, on the part of a man who had genuine thought and true enthusiasm in him, of the rules laid down for other times and other countries, he showed that each nation has peculiarities of taste and disposition that develop themselves in the arts of that country, if they are allowed legitimate play; that the artistic taste and feeling of one race cannot be violently transported into another; that the attempt to do this merely produces a race of copyists, with all the vices and the weaknesses of copyists; whilst each nation can alone develop and enlarge its own characteristic art, grafting in, it may be, from time to time some of the excellences perceivable in the arts of other races, but in the main keeping to the old lines. These remarks we do not confine to any one branch of that circle of human endeavours which we entitle fine art; but if it is, as we contend, entirely true of some, it must be true of all, and it will be impossible for some of the arts to rise from their present degraded condition in England until this position is truly recognised; and that as the politics of to-day take their root in, and form part of the whole history of this country, as far back as the mind of man can trace, so the arts of England must trace back their origin to the early and rude attempts of our ancestors, must develop the lines that these suggest, and add thereto whatever grace and beauty can be acquired first from nations kindred in blood and in taste, and next from the universal canon of taste which appeals to our common humanity. A wise artist is like unto a man that is a householder, who bringeth forth out of his treasures things new and old.

Fig. 30.—MOSAIC REPRESENTING ONE OF THE SEASONS.

But to return to the mosaic of Hogarth. The attitude is one of comparative repose, and thus fulfils the conditions we indicated when in a former number we recommended the study of the figures at Ravenna. The characteristics of the man himself, as he himself introduced them, his palette, the comic mask, and his dog, find natural places. The position is easy, and is that of a man contemplating his subject preparatory to active work which he may momentarily begin. This combined effect of a position that we are not surprised to see continued, and at the same time naturally leads to active motion, is highly suited for this material. It should partake somewhat of the calm character of sculpture, and yet the gold background so entirely throws the figure into relief, that we should almost anticipate motion.

The style of colouring is well adapted also to the material. We are not now dealing with the glass mosaic of Venice, for which Messrs. Salviati and Co. are so celebrated; nor with the Comati work from the Pope's workshop in Rome, in which various materials are employed; nor the *opus vermiculatum*, of which Florentine work is the modern representation; but with purely English terra-cotta work which has even been called *opus Anglicanum*. The materials employed are tesseræ of various shapes, principally small cubes and prisms of terra-cotta powder compressed, much as powdered black lead is squeezed in a vacuum until it acquires the hardness required for various kinds of pencils, so that it becomes much more compact and hard than by the ordinary mode of baking, and is capable of receiving a burnished surface. This terra-cotta material, however, naturally does not produce the brilliant colours nor the bright effects of glass; it would consequently be absurd to attempt the same style of colouring as may suit an Italian sky and a vitreous material. And this is a great advantage, especially since other causes have contributed so much towards fostering a taste for a heavy, crude, and over-loaded tone of colouring both in our pictures and our manufactures. Rather dull colours harmoniously disposed, therefore, are suitable to most subjects, and contrast all the more vividly with the bright

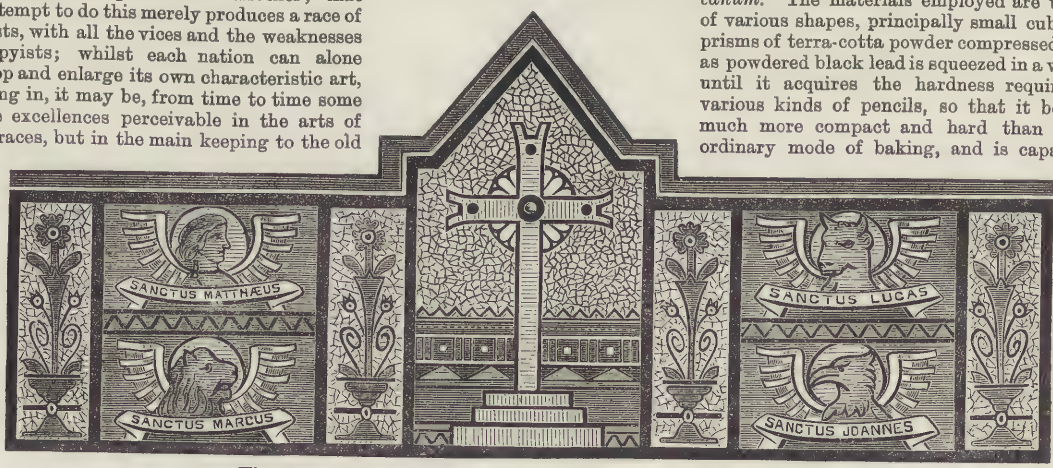

Fig. 32.—DESIGN FOR A PORTION OF A REREDOS IN MOSAIC.

and flat, yet varied, golden background. The necessity for making the terra-cotta tesseræ in moulds, confines the shapes to only a few varieties of surface—squares, rectangles, and triangles of various forms complete the category. It is impossible, therefore, to produce the irregularity either of the old Roman pavements or of modern glass mosaic. This has its advantages and its disadvantages. Among the latter may be esteemed a certain flatness originating from the formality of shape, and the non-appearance of the cement between the interstices of tesseræ, though in this respect the modern glass mosaicists also lose a strong element of beauty, and throw away one of their advantages, by using cement coloured to match their materials. But as a compensating advantage the terra-cotta worker has a wider range of shades, since the blocks being far smaller than the *smalti* are ever broken into, the gradations of colour and shade are better preserved. In order, too, to counteract the flatness of the regular divisions, the English workman breaks up his gold, which, of course, consists of *smalti*, into irregular portions, thus causing a very different effect from the more regularly divided gold backgrounds of the Italians.

In such pieces of workmanship as the portrait of Hogarth, there are, of course, a great many degrees of difficulty and of excellence in the mere work. The flat backgrounds require but little skill to match the pieces to the most convenient forms. The outlines of clothes, the matching of tints, and the drawing of the coarser parts require more delicacy and taste, whilst the hands and heads demand the skill of a regularly trained artistic workman. A very large proportion of the work done at South Kensington and at other manufactories of mosaic is executed by women, and this is a branch of labour well suited to their capacities, since it is rather neatness and taste than bodily strength that is required.

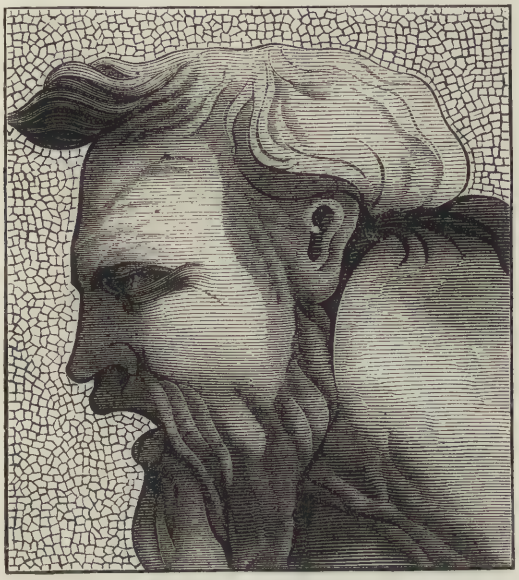

Fig. 31.—HEAD OF THE PROPHET ISAIAH, DESIGNED FOR ST. PAUL'S CATHEDRAL.

We give in the preceding page (Fig. 30) a medallion, one of four on a screen, intended to represent the seasons, a subject common enough amongst the ancients, as we have noticed before. In this case, though only three colours are used, several tints are required to produce the shadows, and to throw up the forms. Fig. 31 is intended for a head of the prophet Isaiah, and is taken from a design by Mr. Alfred Stevens for a pendentive in St. Paul's Cathedral. It is well that the cathedral church in the metropolis should receive the best we can give it in the form of an offering from Art; and it is to be hoped that the effort now being made to decorate the interior in a manner worthy of the original design may be as successful as it deserves to be. The completion of a great work like this must lead to a more elevated taste amongst the many who day by day have this object presented to their view. Recent improvements in London have led to many openings through which the great cathedral can assume its proper proportions; and it would be sad that after the mind had been prepared by these distant views, and by a closer admiration of the colossal size of the structure, that all enthusiasm should be baulked by a bald and cold interior. We hope, therefore, that something may be done worthy of the great building itself; worthy of the city over which it presides; and worthy of the nation of which it is, from a civil if not from an ecclesiastical point of view, the principal church. The design before us is worthy of such a building. Bold and massive in its treatment, it is suitable for contemplation at a distance: we may, therefore, be sure that it will be worked out in a forcible manner, with tesseræ of considerable size, and shades plainly delineated. We trust to such work as this to elevate both artist and workman, and to prepare the way for further advances on the same road.

Fig. 32 is intended to represent a portion of a reredos for a parish church. The ordinary emblems of the Evangelists have their names beneath them. These stand out from a dull background; but in a still more striking manner does the central emblem of the cross in pure white arise from a background of gold. The intervening spaces are filled with conventionalised flowers. The effect of good mosaic with a large admixture of gold in it in lighting up and enlivening our churches, generally either devoid of colour, or else relying on paint and hangings for the tone that should be obtained from the structural materials, ought to be studied by all those who are anxious to help on the progress that architecture has been making for many years, and which we hope it will long continue to make. As we said at first, mosaic is an architectural art, and unless it subserves the main purposes of a building, it is not likely to gain a permanent hold on the taste and feelings of the nation. We hope to see the day when amongst the English who are true lovers of the real, the solid, and the permanent, mosaic may find a place as much its due, and as consonant with our feelings, as it was with those of the Romans of old, when a man of taste and property felt that his house was not properly finished, nor his furniture fitly decorated, unless they were alike adorned with mosaics of the highest order of merit.

BUILDERS' QUANTITIES AND MEASUREMENTS.—XIV.

BY E. WYNDHAM TARN, M.A.

SMITH'S WORK AND BELL HANGING.

THE smith's work in a building includes all heavy materials of cast or wrought iron, as furnace and chimney bars, girders, columns, iron joists, heads to king and queen posts, tie-rods and bolts, newels, brackets, cantalivers, rain-water pipes and gutters, iron railings, guard bars, cramps, cisterns, tanks, furnace and soot doors, grates, stoves, ranges, stable fittings, iron roofs, etc. Most of the smith's work is taken by weight, even where it has to be measured, the sizes of the articles being entered in the dimension book, and afterwards brought into lbs., cwts., or tons by means of a table of the weight of iron of given breadth and thickness. Articles in cast iron that require a pattern to be made expressly for them must be taken by weight, and the patterns numbered separately; but for articles in common use, or where a large number of the same pattern is required, the pattern is not charged. All labour in filing and fitting cast-iron work must be taken by the foot-run. Measure the length of cast-iron columns or cylinders, and enter it in the dimension book, stating the diameter externally, and also internally if hollow; the weight per foot-run can then be ascertained by help of the following

TABLE OF WEIGHT OF SOLID ROUND CAST-IRON COLUMNS PER FOOT-RUN.

DIAM.	WT.	DIAM.	WT.	DIAM.	WT.	DIAM.	WT.
in.	lb.	in.	lb.	in.	lb.	in.	lb.
1	2½	2½	15⅓	4	39¼	5½	74¼
1½	5½	3	22	4½	49⅔	6	88⅓
2	9¾	3½	30	5	61⅓	7	120¼

To find the weight of a hollow column or cylinder by means of this table, deduct the weight of a solid column having the given internal diameter from that of a column having the given

external diameter. Thus the weight per foot of a hollow column 6 inches outside diameter, and 5 inches inside, or with $\frac{1}{2}$-inch metal, is $88\frac{1}{3}$ less $61\frac{1}{3}$, or 27 lb.

The weight of cast-iron girders may be found by taking each part separately—namely, the top and bottom flanges and the web, giving the width and thickness of each, and finding their weight from the following

TABLE OF WEIGHT OF FLAT CAST IRON, 1 INCH WIDE, PER FOOT-RUN.

THICKNSS.	WT.	THICKNSS.	WT.	THICKNSS.	WT.	THICKNSS.	WT.
in.	lb.	in.	lb.	in.	lb.	in.	lb.
$\frac{1}{4}$	$\frac{4}{5}$	1	$3\frac{1}{8}$	2	$6\frac{1}{4}$	$3\frac{1}{2}$	11
$\frac{1}{2}$	$1\frac{1}{2}$	$1\frac{1}{4}$	$3\frac{7}{8}$	$2\frac{1}{2}$	$7\frac{3}{4}$	4	$12\frac{1}{2}$
$\frac{3}{4}$	$2\frac{1}{3}$	$1\frac{1}{2}$	$4\frac{3}{4}$	3	$9\frac{1}{3}$	5	$15\frac{2}{3}$

For example, to find the weight per foot-run of a cast-iron girder with parallel flanges, the flanges being $10'' \times 2''$ and $3'' \times 1\frac{1}{2}''$, and the web $12'' \times 1\frac{1}{4}''$; $10'' \times 2''$ weighs $10 \times 6\frac{1}{4}$, or $62\frac{1}{2}$ lb.; $3'' \times 1\frac{1}{2}''$ weighs $3 \times 4\frac{3}{4}$, or $14\frac{1}{4}$ lb.; $12'' \times 1\frac{1}{4}''$ weighs $12 \times 3\frac{7}{8}$, or $46\frac{1}{2}$ lb.; and by adding these weights together, we find that of the girder to be $62\frac{1}{2} + 14\frac{1}{4} + 46\frac{1}{2} = 123\frac{1}{4}$ lb. per lineal foot.

The weight of cast-iron stanchions, storey-posts, etc., can be also found by help of this table. The weight of flat plates of cast iron can be found by means of the following

TABLE OF WEIGHT OF FLAT CAST-IRON PLATES PER FOOT SUPERFICIAL.

THICKNESS.	$\frac{1}{8}''$	$\frac{1}{4}''$	$\frac{3}{8}''$	$\frac{1}{2}''$	$\frac{5}{8}''$	$\frac{3}{4}''$	$\frac{7}{8}''$	$1''$
	lb.	lb.	lb.	lb.	lb.	lb.	lb.	lb.
	$4\frac{2}{3}$	$9\frac{1}{3}$	14	$18\frac{3}{4}$	$23\frac{1}{2}$	$28\frac{1}{8}$	$32\frac{7}{8}$	$37\frac{1}{2}$

Cast-iron rain-water pipes, and eaves gutters are taken by the yard-run, every fraction of a yard being taken as a full yard; the heads, shoes, nozzles, angles, sockets, bends, T and L pieces, etc., are numbered. The size and pattern of the gutters and pipes must be described, and whether galvanised. Cast-iron balconies, and other railings, are often taken by the foot-run, describing the height and character of design. Cast-iron copings are taken by the foot-run; coal-plates, scrapers, bell-traps, pumps, etc., are numbered according to size. Stoves for open fireplaces are valued at per inch width of frontage, and according to quality; it is common, however, to state the value per stove. Ranges and kitcheners are also valued according to the width of opening, and numbered in the bill. Cast-iron frames and doors for furnaces are taken by the pound weight.

The iron ramps, sills, posts, mangers, troughs, etc., for stable fittings are generally numbered; the cast-iron channel guttering being taken by the foot-run. Cast-iron gratings are taken by weight, which can be determined by the foregoing tables; small gratings, as air-bricks, etc., are generally numbered.

Wrought iron, when used in large quantities or dimensions, is taken by weight, the length being entered in the dimension book, describing diameter, width, or thickness, as the case may be. The weight per foot-run of round wrought iron can be found by the following

TABLE OF WEIGHT OF ROUND WROUGHT IRON PER FOOT-RUN.

DIAM.	WT.	DIAM.	WT.	DIAM.	WT.	DIAM.	WT.
in.	lb.	in.	lb.	in.	lb.	in.	lb.
$\frac{1}{4}$	$\frac{1}{5}$	1	$3\frac{1}{3}$	2	$13\frac{1}{2}$	$3\frac{1}{2}$	$41\frac{1}{6}$
$\frac{1}{2}$	$\frac{7}{8}$	$1\frac{1}{4}$	$5\frac{1}{4}$	$2\frac{1}{2}$	21	4	$53\frac{3}{4}$
$\frac{3}{4}$	$1\frac{7}{8}$	$1\frac{1}{2}$	$7\frac{1}{2}$	3	$30\frac{1}{4}$	5	84

The weight of wrought-iron girders, joists, flat bars, etc., can be found by taking separately the different thicknesses, the weight of which per foot-run is given by the following

TABLE OF WEIGHT OF FLAT WROUGHT IRON, 1 INCH WIDE, PER FOOT-RUN.

THICKNESS.	WT.	THICKNESS.	WT.	THICKNESS.	WT.	THICKNESS.	WT.
in.	lb.	in.	lb.	in.	lb.	in.	lb.
$\frac{1}{8}$	$\frac{2}{5}$	$\frac{3}{4}$	$2\frac{1}{2}$	2	$6\frac{3}{4}$	$3\frac{1}{2}$	$11\frac{3}{4}$
$\frac{1}{4}$	$\frac{7}{8}$	1	$3\frac{1}{3}$	$2\frac{1}{2}$	$8\frac{1}{2}$	4	$13\frac{1}{2}$
$\frac{1}{2}$	$1\frac{1}{2}$	$1\frac{1}{2}$	5	3	$10\frac{1}{12}$	5	17

The weight of flat plates of wrought iron of various thicknesses can be found by means of the following

TABLE OF WEIGHT OF FLAT WROUGHT-IRON PLATES, PER FOOT SUPERFICIAL.

THICKNESS.	$\frac{1}{8}''$	$\frac{1}{4}''$	$\frac{3}{8}''$	$\frac{1}{2}''$	$\frac{5}{8}''$	$\frac{3}{4}''$	$\frac{7}{8}''$	$1''$
	lb.	lb.	lb.	lb.	lb.	lb.	lb.	lb.
	5	10	$15\frac{1}{8}$	$20\frac{1}{6}$	$25\frac{1}{5}$	$30\frac{1}{4}$	$35\frac{1}{3}$	$40\frac{1}{3}$

The lengths of wrought-iron chimney bars are entered in the dimension book with their width and thickness. Iron hooping is taken by length, the width and gauge being described. Sheet iron, used as linings to the panels of doors or shutters, is measured by the superficial foot, and thickness described. Screw bolts, with nuts, plates, etc., are numbered, with a description of the diameter, length, etc.

Wrought-iron sashes, fanlights, skylights, casements, etc., are taken by the foot superficial; guard or saddle bars by weight. The lead used in running iron into stone is to be taken by weight.

Iron roofing is measured by the square of 100 feet, taken on the slope of the rafters; and corrugated iron roofs must have an allowance, in taking the dimensions, of one-fourth for the laps.

Wrought-iron doors and frames are taken by the foot superficial, except those for furnaces, which are usually taken by weight.

If iron is galvanised, the area of the surface must be measured for the value of the galvanising.

Iron set-pots and coppers are taken by weight, the labour of fixing being taken with the bricklayer's account.

When copper is used for the covering of roofs, flats, or gutters, measure it by the foot superficial, describing the number of ounces to the square foot.

To estimate the cost of bell-hanging in private houses, take the number of the bells, including with each bell the wire, cranks, tubing, springs, carriages, etc.; state at the same time whether they are hung in peals; pendulums, levers and other pulls are usually numbered separately. Large bells are taken by the pound weight, the hanging being valued separately. Electric bells are valued according to the number of pulls which are supplied, and the distance which the wires have to be conveyed.

We will now further elucidate the measurement of the smith's work by an example of entries in a dimension book:—

2)	10 6	21 0	C. i. holl. col., 6″ external and 5″ internal diamr.
2)	14 6	29 0	C. i. T girder, flanges 10″ × 2″ and 3″ × ½″, web 12″ × 1¼″.
	25 6	25 6	5″ O. G. gutters.
	28 6	28 6	6″ ½ round eaves, ditto.
	48 0	48 0	3″ R. W. P.

No. 2 heads. 2 shoes. 2 nozzles. 2 angles to O. G. gutter.

	10 6	10 6	C. i. balcony, 21″ high, with w. i. top rail and standards.
	25 0	25 0	Ditto coping to 9″ wall.

No. 2 c. i. coal plates with hooks.
„ 4 air-bricks.

	2 6 1 6	3 9	C. i. casement and frame.
6)	8 0	48 0	W. i. chimney bar, 2″ × ½″.
10)	6 6	65 0	1″ round w. i. guard bar.

5 lb. lead for running bars.

2)	5 6 1 3	13 9	½″ in. w. i. shelf.
	25 0	25 0	W. i. top-rail, $2\frac{1}{2}''\times\frac{1}{2}''$.
40)	3 3	130 0	1″ sqre. w. i. bars.

No. 40 pointed ends to bars.
,, 40 cutting holes for bars in rail.
10 lb. lead for running.
No. 1 w. i. frame and door to copper.

	6 0 2 6	15 0	½″ w. i. door and frame.
4)	2 0 1 3	10 0	⅛″ sheet-iron linings to panels.

No. 1, 4 ft. 6 in. kitchener.
,, 2, 3 ft. register stoves, polished steel front.
,, 4, 2 ft. 6 in. ditto, Berlin black.
,, 1, 20″ copper, 20 oz. to the foot.
Hanging 10 bells with copper wire, cranks, concealed tubing, springs, brass T-plate back carriage, pendulum, etc., complete.
No. 4 ornamental lever pulls.
,, 1 brass knob, pull, and plate. 1 brass slide pull.

TECHNICAL DRAWING.—LXXI.

DRAWING FOR BRICKLAYERS.

EXTERNAL OR CAMBER BRICK ARCHES, AS APPLIED TO DOORS AND WINDOWS.

OUTSIDE arches are of two kinds, straight and semi-circular, or segments of a circle. Straight arches are perfectly horizontal above, and have the same appearance below, and unless the drawing be very large they are so represented. They should not, however, be quite straight, but should always have a rise of about half an inch in three or four feet, so that their intrados is an arc of a circle, like that of a segment arch; but the joints always radiate to some point much nearer than the centre of the said arc.

The bricks used in arches always show their thickness or edge in the face of the wall, which thickness being from two and a quarter to two and three quarters at the utmost, this dimension is used at the top of the straight arch, or at the extrados of the curved one, and thence it diminishes, owing to the splay of the arch-bricks, to the soffit of the straight arch, or to the intrados of the curved one.

This splay is termed the *sommering* of an arch. The bricks used in external arches are always rubbed with great care to the proper splay or wedge-like form necessary, and according to the gauges or regularly measured dimensions. For this reason they are styled *gauged arches*, to distinguish them from inside or *rough arches*, in which common bricks are used without being rubbed or shaped in any way.

A drawing of a straight-arched window is given in page 263, Vol. I., of THE TECHNICAL EDUCATOR, and to this the student is referred.

It will be evident that in a straight arch no two voussoirs, or arch-bricks, as they may be termed, on the same side of the centre, or key of the arch, are alike; but those of the contrary sides will correspond with each other, pair by pair.

In semi-circular or segment arches, on the contrary, all the arch-bricks between every two of the adjacent radiating points are exactly alike.

The number of bricks in a semi-circular arch is determined by finding how many thicknesses of a common brick are required at the extrados or outside of the arch, and from the points of division drawing lines to the centre of the arch, which will determine the splay, and give the rule for rubbing the bricks to their proper form.

Semi-circular, or segmental arches, are commonly used over the recesses in which doors or windows are situated, and the aperture within is also usually arched over by a concentric arch of a smaller span. In such cases the upper or greater arch is usually made a brick and a half in thickness, but the lower, or smaller arch, within the recess is made only one brick thick, being equal to the face of the thin wall on each side of the aperture within the recess.

The exterior and interior elevations of a segmental window have been given in page 264, Vol. I., of THE TECHNICAL EDUCATOR.

The example given in Fig. 585 represents a semi-circular arch of four feet width and one brick in thickness at top. This is a portion of the elevation of one of the arches over several of the doors of the officers' quarters in the Ordnance Barracks at Chatham. These doorways are 7 feet 6 inches high from the upper step to the spring of the arch. They are situated within a recess, the outline of which only is given in the present figure, the upper or second arch being omitted for the sake of clearness.

Fig. 586 is the half elevation of one of the arches of the recesses about the same doorways, which are one brick and a half in thickness; the arch of the doorway itself, illustrated in the previous figure, appears only in outline in the present example.

It is to be observed that the length of ornamental arches of this description thrown over a recess, as measured from the face of the wall inwards in a barrack or dwelling-house, never exceeds half a brick, or about 4½ inches, unless the thickness of the wall should be greater, which is not usual.

In like manner the length of an ornamental arch above a door or window, whether situated within a recess or not, never measures more than half a brick, unless the reveal be thrown

further inwards, which is not usual in buildings of the above description.

Hence, such ornamental arches are mere shells, which support a portion of the wall towards the outside only. Accordingly if, as in the recessed doors alluded to in these barracks, there be a double semi-circular arch—namely, one over the recess and one over the door—these two between them support only eight or nine inches, or a thickness in the wall equal to about one brick, and therefore, of course, the rest of the thickness of the wall (which in the present instance is a two-brick thick wall) must be provided for in some other way. This is done by means of a rough brick arch on the inside, concentric with the two others, but of rather greater span than the smaller of the two, in order to allow for a "reveal" of the dimensions judged necessary.

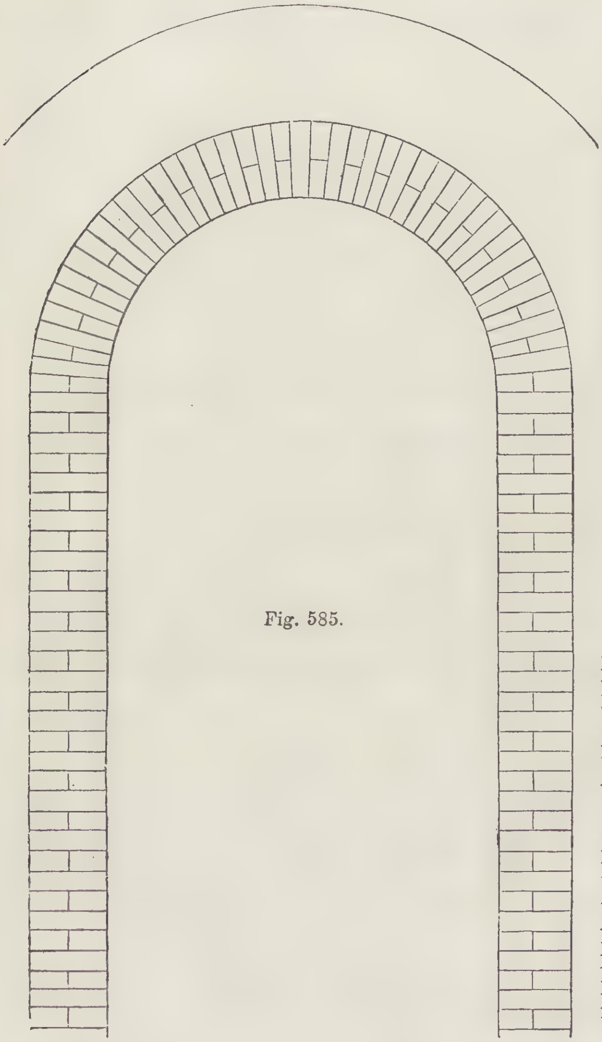

Fig. 585.

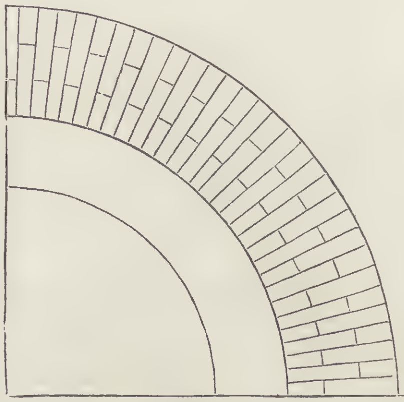

Fig. 586.

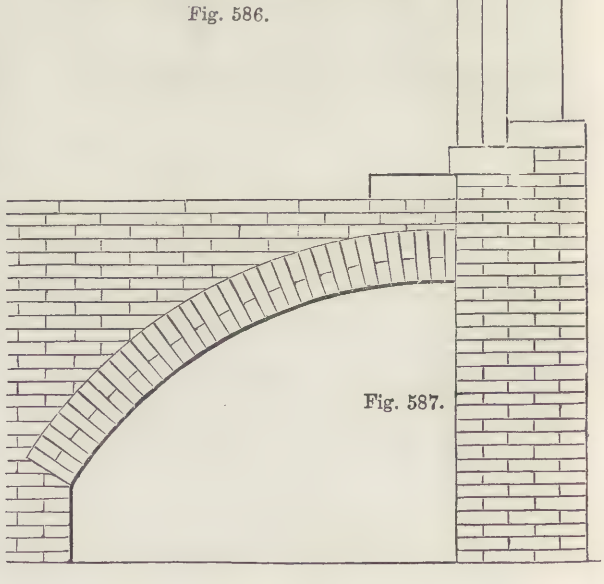

Fig. 587.

Fig. 587 is a section of one of these doorways, and represents this arrangement; *a* is the ornamental or external arch over the recess, which is a brick and a half high; *b* is the ornamental arch within the recess over the door, which is one brick thick. Each of these two arches is half a brick in length, measuring from the face of the wall inwards; *c* is the rough arch afterwards covered with plastering, which is one brick in height and one brick in length.

On examining this figure it will be seen that the two ornamental arches are by no means well connected. In fact, although each may support its own part of the superincumbent brickwork, there is no common bond between them. If, however, they be respectively executed with proper care, and in a workmanlike manner, and if the bricks and mortar or grout used be good, there is no risk of failure.

The execution of all the ornamental or thin arches in the face of a building, such as have been described, should be most carefully attended to whilst in progress. Bricklayers will always take sufficient pains to rub the outside of each arch-brick properly, so that their work may have a handsome appearance to the eye, but often slur over all the other parts of the work which are hidden from view. Hence, in order to save trouble, they are very apt to cut away the inside of the bricks of those arches to such a degree as may even deprive them of their proper wedge-like form everywhere except at the external surface. This neglect produces cracks, and causes the arch to bulge forward. It may even cause one of the bricks of a straight arch to drop down lower than the soffit or bottom of the arch, which defects may frequently be observed over the windows of common brick buildings.

In respect to ornamental arches of one brick in thickness and only half a brick in length, of which a specimen is given in Fig. 585, it is advisable that none but whole bricks should be used in constructing them, because the use of the two bats in every alternate voussoir, as appears in the figure alluded to, would in practice weaken the arch in some degree. But in this case false joints may be represented in every alternate voussoir, should it be thought that the mixture of small joints would better accord with the general effect of the other parts of the brickwork.

FARMING AND FARMING ECONOMY.—XIV.

By Professor Wrightson, Royal Agricultural College, Cirencester.

SHORT-HORNS.

INTRODUCTORY REMARKS—SKETCH OF HISTORY—PRINCIPLES INVOLVED IN BREEDING CATTLE—IN-AND-IN BREEDING—"POINTS" OF SHORT-HORNS.

We propose to devote a chapter to the study of short-horns. We do so because no race of cattle has had such a rapid rise, has been so "artificially" produced, has obtained such a wide-spread popularity, or possesses such a combination of those aptitudes for which cattle are prized. The skill of the breeder has been lavished upon it, and the material upon which such skill has been exerted has possessed the necessary plasticity to ensure success. Reference has already been made to the extraordinary prices recently paid for short-horns, and the records of public sales during the last year clearly indicate the high estimation in which these animals are held. We, however, fear that the exaggerated value now set upon pedigree is introducing an element of decay. Rigorous selection and a keen regard for personal merit especially require enforcing, and without undervaluing pedigree we think that it is too much relied upon at the present day as the test of value. Without further comment we propose to commence the consideration of this remarkable race of cattle with a short history of its rise and gradual diffusion over this country. We shall next devote a little time to the principles that guided its early promoters, and lastly, give the points looked for in first-rate examples of the breed.

The short-horn must be a familiar object to almost every one. Who has not admired the tranquil scene of cattle grazing or resting in rich meadows, or standing knee-deep in water, shaded from the sun by magnificent trees? Such pleasing additions to the landscape cannot fail to attract and charm the eye, and we accept them as the happiest manner of introducing our bovine friends. But are these short-horns? If, we answer, the herd consists of red and white horned cattle, in which the two colours named are pleasingly diversified, one animal being red, another white, a third red and white, while a fourth is probably a rich roan, we may generally assume that we are either looking at short-horns, or animals strongly impressed with short-horn character. Such cattle are now generally distributed throughout the United Kingdom; but within the last seventy years they were almost exclusively confined to the counties of Durham, Yorkshire, and Northumberland. To give more than the merest outline of the history of short-horn cattle would be impossible in a short article like the present; we must therefore deal with the subject generally, and at the same time with the utmost conciseness.

Robert Bakewell, of Dishley, Loughborough, Leicestershire (born 1726, died 1795), must be credited with having first turned the attention of agriculturists in the direction of improving their live stock. It was in his hands that the old English black horse, the Leicester sheep, and the famous long-horn or Leicester cattle, were brought to perfection; and there is no doubt that his example and precepts were followed by the brothers Colling, of Barmpton and Ketton, in their successful endeavours to improve Durham cattle. Long previous, however, to the time of the Collings, the Durham breed had been preserved with care. Thus pedigrees had been kept in some cases from the time of the cattle murrain, in 1745, and the Dukes of Northumberland, the St. Quintins, the Pennymans, Milbanks, and other county families, had long taken just pride in their cattle. It also appears that a Mr. Dobison, of The Isle, Sedgefield, used a Dutch bull with success, and other breeders followed his example with rather prejudicial effects. The improvement of the county cattle, thus commenced, received a wonderful impetus from the labours of Charles and Robert Colling, who, by collecting together the best females, and allying them to sires of unrivalled merit, succeeded in laying the foundation of a breed which has found admirers in every district of this country, and seems destined to extend over a large portion of the civilised world. In 1810 Mr. Charles Collings' short-horns were sold at Ketton by Mr. Kingston, auctioneer, at an average of £151 8s. over forty-seven head, and in 1818 Mr. Robert Collings' cattle were dispersed at Barmpton, realising an average of £128 14s. 9d., over sixty-one head, old and young. In the first-named sale the bull "Comet" was sold for a thousand guineas, and in both many animals realised two, three, and four hundred guineas. The purchasers of this celebrated stock in turn became noted as the possessors of pure blood, and further extended the breed. The Chilton cattle, under the fostering hand of Mr. Mason, had long been famous, and the sale of this herd in 1829, at which Lord Spencer was a principal buyer, may be looked upon as the next leading event in short-horn history. Mr. Whitaker, of Burley, held his sale soon after, and in the language of "The Druid," Sir Charles Knightley, of Fawsley, gradually became quite a Whitaker of the Midlands. Mr. Richard Booth, of Warlaby, Yorkshire, and Mr. Bates (afterwards of Kirklevington), on the banks of the Tyne, were contemporaneous with the Collings. Both purchased bulls at Barmpton and Ketton, and both became so famous as breeders of short-horns that we shall again have to

SHORT-HORNED COW.

a, Shoulder-top; b, crops; c, chine; d, hook, hip or pin bone; d', space; e, loins; f, ridge; g, beef-bed; h, set-on of tail; i, rump-bone; k, twist; l, buttock; m, flank; n, hock; o, udder; p, fore-udder; u, dew-lap; v, breast; w, shoulder-points; x, neck-vein.

notice their proceedings. Such were the most eminent early improvers of short-horn cattle. With good material to work upon, they brought out animals which probably have never been excelled, and from their time down to the present the successes of breeders have rather been in the direction of maintaining and diffusing than in improving their favourite breed. No greater monument of the care taken in maintaining the purity of the race can be shown than the Herd Book, now numbering nineteen volumes, and containing the pedigrees of some 30,000 bulls, as well as a corresponding number of cows. Such a work also clearly shows the impossibility of giving in a single chapter even a faint idea of the many well-known strains of blood, the rival merits of which are keenly discussed by "short-horn men." Leaving, then, such highly technical details, let us turn to the consideration of those principles which were steadily adhered to by the early breeders of short-horns, and which led to such unprecedented success.

Previous to the time of Bakewell and the Collings it was usually thought impossible to fatten an ox under five years old, and Mr. J. Baily, who wrote the history of Durham, says, "I remember going to see a curiosity in 1786, a steer, three and a-half years old, of Mr. Robinson's, of Hutton, that was supposed to weigh eighty stones (fourteen pounds), and sold for £20." One principal improvement which has been effected is that of an earlier maturity, short-horn cattle now readily fattening at two to two and a-half years old; secondly, an increased aptitude to fatten, or an increase in the relation of beef produced to food consumed; thirdly, undiminished milking properties; fourthly, the reduction of offal or useless portions of the carcase, including bone; fifthly, beauty of form and colour; sixthly, "quality;" seventhly, docility. All these excellences have been developed in a marked degree in the improved short-horn, without any deterioration of constitution or hardihood, by observing certain rules, simple in themselves, but requiring a discerning eye, a practised touch, an almost passionate attachment to the pursuit of cattle-breeding, and, lastly, a bold outlay of money. With these requisites the improvement of cattle becomes a certainty; without them, an impossibility.

The rules or principles which the breeder keeps before him are apparently simple, but involve in their successful application great judgment and long experience. First, it is an axiom that "like begets like," which fact brings us face to face with the whole question of judicious selection. Good animals beget good animals, but the power of transmitting valuable characters varies in individuals. The direct influence of the parent upon the offspring is backed up by the more remote effect of past generations. This singular fact, so well known to every one, and yet so mysterious, is termed *atavism*, from *atavus*, an ancestor, and leads us at once to consider the value of pedigree or lineage. Offspring may therefore resemble a remote ancestor, a fact expressed by the term "reversion," and exemplified by the fact that well-bred cattle will occasionally throw inferior calves, representing unimproved and remote progenitors. These must be rigorously "weeded." The longer a tribe of cattle has been purely bred, the less likelihood is there of reversion to a bad type, and hence the importance of purity of blood, or pedigree. Thus we see that individual merit and an unstained lineage must both be regarded as essential. It will now be perceived that the breeder's art is complicated by various considerations, such as the personal merits of parents, descent, the judicious pairing of animals with a view to correct defects or develop good qualities, and, lastly, the feeding and treatment of the animals.

It is also worthy of attention that however unnatural a system of breeding from near affinities may be, it has succeeded admirably in the case of short-horn cattle. We often hear in-and-in breeding, or the breeding from close relationships, at once condemned as leading to disease, deformity, and imbecility. All races of animals cannot, however, be thus generally spoken of. With some, as in the case of horses and the pig, in-breeding is followed with pernicious results, yet cattle and sheep may be bred in this way for many generations, with advantage rather than otherwise. The bold policy of in-breeding pursued by early short-horn breeders is indeed singular, and, we cannot help thinking, conclusive in favour of the system as applied to cattle. Let us now briefly trace the origin of the Barmpton and Ketton short-horns, from which so many herds of the present day are descended. The Messrs. Colling possessed good cattle of the neighbourhood, but Mr. Robert Colling confessed that they never had better cattle than other people, until Mr. Charles Colling purchased the cow Favourite and her daughter Young Strawberry from Mr. Maynard, of Eryholme. Other good cows were also gathered together at Barmpton, and such formed the nucleus of the future herd. We now turn to the sires. The first bull which left his mark was the now celebrated "Hubback" (319), a bull picked up almost accidentally by Mr. Charles Colling, but which was subsequently shown to be possessed of a pure short-horn pedigree for several generations. This bull possessed, in a most wonderful degree, the power of transmitting his good qualities to his offspring, and his name lies at the foundation of all the pedigrees in at least one very important section of our short-horn herds. "Foljambe" (263) succeeded "Hubback," and "Favourite" (252) succeeded "Foljambe." Favourite (252) was himself the result of close interbreeding, as is shown by the following tabular view of his pedigree, commencing with the cow Favourite and her daughter Young Strawberry.

$$\underbrace{\text{Young Strawberry (cow).}\quad \text{Foljambe (bull).}}_{\text{Bolingbroke (bull).}} \quad \underbrace{\qquad\qquad \text{Favourite (cow).}}_{\text{Phœnix (cow).}}$$

$$\underbrace{\text{Bolingbroke (bull).}\qquad \text{Phœnix (cow).}}_{\text{Favourite (252).}}$$

And yet Favourite was often used, without ill results, upon his own offspring for two generations. A cow by Favourite was put to Favourite, and the result was "Princess." Princess brought Nell Gwynne by Phenomenon (491), but on consulting the Herd Book we find that Phenomenon is by Favourite. Nell Gwynne put to Layton (366) brought another Nell Gwynne, and on investigating Layton's pedigree we find that he was by Minor (441), himself the result of two consecutive Favourite crosses, and out of a dam similarly imbued with Favourite blood. Again, taking the case of Janette by Wellington, a name which occurs far back in the pedigree of the "J" family, we find the following. Wellington was a grandson of Phenomenon, and by three previous crosses he was at once great, great-great, and great-great-great-grandson of Favourite. Still further, Janette's dam was by Phenomenon a son of Favourite, and, lastly, Janette's grandmother, great-grandmother, and great-great-grandmother were each by Favourite. Such was frequently the breeding of those earlier animals, whose progeny now rank highest in public estimation, and instances might be given to show that a similar system of close breeding has been pursued without apparent ill effects down to the present day.

At an early date in the history of short-horns two rival breeders, Mr. Bates, of Kirklevington, and Mr. Booth, of Warlaby, both of Yorkshire, came prominently before the public. It is scarcely too much to say that our most highly esteemed short-horns trace back to animals bred by either one or the other of these breeders. Booth and Bates' cattle are familiarly spoken of by short-horn breeders as representing two rival strains of blood, each party claiming special merits for his favourite. We do not propose to discuss this subject, as it would lead us into undue prolixity, but it is necessary to mention it, as the two strains are for the most part kept apart, and as a consequence certain distinctive characters have asserted themselves as peculiarly belonging to each family. Among the best examples of Bates' cattle at the present time are the Wetherby Duchesses, the property of Colonel Gunter; the Duke of Devonshire's herd at Holker, Lancashire; and Lord Dunmore's and Mr. Bowly's Kirklevingtons. Among Booth cattle we may mention the Warlaby herd, now in the possession of Mr. John Booth; the Aylesby herd, so long and carefully bred by Mr. Wm. Torr; and the Towneley herd, associated with the name of Colonel Towneley. We must conclude this brief account of short-horn cattle with the points of excellence usually looked for, many of which are common to other breeds of cattle.

The colour may be red, white, red and white, or roan, but black is not allowed on any part of the body. The hair is plentiful, long, lying in various directions, and of mossy, rich appearance. The animal is docile, the female carrying a sweet-looking head, with a quiet eye. Horns of moderate length in the cow; short, thick, and spreading in the bull. The muzzle is cream-coloured, and the horns are waxy, with streaks of red at the base. The bull has a noble carriage, and fine head, with hair curling over his forehead and between his horns. It is the head which gives what is termed "character" among

breeders. The rump-bone, when the animal is lean, should be about two inches off, and the upper portion of it level with, the under side of the tail. When an animal is narrow at this point there is often a want of lean flesh and substance between the rump and hips. The quarter, or length from rump-bone to hip, should be long and full of lean flesh; the hips should be wide across, especially in the female, and the hip-bones rounded and well covered; the loin must be flat and wide; the space between hips and ribs moderate; the ribs well arched and deep, giving a round "barrel;" the back straight; the breadth of the loin maintained by the spring of the ribs, and shoulders wide across; the belly line parallel with the back, giving a uniform cylindrical body; the flank well let down; thighs heavy-fleshed and deep; buttocks full on both sides; shoulders snugly laid back into the crops; the bosom deep, wide and prominent; the neck thick at the base, but tapering to the head; the head broad between the eyes, and tapering to the muzzle. Whether viewed from front, back, sideways, or from above, the animal should approximate as nearly as possible in general outline to a parallelogram form. This is difficult to realise, but a glance at truly well-made cattle will convince the observer that a certain squareness of form is the best type of bovine symmetry. In addition to a correct form, short-horns must also possess the essential trait of "quality" or "touch." In other words, the skin must be soft, pliant, neither too thin (papery) or too thick (heavy), and moving with a certain characteristic ease upon the cellular matter beneath. This peculiar handling of cattle accompanies aptitude to fatten, and it is spoken of as "quality." Quality is also indicated by an abundant coat of fine silky, well laid hair. On comparing Bates and Booth cattle, we find the following points of difference. The former are unrivalled in "touch" or quality; the bulls have grand "Bates' character" heads, noble necks, and upright shoulders, rather hollow or deficient behind. Mr. Carr, the historian of Booth cattle, says: "The late Mr. Booth succeeded in imparting a length of quarter such as no other herd can boast, a marvellous fulness and depth of thigh, and of the twist or junction of the inside of the thighs, and a perfectly parallel and almost perpendicular position of the hind legs. It was, however, to the ample and symmetrical development of the fore-quarters that Mr. Booth's special attention was directed. He increased the obliquity or backward inclination of the shoulder-blade, thereby preserving the level line of the back, and promoting the free and graceful carriage of the animal. It was also his aim to improve the form and enlarge the capacity of the chest, which he did by augmenting the prominence or circularity of the fore-rib, and the width of the sternum or floor of the chest. It is to the success of Mr. Booth's efforts in this direction that we are indebted for those valuable and almost peculiar characteristics of the Warlaby cattle—the perpendicular fore-flank, which drops even with the arm; the roundness of the barrel-shaped crops, and the width or massiveness of the projecting bosom. The necks of the Booth short-horns are remarkable for their bulky and yet symmetrical development, gradually swelling as they approach and blend with the shoulders and breast, and completely hiding the shoulder-points even in the unforced animal."

We are compelled to leave the short-horn here, and to turn our attention to other important breeds. Such a sketch must be of necessity incomplete; but if we have given a good general idea of the history of the breed, the principles kept in view by those agriculturists who interested themselves in its improvement, and some faint idea as to what a good short-horn is, our task has not been in vain. The following works have been consulted in writing the above article:—"The History of the Killerby, Studley, and Warlaby Short-horns," by W. Carr; "History of Improved Short-horn Cattle," by T. Bell; "The Rise and Progress of Short-horns," by H. H. Dixon; Darwin's "Animals and Plants under Domestication;" the *Agricultural Gazette;* Mr. Wright's Essay on Short-horn Cattle; and Mr. Thornton's "Short-horn Circular." In these any of our readers who may be desirous of obtaining further information will find many details, and much that is interesting and important that we have been precluded from entering into here. We need scarcely say that their perusal will amply repay the time spent over them, and furnish the cattle-breeder with many useful hints that might otherwise have been lost to him.

CIVIL ENGINEERING.—XIX.

BY E. G. BARTHOLOMEW, C.E., M.S.E.

LIGHTHOUSES (*continued*).

The very limited period during which it was possible to work upon the Bell Rock—a period seldom exceeding three hours at a time—made it necessary to embrace every opportunity of favourable weather, as well by day as by torch-light by night, and also upon Sundays. The rise of the tide is so sudden that immediately the exterior parts of the rock were covered the workmen had to collect their tools, and betake themselves to the attending boats.

The first thing necessary to do at the rock was to erect a beacon to serve as a residence for the men during the working months. This beacon consisted of twelve large beams of fir timber, occupying a base of 30 feet diameter, and rising to a height of 50 feet above the rock. The spars were strongly framed with oak knees, and connected to the rock by iron bats set into holes, cut 18 inches deep in the rock, and wedged in. The upper part of the beacon was fitted up for occupation, the lower floor being employed as a smith's forge, and for preparing the mortar. Immediately over this was the cooking-house; above this were the cabins of the engineer and foremen, and over all the barracks for the artificers.

The occupied portion of this wooden structure was above the reach of the sea in moderate weather; but the lower floor was often lifted by the waves, and the contents washed away. The position of this beacon was near the site of the lighthouse, and after the erection of the latter had fairly progressed, the two structures were connected by a wooden bridge, which served as a stage from whence the materials employed in the building were raised from the rock. If the peculiar position and circumstances of the Bell Rock are taken into consideration, the great use of this beacon-house will be apparent. The rock was so constantly submerged, and the periods during which it was exposed were so short, and moreover the difficulty of landing upon the rock, owing to the violence of the surf, was so great, that had there not existed a temporary resort upon the rock itself, from which the workmen might without loss of time hasten to their duties, the commencement of the work would have been greatly impeded, and probably many lives lost. The beacon was vacated at the close of the summer, and again resorted to as soon as the storms of the ensuing winter and spring were over.

To facilitate the conveyance of the huge blocks of stone employed in the construction of the lighthouse, from the various landing-places at the rock to the site of the building, tracks of cast-iron rails were laid down and fixed to the rock. Two seasons were thus occupied in erecting the beacon, in cutting out and preparing the rock for the reception of the blocks, and in laying the first four courses of stone, which brought the height of the building 5 feet 6 inches above the foundation; and by the end of the succeeding season the building was raised to the height of 30 feet, which completed the solid portion of the lighthouse.

The state of the weather during the ensuing season, combined with the skill acquired by the men during the operations of previous years, enabled the building to be completed by the following October, at least so far as the masonry was concerned, and the light-room was finished in December of the same year.

This lighthouse is, like the Eddystone, circular. The two bottom courses of the masonry are sunk into the rock, and a very similar system of dovetailing to that of the Eddystone has been employed. The cement used was a mixture of pozzuolana, earth, lime, and sand, in equal parts by measure. The stones which compose the solid portion of the structure weigh from half a ton to two tons each.

The diameter of the bottom course is 42 feet, and the building diminishes in much the same proportion as the Eddystone, until the parapet-wall of the light-room is reached, where the diameter is reduced to 13 feet. The masonry portion is 100 feet high, above which the lantern rises 15 feet.

The first 30 feet from the ground is solid, and at this height the entrance is situated. The ascent from the rock to the entrance is by a kind of rope-ladder with wooden steps, which is hung out at ebb-tide, and taken into the building when the water covers the rock. The staircase rises 13 feet from the end

of the passage, at which place the walls are 7 feet thick, and diminish to 12 inches in thickness at the parapet-wall of the light-room. The building contains six apartments, including the light-room. The floors are all of stone. The casements of the windows are all double, and are furnished with outer storm-shutters. The parapet-wall is 6 feet high, and outside it is a balcony surrounded by a cast-iron rail, resting upon a footing of brass, and surmounted by a coping of the same metal. The smoke-tube of cast iron which conveys away the smoke from the kitchen passes through the several apartments above it, and heats them.

The light-room and apparatus was constructed in Edinburgh. Its shape is octagon, and it measures 12 feet across, and 15 feet in height. The sashes are of cast iron, and the panes measure 2 feet 6 inches by 2 feet 3 inches. The glass is $\frac{1}{4}$ inch thick. The cost of the building and its establishment was about £60,000.

It is easy to perceive that apart from the difficulty of rearing a tall structure having a limited area of base, which is submerged every tide, capable of withstanding the shocks of heavy seas, one of the chief obstacles to be contended against in erecting a lighthouse upon an isolated and exposed rock lies in the difficulty experienced in landing men and materials, and in the limited period of time during which operations can be carried on in the early stages of the work. Some idea of what this difficulty is may be gathered from the narrative of the building of the lighthouse upon the Wolf Rock, and of the admirable precautions which were adopted by the engineer, Mr. Douglass.

The Wolf Rock is situated 23 miles W.N.W. from the Lizard, 20$\frac{3}{4}$ miles E. by S. $\frac{1}{2}$ S. from St. Agnes Lighthouse, Scilly, and 7$\frac{3}{4}$ miles S.W. $\frac{1}{2}$ S. from the Longship's Lighthouse. It consists of a hard porphyry, and its highest part is 17 feet above low water, and 2 feet below high water of spring-tides. The surface is sufficiently rugged to render a landing upon it difficult at all times. The water is very deep on all sides except the S.E., the depth being upwards of 100 feet. There is also a strong tidal current setting upon the rock. Its position is exceedingly exposed, and it receives the full force of the Atlantic waves, which burst upon it with incredible fury. So long ago as 1823 the Admiralty appear to have wished to erect a lighthouse upon this rock, but the estimate of fifteen years to build it, and the cost—£150,000—seems to have deterred them from the enterprise, and an iron beacon was subsequently erected by Mr. Thurburn, occupying in its erection from 1836 to 1840. Five years would appear to be a long period to expend in this undertaking, but the actual time occupied in working upon the rock was only 302$\frac{1}{2}$ hours during the whole five years, this limited period being entirely due to the danger and difficulty attendant upon the exposed position of the rock. The beacon, which consisted of a mast of selected English oak 12 inches in diameter, secured by stays fastened to the rock, cost £11,298 4s. 1d., and it was carried away in November of the same year in which it was completed. It was replaced by one of wrought iron, 7$\frac{5}{8}$ inches in diameter, in August, 1842. During the heavy weather of the succeeding winter this iron mast was bent about 3 feet from the perpendicular, and in October, 1844, it was broken off at about 4 feet above the top of the cone. A second iron mast was subsequently fixed, the diameter being increased to 9 inches, but this also was carried away in the early part of 1848. Another iron mast of equal diameter, but supporting a smaller globe, was then fixed, and this withstood the violence of the sea until taken down, during the construction of the present lighthouse.

These particulars will serve to illustrate the force of the waves beating upon this rock. We shall not enter into a minute description of the magnificent structure which now serves to warn the mariner to avoid the dangers of the Wolf. A few of its leading characteristics will suffice.

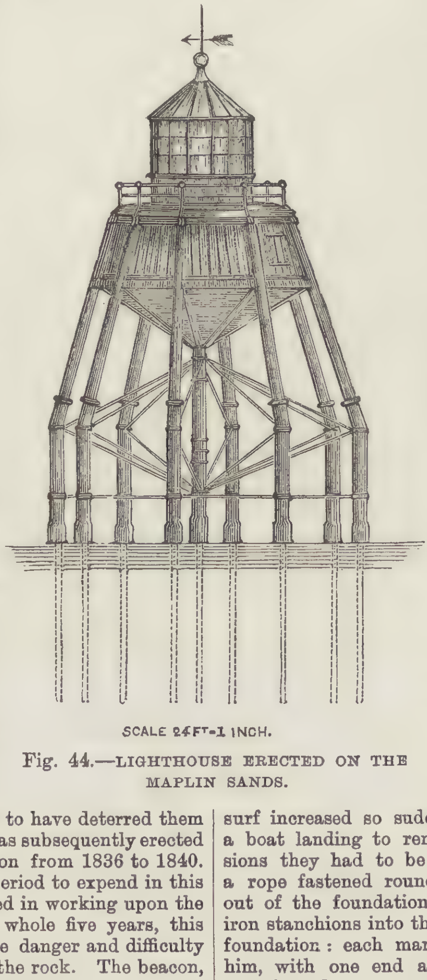

Fig. 44.—LIGHTHOUSE ERECTED ON THE MAPLIN SANDS.

The building is of stone, 116 feet 4$\frac{3}{4}$ inches high; the diameter at the base is 41 feet 8 inches, but near the top, just below the springing of the curve under the lantern, it is reduced to 17 feet. The work is solid for 39 feet 4$\frac{1}{2}$ inches from the base, with the exception of a space formed for a reservoir for fresh water. The walls are 7 feet 9$\frac{1}{2}$ inches thick at the level of the entrance door, and gradually decrease to 2 feet 3 inches at the thinnest part near the top. The exterior face of the shaft is similar to that of the Eddystone and Bell Rock, being perhaps rather flatter in the curve. It contains 44,506 cubic feet of granite, weighing nearly 3,300 tons. Every external stone block is dovetailed to the adjoining block, both vertically and horizontally, the dovetails being 3 inches in height. In addition to this precaution, each block of the two lower courses is secured to the rock by two metal bolts 2 inches in diameter, and sunk 12 inches into the rock and wedged. In the next eighteen courses each exterior stone is secured to the course below by two 2-inch bolts of yellow metal, and each internal stone by two 2-inch bolts of galvanised puddled steel. These bolts are sunk 9 inches into the course below.

In order to economise time upon the rock, the blocks were all prepared and carefully fitted, and the bolt-holes all bored, in the yard on shore. The blocks to the level of high-water spring tides were set in fresh Roman cement, and from this point upwards in Portland cement. The cement was mixed with an equal portion of sharp granitic sand, obtained near Penzance, and salt water was employed in the mixture for all the solid portion of the work. Very little wood is employed in the structure, the ladders for ascending from room to room being of cast iron, as well as the partitions between the rooms and the staircase; whilst the doors, windows, and storm-shutters are of gun-metal. To facilitate landing upon the rock, a landing-platform has been constructed. This consists of small granite ashlar, set in cement, the stones of which it consists being 24 inches × 12 inches × 6 inches, the quantity of masonry being 14,564 cubic feet.

It not unfrequently happened during the early stages of the work that the surf increased so suddenly as to preclude the possibility of a boat landing to remove the workers, and upon such occasions they had to be hauled on board through the surf by a rope fastened round their waist; and during the cutting out of the foundation pit, it became necessary to sink heavy iron stanchions into the rock at intervals around the site of the foundation: each man working with a safety-rope lying near him, with one end attached to the nearest stanchion. An experienced man was always stationed on the highest point on the rock, whose duty it was to watch for the seas, and to give warning to the workmen to hold on to the lines, when, with head to the sea, it would wash over them, and frequently carry away the tools they had been using. In this manner eight working seasons were passed, during which 266 landings had been effected, and 1,809$\frac{1}{2}$ working hours spent on the rock. In spite of the height of this lighthouse—upwards of 100 feet above high-water mark—large quantities of water are not unfrequently thrown over the tower. The total cost of the building, including all incidental expenses, was £62,726.

That most useful material, iron, is not excluded from the construction even of lighthouses, having been successfully employed in more than one instance. One will suffice as an illustration, the cast-iron lighthouse at Bermuda, erected by

Mr. Gordon. The site it occupies is not exposed to the wash of the sea; indeed, it might scarcely be deemed advisable to employ a material so liable to corrosion from the action of salt water as iron is, in a position where it would be subjected to its influence; it would certainly require the most constant and scrutinising attention.

The Bermuda lighthouse stands upon an elevation 250 feet above the level of the sea, and is itself 105 feet 9 inches high, and 24 feet in diameter at the base. It consists of concentric cast-iron plates, 135 in number, and moulded to the external contour of the shaft. The plates vary in thickness from 1 inch to $\frac{3}{4}$ of an inch, and are cast with flanges on the inside 4 inches broad, reckoning from the exterior surface of the plates, which are further strengthened by $\frac{1}{2}$-inch feathers placed at intervals of 12 inches.

Holes $\frac{3}{4}$ inch in diameter are drilled 6 inches apart in all the flanges, both vertical and horizontal, to receive $\frac{3}{4}$-inch screw-bolts, by which the several plates are united. In the centre of the lighthouse is a hollow column of cast iron running from bottom to top, 18 inches in internal diameter, and $19\frac{1}{2}$ inches in external diameter. Upon this rests the optical apparatus, and the weight by which its revolution is maintained descends through this hollow shaft. The column is cast in nine lengths, each length terminating externally in broad circular flanges, which serve the double purpose of connecting the sections together, and of supporting the floor-plates. This shaft is also employed in raising stores from one floor to another, for which purpose there is, at a height of 2 feet above each floor, an opening left, 26 inches high and 15 inches wide, furnished with a door. The lower portion of the tower is filled with concrete to the height of 20 feet, with a well in the centre 8 feet in diameter, lined with brickwork. There are seven floors, each 12 feet high, the lower two being cased with brickwork. The upper five are lined with sheet iron. Each floor is furnished with five windows, 18 inches square, fitted with plate glass. The staircases, with the exception of the treads, which are of oak, $1\frac{1}{2}$ inch thick, are wholly of iron. The light is visible at a distance of upwards of eight leagues. The total cost was under £8,000.

There is a cast-iron lighthouse erected upon the Fastnet Rock, an isolated crag situated a few miles off the southernmost point of Ireland, and rising 60 feet above high-water mark. The dimensions of the tower are—height from base to gallery, 63 feet 9 inches; height of lamp above the gallery, 11 feet; height of lantern, 30 feet; outside diameter of base over the stone moulding, 23 feet; outside diameter of cast-iron shell at base, 19 feet; outside diameter below the cornice, 13 feet $11\frac{1}{4}$ inches; thickness of plates at the base, $1\frac{3}{8}$ inch; thickness at top, $\frac{7}{8}$ inch. The mode of construction is nearly identical with that at Bermuda.

When a lighthouse is required to stand upon a soft, yielding base, as sand, screw-piles are employed with great advantage. There are several instances of such structures. One of the earliest is that at the Maplin Sands, erected in 1841. The building rests upon nine wrought-iron piles, 26 feet long and 5 inches in diameter, furnished with cast-iron screws, whose blades are 4 feet in diameter. The piles are screwed into the sand to a depth of 22 feet, leaving 4 feet standing above the soil. One pile occupies the centre of the building, and the remaining eight stand at the angles of an octagon formed round the central pile. The upper portion of the piles enter the hollows of cast-iron sockets forming the lower extremities of the supporting columns. The central column is perpendicular, the remaining eight incline inwards, and the whole nine support the platform, house, and lantern. The columns are strongly braced together by wrought-iron rods, the braces being horizontal below the water-line, supporting the columns at a point midway between the top of the piles and the bend of the columns; and diagonal from the angle of the bends themselves to the central column, rising and falling above and below the horizontal plane of the bends. The entire absence of opposition to the waves offered by the columns is a notable and excellent feature in this form of structure.

In Fig. 44 we give a sketch of the lighthouse erected on the Maplin Sands.

There are many other lighthouses erected upon piles, all of which have stood well. That at the *Gunfleet* stands on seven screw piles, screwed 40 feet deep into the sand. Another, at the *Point of Ayr*, stands on nine piles, screwed 12 feet into the sand. There is a small lighthouse standing upon piles at *Mucking Reach* in the Thames, a few miles below Gravesend.

A remarkable and successful instance of lighthouse engineering occurred some years since at Sunderland. Owing to the construction of a jetty, the lighthouse, which had stood upon the old pier, became useless in that position, and it became necessary either to pull it down and rebuild it upon a situation where it would be of use, or to remove it bodily. The distance of the new site from the old was no less than 475 feet, and was not in one direct line, and the difficulty and risk attendant upon adopting the latter course will readily be appreciated: adopted it was, however. The weight of the structure was 757,000 lb.; it consists of an octagonal tower 64 feet high, and 15 feet in diameter at the base; and not only had it to traverse the distance mentioned, but it had to be turned upon its axis, and the new site was 19 inches higher than the old.

The method employed was generally much the same as that employed in the removal of large masses of masonry, with certain modifications to suit the shape of the building. A series of openings were made in the base of the tower, and into these beams were introduced, united together by cross-beams, so as to form a substantial and very strong flooring or platform of oak. In order to steady the tower, a framework of shores or props, resting on the platform, abutted against the tower from the base to the summit, the stays being strengthened by crossbeams.

The platform rested on 144 cast-iron flanged wheels, and the masonry below the platform having been very gradually removed, iron rails were introduced below the wheels, and thus by degrees the whole structure was made to rest upon the wheels, which ran on eight parallel rails, laid upon the pier, along which the lighthouse was required to move. The whole mass was moved forwards along the rails by iron chains attached to the platform, and wound upon windlasses. The entire operation was accomplished in about $13\frac{1}{2}$ hours, and so successfully that no interruption occurred in the lighting of the lantern, not even for a single night.

BUILDERS' QUANTITIES AND MEASUREMENTS.—XV.

BY E. WYNDHAM TARN, M.A.

PLUMBER.

THE work of the plumber consists in the laying of lead on the roofs, gutters, etc., of buildings; lining wood cisterns with lead; laying down lead or iron pipes for water-supply; fixing cocks, water-closet apparatus, soil-pipes, pumps, etc.

There are two kinds of lead used for roofs and linings to cisterns, cast lead and milled lead; the former is now seldom used, though it is often found on old buildings. Milled lead, which is now generally used, varies in thickness, which is reckoned according to the number of pounds' weight in each square foot, as 4 lb., 5 lb., 6 lb., etc. In measuring plumbers' work take the exact area of the lead, describing the weight per foot, and multiply the area by the given weight in the abstract, which will give the weight of lead used. In the bill all sheet lead is brought into cwts. and lbs., and the different parts of the work kept separate. In taking the dimensions of lead covering to roofs, sufficient allowance must be made for the laps and dressings over the rolls; and in gutters an allowance is to be made at the drips for turning up the lead.

In taking the lead linings to cisterns, measure the exact quantity of lead, take the run of the soldered angles, and also the nailing to the edges with copper nails. Number the solderings for letting in pipes, washers, etc., to the cisterns, also all plugs, washers and wastes, air-traps, screw or driving ferrules, stop-cocks, bib or ball cocks, stating whether zinc or copper balls are used, and giving the size or diameter of the bore of each cock.

All lead pipe is taken by the foot-run, the diameter of bore being stated, and whether common, middling, or strong pipe is used. The soldering to the joints, which are required in laying or connecting pipes, is generally included in the price of the pipe and laying; but solder joints for attaching cocks, etc., are numbered, describing the size of pipe. Syphon traps formed by bending pipes are numbered as extra upon the measured length. Trumpet-mouthed standing water-pipes in cisterns are numbered, giving the height and diameter at bottom; also

number the lead service-boxes soldered into the bottom of the cistern for the supply of the water-closet. The apparatus for water-closets are numbered and described; the D or P traps thereto are numbered separately, and the soil-pipe by the foot-run, describing the diameter and weight per foot; bends to soil-pipe are measured separately from the straight part, and all soldered joints are numbered. The lead safe, laid underneath the closet apparatus, is measured by the foot superficial as in cisterns, and the soldered joints by the foot-run.

Pumps are numbered, describing the diameter, and whether suction or force pumps, single or double; the pump-rods for deep wells are in lengths of 10 feet with joints and brass couplings, and must be measured by the foot-run.

ZINC-WORKER.

Zinc is used in a similar manner and for similar purposes to those for which lead is applied, as in the covering of roofs and flats, valley and hips, flashings, linings of gutters and cisterns. The area is measured with proper allowance for laps and rolls, and if cut away at a slant the full width of the widest part must be measured, and no deduction made for the part cut away, as there would be in lead. The thickness or gauge is stated as so many ounces to the foot, but it is not brought into cwts. and lbs. in the bill, the price being stated at per foot superficial, according to the position in which it is laid, whether in flats, roofs, gutters, flashings, corrugated, etc. Zinc eaves, gutters and rain-water pipes are taken and billed out at per foot-run, numbering the heads, shoes, bends, nozzles, stopped ends, angle-pieces, etc.

GAS-FITTER.

The pipes used for conveying gas to various parts of a building are of two kinds, iron and tin; the iron pipes being used for the principal part of the work, and in carrying the gas from floor to floor, and the tin pipes for branching therefrom to the burners and chandeliers. The iron pipe is in lengths of from 4 ft. to 12 ft., and must be measured with an allowance of so many lengths: if short pieces of 2 ft. to 4 ft. are used, they are measured separately at per foot, pieces under 2 ft. being numbered; the internal diameter of the tubing must be stated. Number all bends, elbows, tees, cross-pieces, connecting pieces, plain or diminishing sockets, flanges, union joints for tin pipe, stop-cocks, nose pieces, etc. Tin gas-pipe is to be measured by the foot length, describing the diameter. Gas brackets are numbered and described, giving the length of the tube, whether single, double, or treble jointed. Pendants, chandeliers, standards, etc., are numbered and described.

GLAZIER.

In measuring the glass stopped into sashes, sash doors, fanlights, skylights, etc., take the dimensions between the rebates, if the opening is rectangular, and the greatest width and length, if the shape is irregular; bring into superficial feet, describing the size of the squares, and the quality of the glass, whether best, seconds, or thirds crown; if sheet glass, state the number of ounces per foot superficial, as well as the quality; if plate glass, state whether best or seconds glazing quality, the size of each square and the thickness. If the glass has to be bent to a sweep, it is measured extra per foot superficial.

Glazing in lead quarries, with crown or cathedral glass, is taken by the foot superficial, including the lead-work and copper ties, an allowance all round being made for letting into the groove in the stone-work; and if the heads are arched they must be measured the full height by the width, as if square. Saddle bars are taken separately, by weight, with the smith's work.

Hacking out old or broken glass is taken by the foot superficial, in addition to the stopping in of the new glass. Also obscuring or frosting glass to imitate ground-glass is taken by the foot superficial.

Cleaning windows is numbered by the window, and if in small squares of glass, by the dozen squares. Grinding or polishing the edges of plate glass is taken by the inch-run, and circular cutting by the foot-run. Glass tiles or slates are numbered according to their respective sizes.

PAINTER AND DECORATOR.

The painter's work on deal or other woods must be measured separately from that on plaster, cement, iron, or other material; as in painting on deal the work has first to be knotted, and any defects stopped, and then primed, after which it receives the stated number of coats, generally described as so many oils. All large works, as doors, framing, walls, etc., are measured by the yard superficial, with an allowance for all edges, mouldings, sinkings, projections, etc., in taking the dimensions. Carved work may be taken by the foot superficial. Skylights of large size may be measured by the superficial yard, but entered separately in the bill.

Where the work has to be cut in on one or both edges, as in edges of stairs cut for carpets, skirtings, rails, newells, rain-water pipes and gutters, reveals, cornices, staff beads, shelf edges, strings of stairs, etc., it is taken by the foot-run.

The paintings to sah frames is taken by number, describing the size, and whether ordinary or Venetian. Sashes and casements have the number of squares taken by the dozen, if small, but large squares are taken singly.

Iron railings and balusters of stairs have the painting measured, as if it was solid work, the height by the length on both sides.

Small articles, as bell-boards, scrapers, shutter-bars, chimney-pieces, etc., have the painting to them taken by number and description.

Graining and varnishing is measured by the yard superficial, except for hand-rails, which are taken by the foot-run; the character of the imitation is described, and also the number of coats of varnish.

The description of painter's work must include the number of coats laid on, whether finished in common or extra colours, or with a flatting coat; also whether prepared for graining. In repainting to old work it must be described as rubbed or pumiced down previous to being painted.

Staining, sizing, and varnishing deal, in order to bring out the natural grain of the wood, is measured by the superficial yard.

Writing or painting letters or figures is taken by the inch-run, describing the height and character of the letters, and whether plain or shaded.

Gilding is measured by the foot superficial, carved work being taken separately; and mouldings by the foot-run, describing the size.

Distempering is measured by the superficial yard, describing the tints used, and if more than one. Imitations of Scagliola are measured by the foot superficial.

PAPER-HANGER.

The hanging of paper to walls is measured by the foot superficial, and the area thus found is entered in the abstract and divided by 5, to bring it into linear yards of paper 20 inches in width, which quantity is divided by 12, to bring it into pieces, as nothing less than a piece of 12 yards length can be taken. Common papers, however, do not nett more than 11 yards to the piece in the general way, so that a full allowance must be made. If the paper is hung to new walls, describe the sizing of the walls, and hanging with a lining paper previously to hanging the decorative paper. If the walls have been previously papered, then take the pumicing, sizing, and stripping with the description of the papering.

Canvas lining over panelled framing, or where the surface is not even, is measured by the superficial yard. If the paper is hung in blocks, as marbled papers, or if in panels, it must be so described, and whether lined, sized, and varnished.

Borders to paper-hangings are taken by the dozen yards, unless of superior quality, when they may be taken by the single yard.

Gold or black mouldings fixed upon the papering with needle-points are measured by the yard-run, describing the width.

We shall now apply the foregoing rules to taking out the quantities in each of the above-named trades, and then proceed to form an abstract thereof, previously to bringing them into bill.

PLUMBER.

2)	24 0 15 0	720 0	7 lb. milled lead on roof.
	25 0 1 6	37 6	6 lb. ditto gutters.

2) 30 0 1 9	105 0	Ditto, ditto, hips.
34 0 1 3	42 6	5 lb. ditto step flashgs.
15 0 2 6	37 6	6 lb. ditto cisterns.
5 0 2 6	12 6	7 lb. ditto, ditto.
17 6	17 6	Soldered angle to cistern.
15 0	15 0	Close nailing with copper nls.
45 0	45 0	1 in. strong lead pipe.
12 0	12 0	¾ in. ditto.
35 0	35 0	1¼ in. ditto.
16 0	16 0	1½ in. ditto.
32 0	32 0	5 in. soil-pipe.

No. 2 solder jts. to 1¼-in. pipe.
,, 2 ditto, 1-in. pipe.
,, 2 ditto, ¾-in. pipe.
,, 2 ditto, 1½-in. pipe.
,, 2 1¼-in. brass washer and waste.
,, 1 1¼-in. trumpet-shaped standing waste 2 ft. 3 in.
,, 1 lead service-box, soldered.
,, 1 1¾-in. ball-cock and copper ball.
,, 1 1-in. stop-cock.
,, 1 ¾-in. bib-cock.
,, 1 D-trap.
,, 1 W. C. apps.
,, 1 syphon-trap in 1½-in. pipe.
,, 1 brass gratg., soldered.
,, 1 2½-in. br. force-pump.

ZINC-WORKER.

12 0 10 6	126 0	25 oz. zinc in flats.
24 0	24 0	4 in. eaves gutter.
2) 15 0	30 0	2½ in. R. W. P.

No. 2 octagon heads. 2 shoes. 2 nozzles.
,, 4 stopped ends to gutters.

GAS-FITTER.

55 0	55 0	1 in. w. iron welded tubing.

No. 5 short pieces 1 in. w. i. tubing.
,, 3 bends to ditto.
,, 2 tees to ditto.
,, 1 cross to ditto.
,, 1 connecting piece.
,, 1 1-in. stop-cock.

30 0	30 0	½ in. tin pipe.

No. 8 ½-in. union joints.
,, 4 plain brackets, 12 in. long.
,, 2 ditto, double jointed, 24 in. ditto.
,, 1 plain pendant, with hydraulic joint.
,, 5-light chandelier.

NOTABLE INVENTIONS AND INVENTORS.

XXIX.—SIR ISAMBARD BRUNEL (*continued*).

BY JOHN TIMBS.

We mentioned at the conclusion of the first part of this memoir the machine invented by Brunel for making shoes for the army. After two years' trial the manufacture of shoes by this machine was given up from an economical motive. By this and another speculation Brunel got into difficulties, from which he was extricated by a Government grant of £5,000, in consideration of the savings by the use of his block machinery. He then improved the stocking-knitting frame and the steam-engine, the manufacture of metallic paper and crystallised tinfoil, stereotyping, and the treadmill. Among other things he invented machines for making wooden boxes; for nail-making; for ruling paper; a contrivance for cutting and shuffling cards without the aid of the fingers, produced in reply to a playful request from Lady Spencer; a hydraulic packing-press; and a process for building wide and flat arches without centerings. In steam navigation he experimented with a boat on the Thames, fitted with a double-action engine, and made his first voyage in it to Margate in 1814, when he narrowly escaped personal violence from the proprietors of the sailing-boats. Marine engines and paddle-wheels were next improved by Brunel. He constructed a machine for using carbonic acid gas as a motive power; and, assisted by his son, carried on a series of experiments for more than ten years in the endeavour to bring it to perfection. Most of the mechanical difficulties were overcome; but although an intense power was obtained, and with a very low temperature, the economical advantages, as compared with the cost of the vapour of water, did not appear to be such as to compensate for the increased cost of the machinery and the usual difficulties in its use.

In different parts of the United Kingdom are to be found works of engineering construction by Brunel, who thus largely contributed to the wonders which in his boyhood he so ardently desired to see. His greatest work, and that by which he is most popularly known, is the Thames Tunnel, a brick-arched double roadway under the river, between Wapping and Rotherhithe. In 1804, two Cornish miners, Varey and Trevethick, commenced an archway from Rotherhithe to Limehouse, and the excavation had reached 1,040 feet, when the ground broke in under the pressure of high tides, and the work was abandoned. With such failure before them, fifty-four engineers declared it impracticable to make a tunnel under the Thames of any useful size for commercial purposes. Brunel, however, rose superior to this declaration, and planned a tunnel in 1823, when a company was formed, and the Duke of Wellington and Dr. Wollaston were the earliest subscribers to the scheme. A brickwork cylinder, 50 feet in diameter, 42 feet high, and 3 feet thick, was commenced by Brunel, at 150 feet from the Rotherhithe side of the river. Upon this cylinder, computed to weigh 1,000 tons, was set a powerful steam-engine, by which the earth was raised and the water was drained from within it. The shaft was then sunk into the ground *en masse*, and completed to the depth of 65 feet; and at the depth of 63 feet the horizontal roadway was commenced, with an excavation larger than the interior of the old House of Commons. Brunel devised, in 1814, this plan of operation from the bore of the *Teredo navalis* into the keel of a ship, the perforation of the worm being secured at the sides, and lined with a calcareous secretion, so as to be impervious to water. With the auger-formed head of the worm in view, Brunel employed a cast-iron *shield*, containing thirty-six frames, or cells, in each of which was a navvy, who cut down the earth; and a bricklayer simultaneously built up from the back of the cell the brick arch, which was pressed forward by strong screws. Thus were completed 540 feet of the tunnel, when the river burst into the works; but the opening was soon filled up with bags of clay, the water pumped out of the tunnel, and the work resumed. At the length of 600 feet, the river broke in again; six men were drowned, and the rush of the water carried Mr. Brunel's son up the shaft. The tunnel was again emptied, but the works were suspended seven years for want of funds.

In April, 1834, several members of the Royal Society, with Mr. Brunel, one of the vice-presidents, visited the tunnel to its extreme end, and Mr. Brunel showed the whole progress of the work, the great difficulties that had already been overcome in

carrying the tunnel above 600 feet under the Thames; and the data being explained upon which the engineer confidently anticipated being able to complete this great undertaking, if the necessary funds were supplied. Brunel, at considerable length, detailed the exertions which had been made to overcome the difficulties arising from the irruption of the river, and stated that in the course of the work the miners had for twenty-seven days pushed on the tunnel over a quicksand.

The members of the Royal Society, after leaving the tunnel, proceeded to view an experimental arch constructed on a new plan by Mr. Brunel. This structure was built of bricks and Roman cement, and consisted of two semi-arches, springing from the same pier, without any support. By this plan an arch of the greatest span might be constructed without centering, and demonstrating, as the projector observed, the practicability of building a tower of brickwork 50 feet high and 200 feet in diameter, and sinking the whole gradually in one mass. By this method it was intended to complete the circular and winding carriage approaches to the tunnel. It may be interesting to observe that of the two semi-arches one was shorter than the other, and it had been loaded with about eleven tons of iron for the previous nineteen months without any sensible change in its position.

Mr. Brunel was not, however, discomfited by catastrophes in his tunnel, though, as Tom Hood sings—

"Sad is it, worthy of one's tears,
Just when one seems the most successful,
To find one's self o'er head and ears
In difficulties most distressful;
Other great speculations have been nursed
Till want of proceeds send them on a shelf:
But thy concern was at the worst
When it began to *liquidate* itself."

Many plans were now proposed for completing the tunnel, and above £5,000 were raised by public subscription. By aid of a loan sanctioned by Parliament, mainly through the influence of the Duke of Wellington, the works were resumed, and a new shield constructed in March, 1836, between which date and November, 1841, the shaft at Wapping was reached. The new shield consisted of 5,000 pieces, and weighed 150 tons. On March 24, in the same year, Brunel was knighted by Queen Victoria; on August 12, he passed through the tunnel, from shore to shore; and on March 25, 1843, it was opened as a public thoroughfare. On July 26, 1843, it was visited by Her Majesty. The tunnel cost about £454,000, exclusive of the carriage descents. The dangers in the progress of the works were many; yet, with all these perils, only seven lives were lost in constructing the Thames Tunnel, whereas forty men were killed during the building of the present London Bridge. At full tide, the foot of the tunnel is seventy-five feet below the surface of the water. Brunel has left a minute record of his great work in Weale's "Quarterly Papers on Engineering." A fine medal was struck on the completion of the tunnel—*obv.*, the head of Brunel; *rev.*, interior and longitudinal section of the tunnel.

This was the engineer's last work. Commercially, it proved disastrous, which preyed upon the mind of Sir Isambard Brunel, though he lived six years longer, until he had attained his eighty-first year, in 1849, when he died at his house near St. James's Park. In the gallery of portraits of inventors at South Kensington is an engraved portrait of Brunel, from the painting by S. Drummond, A.R.A. As a triumph of engineering skill, the tunnel is complete. Brunel's inventions, and their essential usefulness, show what may be accomplished by genius, seconded by industry and indomitable perseverance.

SANITARY ENGINEERING.—XXII.

THE VENTILATION OF HOUSE DRAINS AND THE DISINFECTION OF SEWER GASES.

In a previous paper we have given some instructions as to the ventilation of pipes—a subject to which hitherto we are afraid public attention has scarcely been sufficiently directed; and we now have to devote a similar amount of attention to the ventilation of house drains. As we proceed further we shall have to consider the question of the ventilation of public sewers; but this important subject has already, from the force of circumstances, fully occupied the attention of competent authorities, and the materials with which we have to deal are ready to our hand. In the present case it is not so; it is only within the last few years, or few months, we may say, that attention has been sufficiently drawn to the matter in hand, although it is one of the most important features of sanitary engineering.

In olden times—*i.e.*, before the last thirty years or so—when the greater part of our house drainage was carried by the old-fashioned brick-built "barrel-drain," the porosity of the brickwork, and the occasional imperfection of the joints provided, as it were, a system of natural ventilation, and although the subject really never had due consideration, the drains to a great extent ventilated themselves. But now that thoroughly glazed impervious pipes are used, with all the recent improvements in their manufacture, this is not the case; and if the matter is not duly considered and provided for, the better the character of the actual workmanship of the drainage, the greater the danger to health if ventilation is neglected, as the drains then become so many ducts for sewer gas, which is drawn into the house, and may, and not unfrequently does, exercise a most prejudicial influence on the health of the inhabitants. In rural districts, with detached and independent systems of drainage, as alluded to in our last paper, the question is comparatively easily dealt with, as if the reservoir or cesspool is away from the house, and is properly ventilated, no further danger can arise, except from an occasional or accidental obstruction; but in town houses, more especially large establishments draining into a large general system, further precautions are required, and as to the method of their practical adoption we give the following details.

In Fig. 47 is shown Mansergh's Patent Ventilating Trap. The section S is the pipe from the sink, drain, or closet, as the case may be. G is an open grating for surface-water, the water-line being clearly shown, and P is the ventilating pipe by which the sewer gas is allowed to escape. Objection is sometimes taken to allowing an escape of sewer gas "under the windows," as the phrase goes, as houses in streets must, of course, obtain their light and air from front or back. The remedy in this case is to carry the ventilating pipe up to the top of the house—not by any means a costly matter, as a common cast-iron rain-water pipe will answer the purpose perfectly—and the sewer gases are then discharged into the atmosphere at the level of the chimneys, where they are dissipated in the air, and become perfectly harmless. In cases where from peculiarities in the construction or position of the house this is difficult, still a ventilator of some sort should always be provided; and this axiom may be safely adopted, that outside the house sewer gas is rarely or never dangerous, but that it is when freely admitted within that its deleterious effects are felt. And here we may remark that water possesses an extraordinary power of absorbing these peculiar gases, and that the waste-pipe of a closed cistern may become the means, if improperly constructed, of impregnating the drinking-water of a whole family with ingredients which may without exaggeration be called poisonous.

We next give an illustration showing the facilities for ventilating a system of drainage at any part of its course, with the benefit of using a cane for the removal of obstructions. The system is known as Lovegrove's Patent, and may be employed either with or without a separate ventilating shaft if left open at the top. Fig. 48 shows the construction with the ventilating pipe, and Fig. 49 without it.

These are, of course, not the only methods in use; there are many others, but we quote those given as lucidly illustrating and exemplifying the principles to be adopted, and we now proceed to the second head of our subject—the disinfection of sewer gases. This is a question only recently brought before the public in a practical form, and the agent hitherto found most efficient, and therefore most generally used, is charcoal. We quote Dr. Watson on the *rationale* of its use:—

"All decaying animal and vegetable matters give off during decomposition fœtid and deleterious gases, which in the end tell as fatally upon the human constitution as the bite of a viper, or the most insidious poison known to the chemist. These deadly gases become in their passage through charcoal inodorous, and comparatively harmless. The explanation of this result is beautiful and simple.

"Charcoal is an extremely porous substance, presenting throughout its mass an almost incredible amount of surface, and upon this depends its power of absorbing various gases in

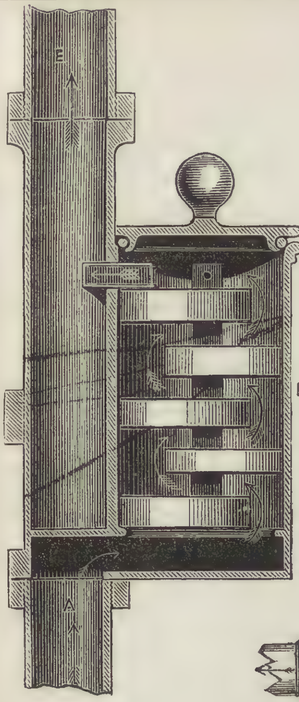

Fig. 50.

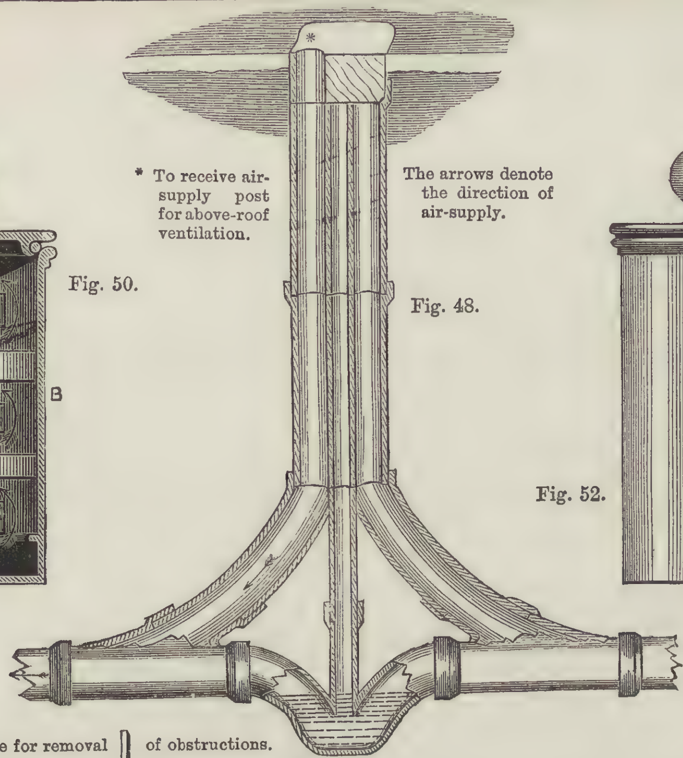

Fig. 48.

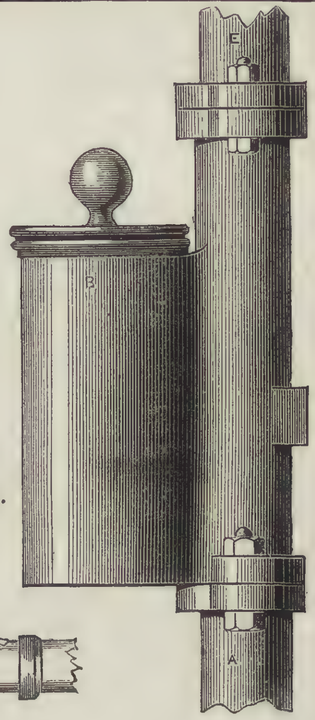

Fig. 52.

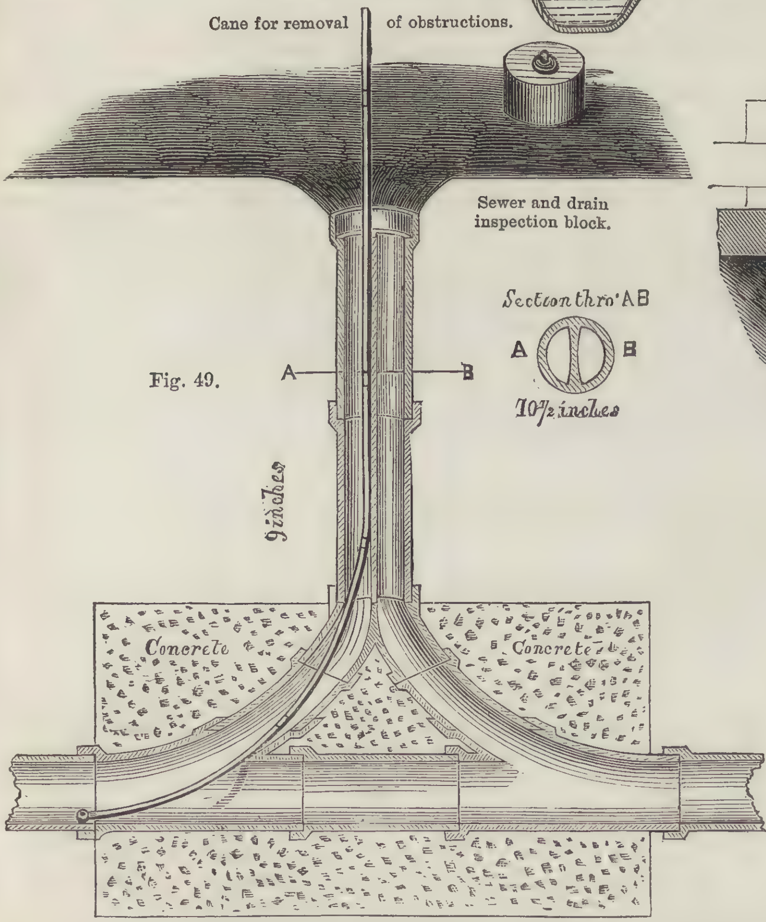

Fig. 49.

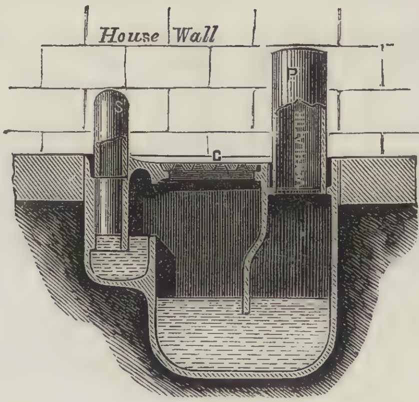

Fig. 47.

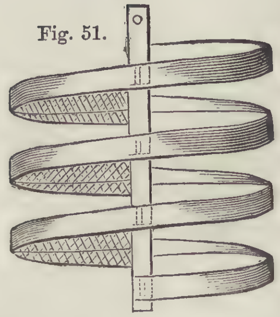

Fig. 51.

large quantities. The oxygen of the air is the great vivifier of nature. The deadly emanations given off by decomposing matters are in what is called a low state of oxidation—that is, they contain a comparatively small proportion of oxygen; combine them with, or force them to take up more of this purifying element, and the point is gained—that which perhaps an instant before would have proved most hurtful if breathed, becomes now entirely resolved into comparatively harmless combinations. Now, as charcoal contains within its pores a very large proportion of oxygen, amounting to rather more than eight times its bulk, its efficiency as a disinfecting agent is thus satisfactorily proved, not only in theory, but also practically by experiment."

There are many ways of employing it. In one of our previous papers we gave a sketch of a patent trap invented by Mr. Cottam, the engineer, where the ventilator at the ground level was covered or protected by a layer of charcoal; and we now proceed with some sketches of another adaptation of the same principle. Referring to the earlier part of our article, recommending the adoption of a ventilating pipe, we now show how the gases passing up this pipe may be thoroughly deodorised by the intervention of a series of shelves containing charcoal (Fig. 50).

In this A is the upcast pipe from the drain, B the ventilator containing the shelves, and E the pipe that discharges the deodorised gases into the open air. These trays may be replaced by a spiral tray, as in the sketch below (Fig. 51), known as Latham's patent. Fig. 52 shows the outside appearance of the disinfecting apparatus when fixed complete.

The above illustrates the general principle, which is capable of many modifications. In a large pauper asylum recently erected at Wandsworth the object was specially provided for by means of flues constructed in the body of the building, and carried up to the highest point of some angle towers, that form a marked feature in the elevation; at the topmost level boxes of charcoal were provided, through which the sewer gases, thoroughly disinfected, were allowed to escape into the open air.

The same result may be attained by various other chemical means, into which our space will not allow us to enter in the present paper; but in a later branch of the subject, the ventilation of sewers as distinguished from house-drains, we may probably deal with the question in rather fuller detail.

Whenever from circumstances the outfall of the drainage of any particular district takes place during only a few hours of the twenty-four, ample provisions for the ventilation of house drains are most especially requisite. We may instance some of the low-lying districts adjoining the Thames, for which, when the tide is high, the sewers are what may be called water-locked for perhaps more than twelve hours out of the twenty-four; and the recent shortcoming so prominently brought before public notice in the case of Scarborough is another exemplification of a similar state of things. Another point worthy of attention is the fact that the greater portion of sewage water, properly so called, passes through the drains during the day only; the quantity passing during the night being comparatively small; while the rainfall only is, of course, about equally divided as a matter of average during the twenty-four hours; although storm-waters, as they may be called, at certain times of the year fall in such quantities within sometimes the space of an hour or two as entirely to overcharge all ordinary systems of drainage. These, however, are not much to be feared upon sanitary grounds, as their first action is thoroughly to flush the drains, and wash away the sewage properly so called, the surplus or overflow consisting for the most part of rain-water only, which has to find its way by degrees, when the drains are overcharged, through the adjacent ground.

We need hardly say that when any system similar to Moule's is introduced, the remarks and illustrations of this paper do not apply to the case with equal force, although even then, the necessary constructions for the removal of rain, surface, and subsoil water are all the better for due provision being made for their thorough ventilation.

In our next paper we shall take up the question of the construction of sewers; giving a certain amount of attention to village and suburban districts, and probably a few particulars as to the last improvements in construction, as adopted in our recently completed metropolitan system.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXXII.—BENJAMIN ROBINS.

BY JAMES GRANT.

THIS celebrated English mathematician, philosopher, and experimentist was born at Bath in the year 1707. Although his parents, who belonged to the Society of Friends, were unable to give him much education, yet so strong was the inborn vigour of his own mind, that he taught himself various branches of knowledge, and more particularly the science of mathematics, of which his friends wished him to become a teacher, and to settle in London. With this view he travelled to the metropolis, carrying with him a letter of introduction to Dr. Pemberton, who conceived and expressed a very high opinion of his scientific acquirements.

To prepare himself more fully for the important office of tuition, he perused the works of the most eminent mathematicians, and while in the course of these studies he was led to demonstrate the last proposition of Sir Isaac Newton's "Treatise on Quadratures," which appeared in the *Philosophical Transactions* for the year 1727.

In the year following Robins published "The Present State of the Republic of Letters," in refutation of the dissertation of John Bernouilli on the laws of impact in moving bodies. The paper referred to was the production of John, brother of James Bernouilli, the famous mathematician of Basle, and it had lost the prize offered by the Academy of Sciences in 1726.

Having now brought himself before the world of letters as a mathematician, Robins relinquished the peculiar costume of the Society of Friends, and began to take pupils; but the great activity of his mind, however, did not permit him to be satisfied with his theoretical studies; and singularly enough, for one who had been reared in the peaceful tenets of Quakerism, he began a series of the most elaborate experiments in gunnery, with the view of establishing the influence of the resistance of the air upon projectiles. He also directed his attention to the various branches of a great art that was as yet in its infancy—civil engineering; and he made several tours in the Low Countries for the purpose of studying fortification.

In 1734, on his return to London from one of those tours, he found the scientific world in a state of commotion occasioned by the publication of the "Analyst," by the learned Dr. George Berkeley, Bishop of Cloyne, in which that ingenious author attempted to refute the Newtonian doctrine of fluxions. He further styled Dr. Halley an "infidel mathematician," and endeavoured to prove that mysteries in faith were unjustly objected to by mathematicians, who, he thought, admitted much greater mysteries and even falsehoods in science, of which he affirmed the doctrine of fluxions was a pregnant example. This occasioned a long and angry controversy between the bishop and many men of science. Robins requested special permission to devote himself to a refutation of the charge, and accordingly in 1735 he published "A Discourse concerning the Nature and the Certainty of Sir Isaac Newton's Method of Fluxions, and of Prime and Ultimate Ratios;" but some exceptions that were taken to this production, even by the adherents of the fluxionary system, led him to publish more papers on the same subject.

The year 1738 found him defending Newton against an objection in the "Matho" of Andrew Baxter, the eminent Scottish metaphysician. In the following year he published his remarks on Leonard Euler's "Mechanica sive motus scientia analytice exposita," which had been published at Petropoli; a paper on Smith's "System of Optics," and another on Jurin's "Distinct and Indistinct Vision," published at the end of the last of these works. But the talents of Robins were not restricted to their proper sphere of natural philosophy and mathematics; he took a keen part in the angry and bitter politics of the day, and issued three pamphlets on the public affairs of the times, which created a great sensation.

The first of these was entitled "Observations on the present Convention with Spain;" the second was "A Narrative of what passed in the Common Hall, and the Citizens of London assembled for the Election of Lord Mayor;" and the third was an "Address to the Electors and other Free Subjects of Great Britain, occasioned by the late Succession; in which is contained a Particular Account of all our Negotiations with Spain, and its Treatment of us for above ten years past."

These pamphlets were all anonymous; and the first and last were so pungent that they were currently believed to be the production of Mr. Pulteney, who was then the active opponent of Sir Robert Walpole, and when the latter was ultimately defeated by the opposition, Robins was actually chosen secretary to the committee of the House of Commons appointed to examine into the conduct of that minister!

In 1742 he published his "New Principles of Gunnery," a work of which an account was given by himself in the *Philosophical Magazine* for the same year. In this book he concludes, from experiments he had made, that the force of gunpowder, at the instant of its explosion, is the same with that of an elastic fluid of a thousand times the density of common air, and that the elasticity of this fluid is proportional to its density, and in illustration proposes the following problem, which refers, of course, to *round* shot:—

"The dimensions of any piece of artillery, the weight of its ball, and the quantity of its charge being given, to determine the velocity which the shot will acquire from the explosion, supposing the elasticity or force of the powder at the first instant of firing to be given." In the solution of this important problem he assumes the two following principles:—

"1. That the action of the powder ceases as soon as it is out of the piece.

"2. That all the powder of the charge is fired, and converted into an elastic fluid, before the shot is sensibly moved from its place.

"These assumptions, and the conclusions above mentioned, make the action of fired gunpowder to be entirely similar to that of air condensed a thousand times, and from thence it will not be difficult to determine the velocity of the shot." Robins also gave an ingenious method of determining by experiments the velocity with which any shot moves at any distance of the piece it may be discharged from, by the adoption of a pendulum, a description of which would occupy too much space. By this he ascertained that the velocity of the common cannon-ball was 1,641 feet per second, when fired point blank. His work also combined an introductory history of modern fortification, with the invention of gunpowder, and the whole theory of gunnery.

In consequence of a paper having been published in the *Philosophical Transactions* against some of his opinions, he was led to submit to that learned body several treatises on the resistance of the air, and to exhibit the experiments on which they were founded, in the years 1746 and 1747. For this he was presented with the gold medal of Sir Godfrey Copley. When Lord Anson returned from his voyage round the world, the Rev. Richard Walter, chaplain of the *Centurion*, had proceeded to draw up a history of the expedition, but it was deemed advisable to have the whole rewritten by Robins. It appeared in 1748 with Mr. Walter's name on the title-page. The work went, however, through several editions, and the fifth was corrected by Robins himself in 1749.

In the same year he published in London "An Apology" for the defeat of the King's troops by the Highlanders under Prince Charles Edward at Prestonpans; and this paper formed a preface to "The Report of the Proceedings and Opinion of the Board of General Officers on the Examination into the Conduct of Lieutenant-General Sir John Cope."

Through the influence of Lord Anson opportunities were afforded him of making further experiments on his favourite subject of gunnery and all warlike projectiles; and through the same kind influence he procured for the Royal Observatory at Greenwich a second mural quadrant and other instruments. The services of Mr. Robins in science and politics had now become so prominent and so numerous, and his general reputation was so high, that the ministry of George II. became desirous of bestowing upon him some lucrative appointment. It was accordingly put in his option whether he would go to Paris as one of the government commissioners for adjusting the then vexed question of the limits of Acadia (the name originally given by the French to Nova Scotia and New Brunswick, and, indeed, to the whole of the North American Continent from the 40th to the 46th parallel), or to be the Engineer-General to the East India Company, the ruinous condition of whose forts required an able engineer to put them in a state of defence; and the somewhat military predilection of Robins, fatally for himself, induced him to prefer the latter. A regular corps of military engineers did not at that time exist in Britain, though officers termed civil engineers had occasionally been attached to the Ordnance Department from 1627, when the name of Thomas Rudd first appears on the list; and the first colonel-commandant appears in 1802.

Provided with a complete set of astronomical and other instruments for making scientific observations and experiments in the East, then a remote land and but little known to us, Robins, full of enthusiasm and ardour, sailed from London on Christmas Day, 1749, and after a hazardous and rough voyage he landed at Madras on the 13th of July, 1750. There he immediately set about the preparation of plans for the complete repair of Fort St. George, and Madras, which had been taken by the French in 1744, and had just been restored to us by the peace of Aix-la-Chapelle. The constitution of Robins was totally unsuited to the climate. In September he was attacked by fever, and though he recovered partially from its effects, he was unable to work or study, and fell into a languishing condition, which continued until the 29th of July, 1751, when this eminent English philosopher expired: thus he had only gone to India to find a grave in the Carnatic in the forty-fourth year of his age.

By his will he bequeathed the publication of his mathematical works to his friends Dr. James Wilson and Martin Folkes, and they published them in three vols. octavo, in 1761. His "New Principles of Gunnery" was translated into several languages; and they appeared in German from the pen of the illustrious Leonard Euler, accompanied by a copious commentary. This work was afterwards translated into English in 1779 by Mr. Hugh Brown. Besides the books already referred to, Benjamin Robins wrote a paper on the height to which rockets will ascend, which appeared among the *Philosophical Transactions* for 1749.

TECHNICAL DRAWING.—LXXII.

DRAWING FOR BRICKLAYERS.

PLAIN BRICK ARCHES.

PLAIN or rough arches are those in which none of the bricks are rubbed to suit the splay. Hence the joints which are quite close to each other at the intrados, are necessarily wider towards the extrados of the curve.

When the radius of curvature of a brick arch is small—that is to say, when it is under or not exceeding three or four feet—the best arrangement is to build two or more four-inch concentric brick arches over each other until the whole necessary thickness is obtained: each of these successive rings being built as an independent arch, without attempting to bond the upper or larger arch of any two into that which is immediately below it.

Fig. 588 represents a part of a semi-circular arch of this description supposed to have a span of 6 feet, and consequently a radius of curvature of 3 feet, and consisting of four concentric four-inch-thick arches combined into one arch of two bricks in thickness.

The bond of brickwork used in any arch is always judged by the appearance which it exhibits to the eye of the spectator looking up towards the intrados or lower surface of the arch. Hence in the present illustration, since all the bricks used, if so viewed, would have the appearance of stretchers, the whole arch is said to be built with stretchers, or in "stretching bond," being composed entirely of whole bricks laid as stretchers, excepting only at the two extremities of the arch, where each alternate voussoir is a bat or half-brick, without introducing which bricks composing a four-inch arch could not be properly bonded together.

The reason for building an arch of small radius with a series of four-inch rings, and without attempting to bond the successive parts into each other, is sufficiently obvious. The joints of such an arch diverge so very rapidly from the intrados outwards, that if it were built otherwise the brickwork would not be sufficiently compact, for at the upper part of the arch the bricks would be separated to an extraordinary and inconvenient degree. In some cases, headers—*i.e.*, whole-length bricks—are inserted at certain distances—that is, where three or four or more bricks of the inner ring cut in with four, five, or more bricks of the outer ring.

Fig. 589 shows the unfavourable effect which would be produced by building an arch of a small radius in the manner just alluded to. From this it will be seen that if the span of the arch were 3 feet, the external spaces between the bricks of a

two-brick-thick arch would be $2\frac{1}{2}$ inches. These joints, if filled entirely with mortar, would be prejudicial to the solidity of the work; and if filled with harder materials, such as pieces of stone, slate, or fragments of brick, the arch would have a motley and unseemly appearance.

It must be pointed out to the student that although the bricks in rough arches are said to radiate, it is their *centre lines* which do so, not their sides; the ends of the bricks are parallelograms placed on their narrow ends, and it will be readily seen that their sides could not converge to the centre. This cannot be clearly represented in Fig. 588, and therefore a few bricks are drawn on an enlarged scale in Fig. 590.

To draw a rough arch, having described the two arcs between which the ring of brickwork is to be contained, set off on the *inner* arc the true widths of the edge of the bricks of which the arch is to be composed, as *a, b, c, d;* find the middle of each of these spaces, as *e, f, g;* and through these draw lines converging to the centre from which the arcs are struck; then the sides of the bricks, *a k, b l,* etc., will be parallel to *e h, f i, g j,* etc.

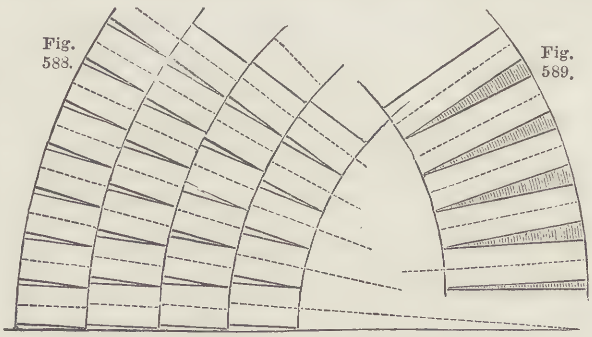

Fig. 588. Fig. 589.

In drawing gauged arches, the thickness of the separate bricks are set off on the *outer* arc, and from the divisions lines are drawn to the centre; the wedge form is thus given to the bricks, the inner end becoming narrower than the outer.

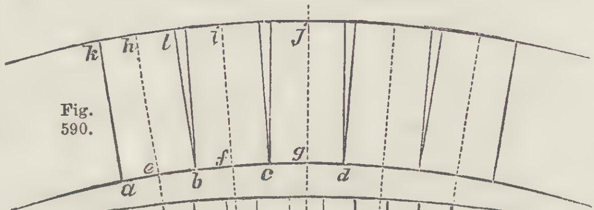

Fig. 590.

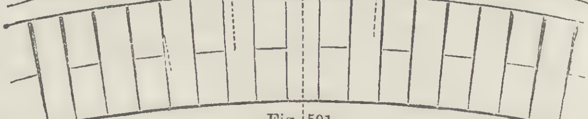

Fig. 591.

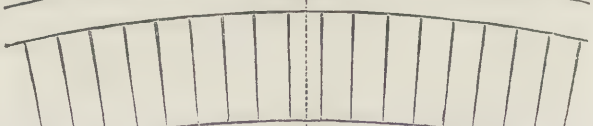

Fig. 592.

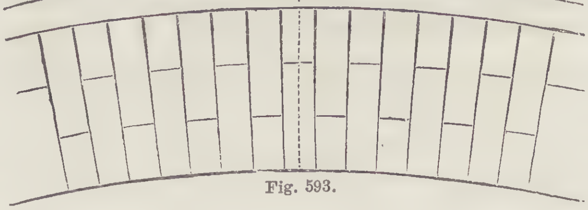

Fig. 593.

As the radius of the curvature of an arch increases, the joints diverge less rapidly, so that the use of nine-inch arches formed with heading bricks ceases to be objectionable.

For example, in a semi-circular nine-inch arch of 12 feet span (whose radius of curvature is of course 6 feet) the radius of the curve of the intrados is to its radius at the extrados as 6 feet to 6 feet 9 inches, or as 1 to $1\frac{1}{8}$. Hence the joints at the upper part of the curves will not exceed one-eighth part of the width of an arch-brick, or about five-sixteenths of an inch, which is neither inconvenient nor unseemly. If the radius of curvature be greater than 6 feet, the width of joint at the extrados of a nine-inch arch will be further diminished, so that in a semi-circular arch of 18 feet span it will scarcely amount to so much as one-fifth of an inch.

A nine-inch brick arch may be built according to three different methods—

1. The bricks composing the voussoirs may consist partly of headers and partly of stretchers, built according to Flemish bond. Fig. 591 represents the end elevation or section of part of an arch of this description, supposed to have a radius of curvature of 9 feet.

2. The bricks composing the voussoirs of a nine-inch arch may consist of headers and stretchers built according to English bond. In this case the extremities of the arch have the same appearance as in the former arrangement, which is likewise a correct section of this method. But the appearance of the brickwork of the intrados of this arch is different, being similar to common English bond in the face of the wall.

3. The bricks composing the voussoirs of a nine-inch arch of the same span and curve may be laid all heading bond, so that the transverse section of the body of the arch will everywhere be that represented in Fig. 592.

In an arch of this description no false headers are used, nor are stretchers used anywhere, excepting at the extremities of the arch, where they are introduced in alternate voussoirs for the sake of breaking the bond, the same being done in the face of a wall of this description.

Hence in a nine-inch arch built all in heading bond the section is as in Fig. 592, but the end elevation is the same as that of an arch of equal thickness built according to Flemish or English bond (see Fig. 591).

OF PLAIN ARCHES ONE BRICK AND A HALF IN THICKNESS.

In this case, if the radius of the curvature do not exceed three or four feet, such arches would of course be built in three concentric four-inch arches, according to the rule already laid down. In arches, however, of greater radius, such as from six to eight feet, the usual method is to build the voussoirs in alternate courses of headers surmounted by stretchers, and stretchers surmounted by headers from one side of the arch to the other.

Fig. 593 represents this arrangement, which is not only an end elevation, but a correct section of the arch throughout.

OF PLAIN ARCHES, AS APPLIED TO COMMON BRICK BUILDINGS.

The plain or rough arches used in common buildings are generally concealed from view. They are applied under the following circumstances:—

1. To cover the aperture of an external door or of a window in addition to the ornamental arch, which is generally a mere shell, as has already been explained.

When the arch of an external door or of a window is a semicircle or segment, the rough internal arch follows the same form, and no woodwork is used in aid of such an arch.

But when the ornamental arch of an external door or of a window is a straight or flat arch, pieces of timber, called *lintels*, are laid over the remainder of the aperture in rear of the ornamental arch, and in the internal doors of a building these lintels cover the whole space with a bearing of about 1 foot or 18 inches at each end.

In this case a rough arch is also usually thrown over the aperture above the said lintels, in order to relieve them of their weight of the superincumbent brickwork.

The annexed cut (Fig. 594), repeated from "Building Construction," represents the mode in which such rough arches should be formed in aid of a lintel. The intermediate space between the bottom of the arch and the woodwork is filled with bricks and bats cut to the curve and laid in mortar.

2. Rough arches are used for fireplaces.

In this case a bar of iron from $\frac{1}{2}$ to $\frac{3}{4}$ inch thick, and usually not less than 4 inches wide, is prepared beforehand suited to the form of the arch, and extending across the chimney-breast from one side to the other, so that it comprehends the width, not only

of the proposed arch, but also of the piers on each side or of part of them.

Upon this bar, the ends of which are turned back in contrary directions, and which is technically called a *turning-bar*, the arch is built, which bar, however, is not removed like common centering, but remains permanently in the same place in aid of the arch.

3. Rough arches are used beneath the hearths of fireplaces.

It has been explained in "Building Construction" that no woodwork is admissible below a fireplace, and that joists extending in that direction are framed into a transverse piece of timber called the *trimmer*, which is usually two feet distant from the chimney-breast, in buildings of importance. Between this trimmer and the bottom of the fireplace a four-inch segment brick arch, rather less than a quadrant, is constructed, which rests on one side against the upper part of the trimmer; and this is the vertex of the curve. On the other side, which is on a

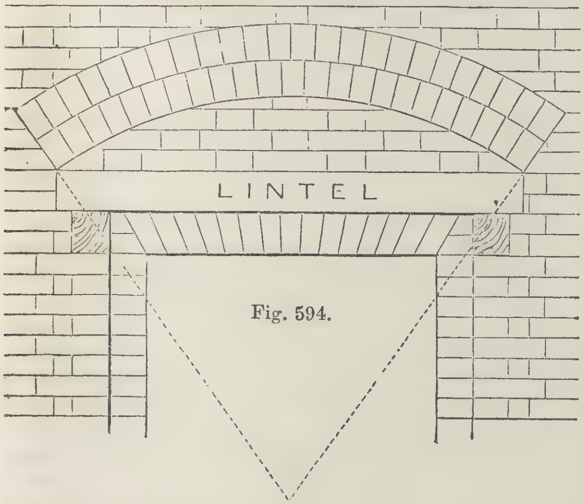

Fig. 594.

level with the bottom of the trimmer, it springs with a skewback from the wall; the space between the top of the arch and the under surface of the hearthstone is filled in with brickwork. This arch has been illustrated in Lessons on "Building Construction" (TECHNICAL EDUCATOR, Vol. II., page 5).

4. Rough arches are used beneath the entrances of all buildings having an area to the basement storey. In this case a leaning arch is used, which on one side abuts against the area wall, while on the other it leans against the wall of the building. Above this arch, and extending partly across the area, and on the same level with the pavement, or sometimes one step above it, large flag-stones are laid; beyond which a flight of two or three steps, at least, usually leads from that level to the entrance-door of the building. Fig. 587 (page 384) exemplifies this arrangement. These arches are technically termed *bridgeways*.

PHOTOGRAPHY.—XI.

By J. C. LEAKE.

PHOTO-LITHOGRAPHY.

ALTHOUGH the process of printing in carbon or pigments, described in our last paper, has to some extent superseded the photo-lithographic process, the latter is of so important a character, especially when copies of maps or line-drawings are required, that a knowledge of the process is essential to the practical photographer. We will therefore devote this paper to the consideration of the subject, merely observing that, beside the photographic part of the process, it is desirable that the operator should possess some knowledge of the system of ordinary lithographic printing. An ordinary lithographic press will be required, with stones, inking-rollers, and suitable ink.

One of the most important points, in order to ensure success in photo-lithographic work, is the production of a negative of exceeding density and clearness. The lines must be perfectly sharp and transparent, the smallest trace of fog being fatal to anything like clear delineation. In order to ensure these conditions some variations from the ordinary photographic processes are required, and these we will proceed to describe. The collodion should be one which adheres well to the glass, and should be rather old. Unless it works perfectly clear in the shades it should be mixed with a little dilute tincture of iodine, made by dissolving iodine in pure alcohol. Enough of this may be added to bring the mixture to a dark sherry colour. It must also be allowed plenty of time to settle, and be perfectly clear. The nitrate bath should be of full strength—from thirty-five to forty grains of silver to the ounce, slightly acid, and perfectly clear and clean. The exposure should be enough to secure a tolerably rapid development, as unless the image can be obtained upon one application of the developer there is danger of fogging the lines and destroying their sharpness. The best developing solution is a fifteen-grain solution of sulphate of iron with the same proportion of acetic acid, to which is added as much alcohol as may be needed, in order to make it flow evenly over the plate. As soon as the lines of the drawing are visible the plate should be well washed and slightly intensified in the ordinary way with pyrogallic acid solution and nitrate of silver.

The negative should then be fixed with hyposulphite of soda, and thoroughly washed. It should now be carefully examined in order to ascertain that the image is sharp, well-defined, and free from fog. The lines should be perfectly sharp, and without the slightest trace of deposit. This being the case, the negative may be intensified by pouring over the surface a saturated solution of bichloride of mercury, washing, and afterwards darkening with a very dilute solution of hyposulphite of soda. Should the negative not be sufficiently intense this operation may be repeated, when the film should be very thoroughly washed in order to remove all trace of the hyposulphite.

It should be borne in mind that for copying drawings and maps by this process the negative must be perfectly opaque in the lights and as perfectly transparent in the shadows, as upon these two conditions the whole success of the work will depend. The negative should be left unvarnished. The next operation is the preparation of the photo-lithographic paper. For this purpose the ordinary Saxe paper will answer very well, as will also that known as bank-post. The gelatine is prepared as follows:—Take three ounces of fine gelatine, and dissolve in forty ounces of hot water. While still hot filter through warm wet flannel or fine muslin. For use the gelatine must be kept in a fluid state by means of heat. If used in a dish the first must be placed in a second and larger vessel, filled with hot water. The surface of the fluid gelatine should be skimmed with a slip of paper, and the sheets to be coated, after being cut to the requisite size, be floated upon the surface, taking the utmost care to avoid air-bubbles. When coated the paper may be suspended until dry. Another and excellent plan is to procure a sheet of glass of the required size, and having immersed it in warm water, to place upon it the sheet of paper to be coated, and which has also been damped in water of the same temperature. The sheet should then be pressed down evenly upon the glass by means of the india-rubber "squeeze" mentioned in our last paper on carbon printing, and the superfluous moisture removed from its surface. While still warm the melted gelatine may be poured over the surface, and the sheet coated by tilting the plate precisely as if coating a plate with collodion. It should then be placed perfectly level upon a suitable stand, and allowed to set, which it will do in a few minutes.

The sheet may then be slipped off and suspended to dry. This is an excellent plan where a few sheets only are required, as a small quantity only of gelatine is employed, and there is little or no waste. Paper thus prepared resembles that which has been albumenised, as it is insensitive, and will keep an indefinite time in a dry drawer or box.

The sensitising of this paper is effected by immersing it in a saturated solution of bichromate of potash. It should remain in this for a few minutes, and after removal be thoroughly dried, when it will be ready for exposure to light under the negative. As we before remarked with respect to this part of the carbon process, it is well-nigh impossible to give any definite rule as to the time required, but with an average light about five or ten minutes will be necessary.

The next operation is that of inking the impression, and is performed as follows:—(For this purpose the lithographic press

will be required.) Take a clean polished lithographic stone, and charge it by means of the litho-roller with a smooth and perfectly even coating of litho-transfer ink. The thickness of the ink will cause a considerable variation in the result, and can only be determined by practical experience. The print should then be allowed to soak in cold water for about a quarter of an hour, when the excess of moisture should be blotted off, and the paper with the impressed image placed, gelatine side downwards, upon the inked stone. The whole may now be passed through the press in the usual manner, using rather less pressure than would be required in the ordinary process of lithographic printing. When removed from the stone the print will be found to have received a uniform coating of ink, and the more uniform this coating is the sharper and better will be the final result.

In order to remove the superfluous ink the print should be well soaked in cold water. A solution of gum-arabic should then be prepared of rather more than the average strength, and to this should be added a little weak solution of nitric acid. This mixture should be applied to the print with a soft sponge, when it will be found that the ink may be readily removed from all those portions of the surface upon which the light has not acted, while it will adhere tightly to those which have been exposed to its influence, thus leaving an impression in lithographic ink upon the surface of the paper. All that now remains to be effected is to thoroughly clean the lights by means of careful sponging with clean gum-water, after which the transfer print is complete, and may be laid by to dry. At this stage of the process the question of success or failure may easily be determined. If it should be found that the finer lines which lie close together, or the angles formed by the crossing of the lines are filled up with ink and are not quite sharp, clean, and well-defined, then there has probably been too much ink upon the stone; while if, on the other hand, the lines are clean and well defined, but wanting in vigour and in sufficient body to transfer themselves well to the stone, the defect will probably arise from the inking having been insufficient. This latter defect, however, is seldom met with in practice. The ink should leave the paper quite freely and easily as well as completely; and when this is not the case, and if there should remain upon what should be the unaltered portions of the film traces of ink in patches over the drawing, in all probability light has reached the paper either through a defective negative or from some carelessness during the process. It cannot be too strongly impressed upon the operator that the bichromated gelatine is exceedingly sensitive to light, and that in all processes wherein this substance is employed the utmost care must be exercised in order to protect it from any extraneous action. In fact, it should be as carefully shielded as a sensitive collodion plate. Should the lines appear broken, and betray an inclination to leave the paper, it is most likely that the exposure to light has been insufficient to completely alter the character of the gelatine, which is consequently still partially soluble. It frequently happens that, while the coarser lines are bold and vigorous, the finer ones are weak, ragged, and partially obliterated. This mostly arises from an imperfect negative. If the intensification has not been carefully performed, a very fine deposit, almost invisible except to the most careful observer, is formed in the finest lines, and this is quite sufficient to prevent a proper action upon the gelatine.

It may not be out of place here to remark that the process above described is not suited for the production of pictures in half tint, except the gradations are produced by lines or dots. For instance, a line-engraving or a manuscript may be perfectly reproduced; but an ordinary photograph would be utterly useless if copied by these means. Many attempts have been made in this direction, and some of the results have been most promising, but no process has, up to the present time, been uniformly successful. These remarks are not intended to deter the operator from experimenting in this direction, but simply to prevent his attempting to copy pictures which, from their unsuitability to the process, would probably lead to failure and disappointment.

In conclusion, we would observe that this process is based upon the fact that, while gelatine in its normal state—that is to say, unacted upon by light—is absorbent of water and soluble, it becomes after that action insoluble and non-absorbent. Thus after the exposure under a negative the print is wetted, and water is absorbed in all the unaltered portions, while those which have been exposed remain dry. The fatty ink employed is consequently resisted by the wetted parts of the surface, while it is retained by those which remain dry; thus forming the print which is transferred to the stone. There is often little or no relief in the impression, and the print is formed through this attraction and repulsion of the fatty ink alone.

We have not thought it necessary to describe the transfer of the print to the lithographic stone, as that is effected precisely as in the well-known lithographic printing process; but we should advise the operator to endeavour to see the transfer process performed before attempting to effect it for himself, as he would learn more in a few minutes from actual inspection than could possibly be acquired from mere written instructions, however elaborated.

MAP AND PLAN DRAWING.—III.

By C. C. King.

METHOD OF CONSTRUCTING CHARTS—THE WORK DONE ON SHORE—THE WORK DONE ON THE WATER—ABBREVIATIONS AND CONVENTIONALITIES USED IN DELINEATING CHARTS.

The careful construction of a map of a large territory, conducted as we have described, presupposes an advanced state of civilisation in the country thus delineated. Experienced workmen, a population not adverse to the survey, the assistance to be derived from government or civil authorities, are all essential to accurate work. The necessity for it must be recognised by the people, so that the different stations may remain undisturbed during the operations; and the necessity or value of such a map presupposes an area well populated and cultivated, and with an abundance of large towns and villages, the communications between which are numerous enough to render movement practicable and inspection of the details possible.

But beyond the limit of such countries, there is much to be discovered and mapped, which is useful and necessary to the inhabitants of the civilised districts. An accurate description of the coast-lines and land adjacent to the sea are requisite for the prosecution of commercial enterprises, as well as to enable vessels to move with confidence from point to point. For this purpose charts or hydrographical maps are constructed, and these rarely go beyond the immediate coast-lines of the islands or continents. In barbarous countries a survey beyond this limit would be practically impossible, not merely because of the opposition of the inhabitants, but more especially because of the uncultivated nature of the land rendering an extensive triangulation a matter of extreme difficulty, even if it were permitted by the natives, or if it were to the interest of the nations concerned in knowing the character of the country, to provide the means for carrying out the work. In these cases the coast is alone depicted, and the interior of the area either left a blank, as is usually done with the African continent, or if it cannot be approximately filled in by local information or even maps, which would be done in China or any semi-barbarous realm, some few points are determined by their latitude and longitude, and as much of the neighbourhood sketched in somewhat roughly as time and opportunity will permit.

The chart, however, to be useful and reliable must be carefully completed, as the information it has to give can be readily procured; and as moreover the value of a chart to a vessel depends entirely on the faithfulness of the representation of the coast itself, the accuracy of the soundings taken, and the exactness of the position of all the remarkable features given by their latitudes and longitudes, as well as their respective distances and relative bearings one from the other, must be accurately ascertained.

Chart-making is simply the extension of the land survey of a great country, such as we have imagined, to more distant parts, thus completing the delineation of the remainder of the earth's surface; only in these maps we deal with a bare outline of the foreign countries or an imperfect filling-in of the interior rather than with the careful, laborious delineation of every feature, physical or otherwise, which results from a measured base and a system of triangulation. Some knowledge of astronomy is absolutely required by the operators in this species of surveying, as the distances from one principal point to another can only be determined by their latitude and longitude if far apart.

Instruments have to be constantly adjusted or corrected by astronomical observations, and a rough practical acquaintance with the positions and movements of the heavenly bodies, and the causes leading to variations both of compasses and other instruments, is indispensable.

The construction of a chart, then, divides itself into two parts—first, the work done on shore; second, the work done on the sea. The former is a repetition of an ordinary survey as far as practicable—that is, a point is first astronomically fixed by its latitude and longitude, either by means of a sextant and the artificial horizon, or by means of a small transit instrument. The sextant is a metallic frame constructed in the form of a segment of a circle, the arc of which is graduated in 140 degrees. A movable arm, which is pivoted at the centre of the circle of which the instrument forms a part, extends to the graduated arc, and is capable of being retained in any given position by a clamping-screw. It is furnished at its upper or pivoted end with a mirror, accurately fixed by the maker so as to be always perpendicular to the plane in which the arm moves and parallel to the arm, thus partaking of its movement; and at its lower extremity on the arc it has a vernier for reading minutes and seconds of an angle measured, with a small motion-screw for careful adjustment, and a microscope for accurate observation. A telescope is fitted in a socket at one side of the instrument, and on the other side of the frame is fixed a small glass called the horizon-glass, the lower half of which is a mirror, and which is so adjusted that its plane is perpendicular to that of the sextant, and parallel to the movable arm when it is fixed at zero. Coloured glasses are provided, to be used in taking observations of the sun. In using it the telescope is screwed in, and while one of the two objects between which the angle is to be taken is viewed through the upper or transparent portion of the horizon-glass, the movable arm of the instrument is moved until the reflected image of the second object is thrown from the movable on to the fixed mirror, and the two objects made by a slight motion of the hand to coincide. The arm is then clamped, the exact coincidence of the objects determined by the small motion or "tangent" screw, and the reading, which is the angle between the two points, taken. The artificial horizon is a small flat iron vessel to contain mercury, and is protected from disturbance from wind or other causes, by a glass shade or cover. By it the altitude of the sun at any given time can be ascertained, the observer bringing the image of the sun reflected in the mercury, and seen through the unsilvered portion of the horizon-glass, in close juxtaposition with the image reflected on the movable mirror of the arm, and thence on the lower portion of the horizon-glass. It must be remarked whether the upper or lower limbs of the sun have been brought into contact, and having the time of observation noted down, the latitude can be determined by calculation.* The longitude is, of course, ascertained from the chronometer, by means of which the difference in the time at the station and at Greenwich can be ascertained. The transit instrument is only used in observations where time and opportunity are afforded for the work. It is simply a telescope mounted on a frame, which must be carefully adjusted in the plane of the meridian, and affords the means of obtaining the exact time at which certain planetary bodies cross the meridian, and their distance from the zenith. Thus the longitude can be obtained, or even, by arrangement, the latitude.

From the point thus determined a survey of as extensive a nature as possible would be made. A base-line, measured some few times to ensure approximate accuracy, would be fixed, and from it by triangulation the distances of the more prominent objects would be calculated; but as any materials at hand, such as a deal rod, or a "lead line" used in taking soundings, would be used to effect the measurement of the base, the most important part of any survey, the results arrived at would be only approximately true. The work done on shore, then, is a rough, generally hasty attempt at delineation by the ordinary principles of surveying, a theodolite being employed when practicable for measuring the angles, and in other cases the sextant.

The work done on the sea, which is the more important of the two divisions of the chart, obliges us to use different means of providing our data for calculation, though the application of these data is in principle the same as in a land survey. We are unable to measure any base upon the sea from which to determine the relative positions of our main points, and we have further to ascertain a new series of facts, that do not, of course, enter into our previous work—the depth of water, and the size and character of rocks or shoals which may be concealed beneath the surface of the sea, or be only apparent at certain times of tide.

The instruments required, therefore, are the chronometer to calculate longitude, and which is to be corrected by "lunar distances,"* or other astronomical observations, for its rate—that is, its variation from day to day, and its error of rate, or the error in that variation; the sextant, which has been described above; the ordinary mariner's compass for ascertaining magnetic bearings, which has to be corrected for its variation by taking the true bearing of the sun at noon, and then calculating the variation according to fixed laws; and lastly, the "sounding lead," a line twenty-five fathoms long, furnished with a long leaden weight hollowed at its base, so as to contain a little grease, to which sand or pebbles, showing the character of the sea-bottom, may adhere.

The method of procedure is the same as in a survey on shore. The surveying vessel anchored, and with its true place found by observation, forms the principal point to which all others are referred. A series of boats, each containing a sounding line and an officer for taking the observation, diverge in different directions from it, and at the requisite distances from the ship take angles between it and each other, thus forming a rough series of triangles, which should be as nearly as possible equilateral. These distances are ascertained in two ways: either by reading the angle subtended by the mast of the ship from the truck to the keel, and from prepared tables finding the base of the right-angled triangle, which is the distance required, or by calculating it from the velocity with which sound is known to travel. For this purpose those boats which proceed on a course as nearly as possible at right angles to the direction of the wind are selected, and guns are fired from the vessel to give the necessary data, pocket chronometers or stop-watches being employed to determine with all possible accuracy the intervals of time that elapse between the moment when the flash of the gun is seen and the sound of the report is heard by the observer. If the boats be large enough, one or more may carry small guns, which, if fired with a high elevation with shot, will give a report that can be heard a considerable distance; and thus a series of results may be obtained, which will give a satisfactory and tolerably correct mean. If the weather be calm, and the area to be examined extensive, beacons constructed of small barrels, with a staff and distinguishing flag, may be anchored at convenient points; and these will form intermediate stations of greater comparative accuracy than can be obtained from the boat, influenced as it would be by tide or wind. Thus the data on which the triangles are constructed are given by the position of the ship, the true "bearing" of the boats, and the distance calculated by sound; while the nature of the bottom is arrived at by a series of soundings taken on any given "bearing" at intervals of about ten minutes, when also any alteration in the character of the material composing the bottom is carefully noted.

Thus the area of the shoal, if it be one, is carefully marked out, and the same operations are carried on in the case of a bay, a river, or an inlet; the only difference being that the observations taken by the boats are corrected, and the number of intermediate points increased, by taking the magnetic bearings of any number of the most striking points on the coast (which may be further corrected by astronomical observation), and where also observers may be landed to take a further series of angles, and sketch the nature and form of the coast-line. Beacons are erected at these places when practicable, and even rocks may have white marks painted on them for the con-

* It must be remembered, in using the artificial horizon, that the angle taken is double the true angle of elevation of the sun above the horizon, owing to the refraction of the mercury in the vessel, and that hence half the angle measured by the sextant will give the true elevation.

* The "lunar distance" is that between the moon and sun, or any fixed star or planet lying nearly in its path. When this is determined, the longitude can be found by calculation.

venience of being clearly seen from the starting-point (the ship), and thus promote accuracy of observation from it. A valuable amount of information may be obtained from the ship itself, as the rise and fall of tide, velocity of current, etc., and the direction of mountain-peaks far inland could be observed from the mast-head.

The information provided by a chart, therefore, is chiefly of a nautical character. At the best the delineation of the coast-line, with such inaccurate and untrustworthy means as can alone be employed, can be but approximately correct, and only the positions of the most remarkable features, as well as the variation in the depth of the water, can be deemed really accurate.

Even less complete nautical surveys are undertaken occasionally, as, for example, the examination of a coast or harbour by a hostile fleet of vessels, where the distances are determined

Current — + Rock with one fathom of water.

Flood tide (direction of) — Rock nearly awash.

Ebb tide (do.) — Sand that dries, with depth of water at high water.

Kn. Knots or nautical miles — Mud that dries, with depth of water at high water.

Anchorage for large vessels......... Inside this line less than one fathom

Do. for small vessels .. .. .. Inside this line less than two fathoms

Do. for coasters ... ... Inside this line less than three fathoms

H.W. High water .—.—.—. Inside this line less than four fathoms

L.W. Low water ..—..—..—.. Inside this line less than five fathoms

At low water.

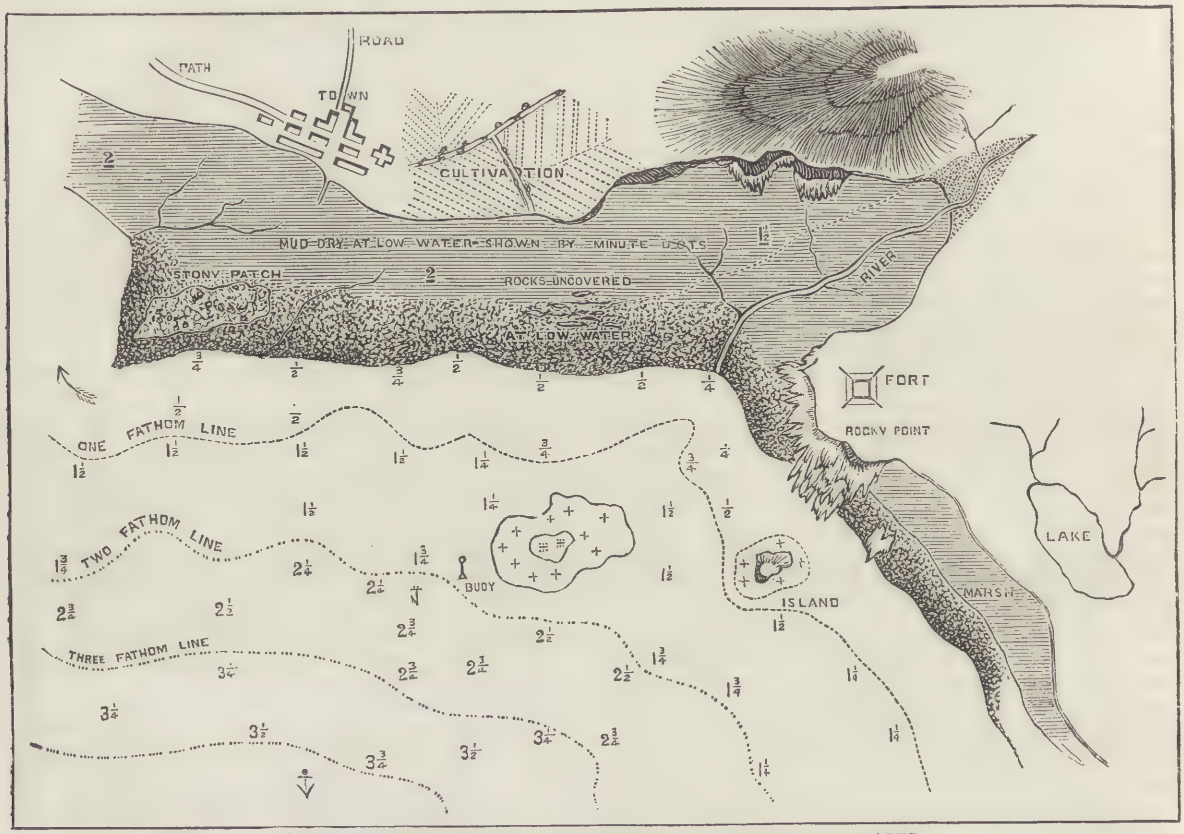

Fig. 9.—DIAGRAM SHOWING THE METHOD OF DELINEATING CHARTS.

by the intervals between the ships, or the measurement between any two observed points or times in the ship's course, by means of the log, which gives the rate at which the vessel has travelled, and the chronometer, which indicates the number of hours taken in traversing that distance.

The information afforded by a chart is first the general outline of the coast, with the positions of the prominent natural features inland, which serve, so to speak, as landmarks; and secondly, the variations in the depths of water, and the nature of the beaches or the sea-bottom. The latter is indicated by abbreviations of the actual name, as—

b,	blue.	*h*,	hard.	*s*,	sand.
bk,	black.	*m*,	mud.	*sf*,	soft.
brk,	broken.	*oz*,	ooze.	*sh*,	shells.
c,	coarse.	*oy*,	oysters.	*sm*,	small.
ch,	chalk.	*p*,	pale.	*sp*,	speckled.
cl,	clay.	*r*,	rocky.	*st*,	stones.
g,	gravel.	*rd*,	red.	*w*,	white.
gn,	green.	*rot*,	rotten.	*wd*,	weeds.

The other conventionalities used in the description of charts are shown as follows:—

Sandy beach — $\frac{\cdot}{5}$ No bottom at this depth.

Gravelly beach — *fm.* fathoms.

Stony beach — *ft.* feet.

F. I. R. Near a lighthouse is fixed, intermittent, or revolving light — *spr.* springs.

B. C. R. W. Near a buoy is black, chequered, red, or white. — *np.* neap-tides.

The north point is marked in several places on the chart, with the variations of the compass. The value of the lines marking the number of fathoms is especially great in certain cases, as, for instance, in the English Channel. So carefully are they shown in charts of this portion of the sea, that navigators, even if they cannot fix their position by observation, owing to atmospheric disturbance, imperfect instruments, or other causes, can ascertain when they are entering it by sounding; and as the lines of equal soundings are definitely marked from coast to coast, they can approximately determine their place on the chart by knowing between which lines they are then passing.

SHIP-BUILDING.—XV.

BY W. H. WHITE,

Fellow of the Royal School of Naval Architecture, and Member of the Institution of Naval Architects.

METHODS OF SHEATHING IRON SHIPS.

PROPOSALS were made many years ago to cover the bottoms of iron ships with wood planking, and to nail upon that foundation copper or other metal sheathing in order to prevent fouling and the consequent loss of speed. The plan was not, however, used until recently, the first example of a sheathed iron ship being found, we believe, in the swift ocean-cruiser, *Inconstant*, designed for the Royal Navy about ten years ago. In this case it was desired to unite very high speed with a very powerful armament, and with the power of keeping the sea for long periods without loss of speed. To reach the high speed, very powerful engines and a very finely-formed ship were required, both of which features tended to produce extremely severe strains that could only be borne without injury by an iron hull. On the other hand, to secure a bottom that should continue clean for long periods, it seemed desirable to use copper sheathing; consequently the experiment was tried, and so far the results have been satisfactory. Several other vessels, including two iron-clads, have been since constructed for the navy on similar plans, but we are not aware that any iron merchant ships have yet been sheathed with copper, the expense of such a mode of construction having probably prevented its adoption. Zinc sheathing has been tried in a few cases both in the Royal Navy and in the mercantile marine, and is preferred to copper by some ship-builders for reasons which will appear hereafter.

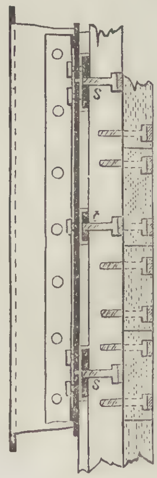

Fig. 49.

Refs. to Fig. 50.—⊙ Butts of outer planking; × Butts of inner planking; o Riveting of plating to frames.

If a piece of copper and a piece of iron are immersed in salt water, and metallic contact is made between them in a manner resembling that made between the two plates of a galvanic battery, galvanic action will be set up and the iron will waste. Hence it is necessary to use great precautions when iron ships are sheathed with copper, in order to prevent galvanic action and the consequent deterioration of the iron hull. Allusion has already been made to the similar caution required in the construction of composite ships, so that we need not dwell upon the matter now, simply stating that direct metallic contact, as well as indirect metallic connection, between the copper sheathing and the iron hull should be avoided as much as possible, and every means taken to make the wood planking and its fastenings sound and tight, in order that the skin plating may be kept dry. These are two most important conditions which ought never to be lost sight of in building vessels of this class.

Without further preface we will proceed to notice two or three plans for sheathing iron ships with copper, taking first one proposed by Mr. Grantham many years ago. The planking is wrought in two thicknesses (see Fig. 48), the inner thickness being fitted directly upon the skin-plating, and the outer thickness being fastened to the inner by copper or metal screw-bolts which do not pass entirely through the inner planks. The inner thickness is secured without using many (if any) bolts; a fact to which Mr. Grantham attributes much importance. Outside the skin-plating Z-shaped iron frames (a, a) are worked longitudinally at frequent intervals; the inner planks are worked in short lengths between these frames, and wedges (b, b) are driven in over the ends to secure the planks. This wedging arrangement has been much objected to by many practical ship-builders, who consider it to afford an insufficient attachment for planks to which all the outer planking has to be secured; and there seems much force in the objection. It is only right, however, to add that Mr. Grantham provides for the use of a limited number of bolts in some cases, these being placed mid-way between the external frames (like c in the figure), and secured by nuts and screws to the skin-plating. Where the main framing is transverse (as in Fig. 48), Mr. Grantham proposes to place the external frames longitudinally; but where the main frames are longitudinal, he would place the outside frames transversely. The principle is the same in both cases, and the whole arrangement for securing the inner layer of planking is based upon the belief that iron bolt-fastening should be avoided as much as possible, because of the probably rapid deterioration of such bolts if the planking became saturated, and galvanic action should be set up between them and the copper sheathing.

To some extent this view is doubtless correct, as experience with composite ships—having their planking in one thickness and fastened with iron bolts—proves. In such cases the large area of the copper sheathing has its action concentrated upon the comparatively small areas of the bolt-heads or shanks, and as a consequence their deterioration is often rapid. But the case is widely different when two thicknesses of planking are used and carefully fastened in the manner explained in page 277;

the iron bolts of the inner thickness then being comparatively distant from the copper sheathing, and not nearly so likely to suffer by galvanic action or other causes. This distinction between the use of one and two thicknesses of planking Mr. Grantham does not appear to recognise sufficiently in his arguments against bolt-fastenings, nor does he note the much greater strength to resist *working* in the sheathed ship. On his plan, too, the planking cannot be regarded as adding much, if anything, to the strength of the ship, because of its comparatively slight attachment to the hull. Of course, the iron hull in itself can be easily made so strong as to require no such assistance; but on the other hand, by arranging and fastening the planking differently, it may be made to help the hull proper considerably, while forming an equally efficient foundation for the copper sheathing, as will be shown almost immediately. It should be added that Mr. Grantham also proposed to use brass stems and stern-posts in sheathed ships, a plan which has been frequently conformed to, when other modes of securing the planking have been followed.

Fig. 49 shows in section the plan of sheathing first used in the Government service. The skin-plating is worked directly upon the frames, no liners being required, and the flush edge-joints are secured by external strips (*s*, *s*). These are made much thicker than the plating, in order to permit the ends of the iron bolts, forming the principal fastenings of the inner planking, to be screwed *into*, but not *through* them. Midway between the edge-strips other thick strips (*t*) are worked, in order to receive the screwed ends of additional fastenings; and the spaces between the strips are filled up with thin planks secured by marine glue, so as to form a flush surface, and avoid any necessity for scoring the inner layer of planking. This is worked transversely, the lengths of the planks extending from the keel towards the gunwale, and the butts being screw-bolted to strips fitted for the purpose. By these arrangements the inner planks are strongly secured to the hull, and yet the bolts leave the skin-plating itself unpierced, so that in case of an accident which stripped off the planking the skin would still remain water-tight. The outside planks are worked longitudinally, and secured by metal screw-bolts kept clear of the iron fastenings, and passing about two-thirds through the inner planks.

This plan is therefore, at least, as efficient as Mr. Grantham's in preventing metallic connection between the copper sheathing and the iron hull; and it makes a stronger and more intimate connection between the hull and the planking. It involves, however, the necessity for great care and considerable expense in order to secure thoroughly good workmanship in connection with the fastenings of the inside planking. For example, in drilling the holes in the strips caution is needed to prevent them from passing *through* the strips, and no less care is required to ensure exactitude in boring the bolt-holes in the planks so that the bolts may be properly hove up. For these and other reasons the simpler plan illustrated by Fig. 50 has been used in the later sheathed ships of the Royal Navy.

The plating is here worked on the common in-and-out plan. Both thicknesses of planking are worked longitudinally, the edges of strakes being brought upon the centre lines of strakes overlying or underlying them. The inner thickness is fastened by iron bolts screwed through holes tapped in the plating, and farther secured by nuts hove up inside the iron skin. Consequently damage to the bottom, even if it were to strip off the planking, would not be likely to cause a leak; because the screwed ends of the bolts would most probably remain in and fill the holes in the plating. And, in addition, if the nuts were broken off or removed by any mischance, the bolts would still have a hold on the plating.

The outer thickness is fastened in the usual manner by metal screw-bolts passing partially through the inner planks, and a reference to the outside view in Fig. 50 will show how these bolts are kept clear of the iron fastenings. A merely casual glance at the arrangement may lead to the opinion that this method of securing the inner layer of planking unduly weakens the skin-plating, and that it is consequently inferior in this respect to the preceding plans. But on a closer examination it will be remarked that the iron bolts are spaced further apart, on any transverse section of the plating, than the rivets are which attach the plating to the frames; so that the unavoidably weakened sections in wake of the latter still continue to be the places where fracture is most likely to take place, and no real loss of strength results from drilling the holes for the bolts. Moreover, it will be obvious that the two layers of wood planking form a skin possessing in itself considerable strength, and so efficiently connected to the iron hull as to be capable of lending it aid to a greater extent than can the planking on either of the other plans. Much has yet to be learnt respecting the limits within which wood and iron so combined may be considered to act jointly; but there is reason to believe that under such strains as may be considered of ordinary occurrence, the wood skin of a ship sheathed as in Fig. 50 would lend valuable aid to the iron plating; and on the other hand, the plating would probably do much to prevent that working in the wake of the fastenings which is likely to take place in the skin-planking of wood and composite ships. The plating of sheathed ships is usually somewhat thinner than that of unsheathed iron ships of equal size; but the difference in thickness is not great, and the reduction actually made is regulated rather by consideration of the fact that the planking has to be fastened to the plates, than by a regard to structural strength.

At the outset it was stated that the prime object of the wood planking was the prevention of metallic contact or connection between the copper and the iron hull; but one indirect advantage gained by the thick coating of wood is the greater strength of the bottom to resist penetration by blows which would break through unsheathed plating. Double bottoms are consequently not so necessary in sheathed ships as in ordinary iron vessels, and they have not been constructed in most cases. However the planking may be arranged, care is required in caulking both thicknesses, making the bolts water-tight, and coating the faying surfaces with some water-tight material, such as marine glue; in short, no means should be left untried to prevent the iron plates and bolts from becoming damp, and wasting by rusting or galvanic action.

There have been many other proposals for sheathing iron ships with copper, to which reference might be made did space permit. One only can be mentioned, which was put forward by Mr. McLaine, and was most novel in conception. His plan was to build the iron ship with frames *outside* the skin instead of inside; then to bolt wood timbers to the frame angle-irons, and upon these timbers to fasten wood planking in combination with a wood keel, stem and stern-post. In fact, his method may be shortly summed up as a combination of the timbers, planking, keel, etc., of a wood ship, with the skin, decks, bulkheads, etc., of an iron ship, the connection between the two being made by the means described. Some high authorities expressed favourable opinions respecting this plan, but it has not, we believe, ever been practically applied, and it would certainly lead to both costly and heavy ships.

Attention must next be turned to zinc sheathing for iron ships, which has been strongly advocated by many persons in preference to copper. When zinc and iron are immersed in salt water, and the circuit completed by metallic connection between the two, galvanic action is set up, the zinc wasting while the iron remains unoxidised. Consequently no injury to the hull need be anticipated from sheathing an iron ship with zinc; and in this respect such sheathing is doubtless superior to copper. It is also much cheaper—about one-third the price of copper; but the question of its anti-fouling qualities as compared with copper is not thoroughly settled, and this is a most important one. Copper when immersed in sea-water becomes oxidised on the surface, and this oxide being soluble is slowly and gradually washed off, so preventing the attachment of marine plants and animals that would otherwise cause foulness of bottom. This process, termed "exfoliation," is often so very gradual that the copper sheets last for very many years under water, and yet keep the bottom of the ship clean. Zinc, on the contrary, when used to sheathe the bottoms of wood ships, does not exfoliate like copper, the oxide formed upon its surface not being readily soluble, and consequently it does not keep the bottoms so clean; still its cheapness leads to its frequent use on wood merchant ships, and under these circumstances it lasts for a long time. To render zinc sheathing more efficient against fouling, it is necessary to establish galvanic action by bringing it into contact or connection with iron or copper bolts in wood ships; or in the case of sheathed ships allowing it to have some contact with the iron plating or other pieces of the hull. Its oxidation then becomes much more rapid, and its anti-fouling properties are increased; but on the other hand it wastes much more rapidly than before, and requires to be sooner renewed. The larger the

surface of zinc and iron in contact the more rapid is the waste of the zinc; and so far the chief difficulties attendant upon the use of zinc sheathing for iron ships have been caused by a want of certainty in our knowledge respecting the regulation of the amount of contact between the two metals. This regulation should be such as to give an amount of contact just sufficient to keep the surface of the zinc clean, so that it should not waste too rapidly (because the zinc might then require to be renewed so frequently as to more than do away with its advantage in first cost as compared with copper); and it should provide the contact in such a fashion as to secure a uniform wasting over the whole surface of the zinc. Experience may help us to decide how these desiderata may be obtained; but at present they do not seem to have been secured, and consequently copper sheathing is preferred.

Passing from these general considerations, we will notice a few of the methods proposed for sheathing iron ships with zinc. One of the simplest plans tried consisted in securing sheets of zinc outside the plating by means of light iron rods riveted around the edges of the sheets, and a few small studs placed near the centres. This appears, however, to have made the surfaces of contact between the iron and the zinc much too great, and as a consequence the latter wasted rapidly, leaving the iron plates exposed.

Mr. Daft's plan for zinc-sheathing has attracted much attention, and has, we believe, been experimented upon on a small scale with some success, but has not been practically applied. He proposes to arrange the plating very similarly to that shown in section *a*, Fig. 34, page 305; but instead of bringing the edges of adjacent strakes close together, to leave narrow spaces between them, and to treat the butts similarly. Into these spaces strips of wood would be driven, and to these strips the edges of the zinc sheets would be nailed. The sheets would consequently require to be of the same size as the plates, and their centres would be secured by a few small studs. Felt or some other material of a similar kind is proposed for use as a bedding to the sheets, in order to reduce the amount of contact between the zinc and the iron. Various objections have been raised to the structural arrangements which this plan would render necessary —the edge-strips, numerous liners, and broader butt-straps that would be needed; the want of proper fitting of iron to iron at the butt-joints; the greater labour of plating and caulking, etc. These objections, doubtless, have some force, and probably have contributed to prevent any ship being thus built and sheathed.

In another plan, proposed by Mr. Bell, the plating would be worked as usual, except that strips of plating would be fitted between the laps of the raised and sunken strakes in order to increase the depth of the recesses over the latter. Thin wood planking, arranged diagonally, would be fitted into the recesses, and secured to the sunken strakes by a few bolts. To these planks the zinc sheathing would be nailed, and would consequently, unless some material were interposed, be in direct contact with all the outer strakes of plating; but it is proposed to regulate the amount of contact by trial. An alternative proposition by the same gentleman is to plate the ship as shown in Fig. 49, and to fit the wood planks between thick edge-strips similar to *s*, *s*. The zinc sheets would then touch the edge-strips only, and their surface of contact would be much less than on the other plan. Iron nails in the zinc sheathing are suggested as a simple means of increasing the metallic connection if that should prove desirable. So far as we know, neither of these plans have been practically tested, and it is unnecessary to criticise them.

The last plan we shall describe is now under trial in one of the iron-clad ships of the navy. It was proposed by the late Mr. Lungley, and is illustrated by Fig. 51. The outside plating is worked on the usual in-and-out plan; and to secure the wood planking to which the zinc sheets are nailed, channel-irons (*a*, *a*) are riveted to the iron skin. The planking is fitted diagonally between these channel-irons, and the zinc sheets consequently come into direct contact with iron only at the edges of the channels. Metallic connection is, however, made by the nails in the sheathing, these passing through the wood and touching the iron plates; and the amount of the action set up on the zinc may obviously be increased by using iron or metal nails instead of zinc. The experiment has not yet extended over a period sufficiently long to lead to conclusive results; but it will probably do much to advance our knowledge of the conditions essential to the successful use of zinc sheathing. Experience of a more decided character is required before ship-builders will be able to employ zinc with the certainty of success; but should this be obtained, the cheaper metal will, no doubt, be extensively used instead of copper.

SEATS OF INDUSTRY.—XXIX.

BRISTOL.

BY WILLIAM WATT WEBSTER.

One of the most ancient cities and centres of trade and manufactures in the United Kingdom, and for a long period second only to the metropolis in commercial and social importance, Bristol, though outstripped by younger rivals, still takes high rank among the towns of Great Britain, and the story of its rise, pre-eminence, and relative decline, forms a singularly interesting and instructive chapter in the history of English commerce. We say *relative* decline, because Bristol has in reality suffered no positive decadence, although it has not recently progressed at the same rate as some other more fortunately-situated towns in this country. There does not appear to have been any very marked falling off either in the enterprise or in the intelligence of the inhabitants of this famous city in more modern times; it is rather the great opportunity that has been lacking to them. The current of commercial prosperity would seem to have changed its course, and left Bristol in an eddy of the stream. An examination of the chief causes that have contributed to raise Liverpool, for instance, into the position it now occupies, and to throw Bristol into comparative obscurity, will show that the latter could not possibly have taken advantage of them. Indeed, the later trading history of Bristol, considered in connection with that of English towns which have increased more rapidly in population and wealth, forcibly illustrates the effect that the introduction of new industries exercises in determining the relative importance of commercial and manufacturing centres. It is to its proximity to the great manufacturing districts of the north of England, as we have seen in a previous paper, that Liverpool is principally indebted for its extraordinary development and growth. Bristol had not in its neighbourhood the resources necessary for the carrying on of such extensive manufacturing enterprises as constitute the foundation of the prosperity of Liverpool.

Nothing is known of the origin of Bristol, but under the names *Caer Brito* and *Caer Oder*—the latter signifying the "town of the chasm," and denoting its position by the "rifted rock" —it is supposed that it can be traced to a period as far back as the time of the ancient Britons. The Romans fortified the place, and after their departure from the island, it fell back into possession of the native princes, and formed part of the territory of the Cornish Britons. It is included in the lists of fortified and eminent towns drawn up by Gildas in the fifth, and by Nennius in the seventh century; and in 584 it was captured by Crida, King of the West Saxons. Its present name is generally believed to be a corruption of the Saxon compound *Brice-stow* or *Bright-stowe*, which means "a pleasant place;" but numerous other explanations of it are given. It would appear to have been visited by Jordan, one of the monks who came to Britain with Augustin; and certain antiquarians contend that Bristol was the scene of the famous conference between the Roman missionary and the British bishops in 603. The first unequivocal mention of the place in history, however, is in the reign of Athelstan, in the beginning of the tenth century. Next to London Bristol was the principal port in the country in Anglo-Saxon times. In a memoir of Wulfstan, the Bishop of Worcester at the time of the Norman Conquest, the following passage occurs:—"There is a seaport town called Bristol, opposite to Ireland, to which its inhabitants make frequent voyages of trade. Wulfstan cured the people of this town of a most odious custom which they derived from their ancestors, of buying men and women in all parts of England, and exporting them to Ireland for the sake of gain. You might have seen, with sorrow, long ranks of youths and maidens of the greatest beauty tied together with ropes and daily exposed for sale; nor were these men ashamed—oh, horrid wickedness!—to give up their nearest relations, even their own children to slavery." In the "Domesday Survey" the town is called *Bristow*, and it was then a royal borough, its governor being a noted merchant, said to be of Danish origin, named Hardinge, whose son, Robert Fitz-

hardinge, the first Lord of Berkeley, succeeded to the government. In the reign of William Rufus the fortifications of the town were strengthened. Bristol was captured in the reign of Stephen by Robert Earl of Gloucester, the illegitimate son of Henry I., and held by him for his sister Maud, during which time the castle was rebuilt and enlarged, and made one of the strongest in the country, its walls being about twenty-five feet thick. In this castle Henry II. was partially educated, and Stephen was for a short time a prisoner. About the year 1140, a monastery of the Augustine order was established at Bristol by Robert Fitzhardinge; it was made an abbey by Henry II., and continued to flourish till the dissolution of the monasteries by Henry VIII. in 1540, at which time its revenues amounted to £767. Fitzhardinge also founded the priory of St. James, the church of which was afterwards made parochial, and a nunnery was built by Eva his widow. William of Malmesbury, who died in 1148, speaks of Bristol as "a very celebrated town in which there was a port, the resort of ships coming from Ireland, Norway, and other countries beyond sea." Henry II. granted the town a charter in 1165, increasing its commercial privileges, and in 1175 he took possession of the castle. Early in the thirteenth century a new channel was cut for the river, and a new quay, adapted to the extensive and growing trade of the port, was constructed. For its time this was a remarkable engineering work. In 1285 Edward I. assembled a Parliament at Bristol. A few years later a Bristol merchant, named Walter Hobbe, seized a ship and cargo in the port, belonging to a merchant from Holland, but after a long course of litigation he was forced to surrender both, and pay £65 for the loss he had caused the Dutchman to sustain. The old chronicler who relates this incident remarks that it would be "a thing of great danger at those times, and such as might occasion a war, to suffer alien merchants, particularly those of Holland and Brabant, to depart without having justice done them," which is surely a sensible comment so far as it goes. Bristol was the seat of a rebellion in the reign of Edward II., and held out for four years against the royal forces. About this date extensive manufactures of soap, cloth, and glass were carried on in the city; and in the reign of Edward III. many of the weavers who had come over to England from Flanders settled in Bristol, and materially contributed to its prosperity by making it the chief centre of the woollen manufactures of the kingdom. Blankets were first made by, and derive their name from a Flemish manufacturer named Thomas Blanket, who, with his two brothers, were among the earliest promoters of cloth-making in Bristol. As a matter of course, Mr. Blanket's innovations were opposed by the civic authorities, who in 1340 fined him heavily "for having caused various machines for weaving and making woollen cloths to be set up in his house, and for having hired weavers and other workmen for this purpose;" but the fine was afterwards remitted by a special injunction from Edward III. After a short time the inhabitants of Bristol perceived that the inventor of the blanket was a public benefactor, and he was made bailiff of the city. He and his two elder brothers carried on an extensive home and foreign trade for many years, and from their time till the discovery of America cloth was the principal article of commerce in Bristol. It was made one of the staple towns for wool by Edward III. in 1353, and twenty years later this monarch constituted the city a county in itself and declared it free from all feudal obligations. As an evidence of the wealth of Bristol at this period, it may be mentioned that it furnished 22 ships and 608 seamen, a force as large as that contributed by London, to the fleet sent to besiege Calais shortly after the battle of Crecy in 1346. Bristol was besieged and taken in 1399 by Henry Duke of Lancaster, who in the same year ascended the throne as Henry IV. In a charter granted by this monarch in the following year, acknowledgment is made of "the many and notable services which very many merchants, burgesses of our town of Bristol, have done for us and our famous progenitors in many ways with their ships and voyages, at their own charges and expense."

During the second half of the fourteenth century there flourished at Bristol a famous merchant and manufacturer, William Canynge or Canning, the founder of a family to which the city was greatly indebted. He was twice bailiff, six times mayor, and three times returned as representative of Bristol in Parliament. In 1396 he died, leaving a large fortune acquired principally by foreign trade, the greater part of which was devoted to charitable objects. His son John was also a merchant of repute, and served the town in the capacities of bailiff, sheriff, member of Parliament and mayor, and at his death, in 1405, he left a third of his goods to his wife, a third to his children, and a third to the poor. Thomas Canynge, the eldest of John's descendants, settled in London, and rose to the dignity of member of Parliament for the City in 1451, and mayor in 1456. When he was sheriff of the metropolis in 1450, he took part in the suppression of Jack Cade's rebellion, as we learn from a petition addressed to Henry VI. by himself and his fellow-sheriff, asking remuneration for the expense, trouble, and danger they had incurred in "drawing the body of the great traitor upon a hurdle by the streets of the City of London," and in distributing the head and quarters as directed; "the which commandments," says the petition, "were duly executed to their great charges and costs, and especially for the carriage of the quarters aforesaid, for and because that hardly any persons durst or would take upon them the carriage of the said head and quarters for doubt of their lives." Thomas Canynge was considered a man of great energy and high character, but his brother William, known as William Canynge the younger, who was born in 1399 or 1400, greatly excelled him and all his family, indeed, in wealth and fame. This was the greatest of Bristol's old merchant princes. By the middle of the fifteenth century there were about 66 ships and about as many boats belonging to the port, and its merchants carried on an extensive trade not only with Ireland and Wales, but also with France, Russia, Prussia, and the Levant. William Canynge the younger, during the eight years preceding 1460, employed on an average 800 seamen in the navigation of his ten vessels, which had an aggregate burden of 2,930 tons. He gave occupation besides to about 100 artisans. Several of Canynge's ships were among the largest of their day; the *Mary and John* being 900 tons, the *Mary Redcliffe* 500 tons, and the *Mary Canynge* 400 tons burden, and the three cost him in all 4,000 marks, or considerably more than £25,000 in our money. By a treaty concluded between Henry VI. and the King of Denmark, the merchants of Bristol and several other towns were forbidden to trade with the inhabitants of Iceland, Finland, and other districts subject to the Danish crown; but the Danish king made an exception of William Canynge, who was permitted, "in consideration of the great debt due to the said merchant from his subjects of Iceland and Finmark, to lade certain English ships with merchandise for those prohibited ports, and there to take fish and other goods in return." In 1449 Henry VI. sent letters of commendation to the Master-General of Prussia and the magistrates of Dantzic, inviting their favour towards certain English factors established within their jurisdictions, and especially towards William Canynge, "his beloved and eminent merchant of Bristol." Canynge, like his grandfather, passed through all the higher offices of his native city, and greatly distinguished himself. He was a staunch supporter of the Lancastrian cause, and at his own expense built "a stately vessel only for war," to protect the city against the Yorkists. In 1456 he entertained Margaret of Anjou when she visited Bristol for the purpose of quickening the interest of the western counties in the falling fortunes of her husband. Five years later, on the failure of the Lancastrian cause, Canynge had to welcome Edward IV. to the city, when that monarch came to ascertain how much money could be levied from the wealthy merchants of Bristol. Being the richest man in the town, and at the same time the most zealous supporter of the Lancastrian house, Canynge had to pay the king 3,000 marks, or about £20,000, "for the making of his peace," but he was also instrumental in securing certain important trading privileges for Bristol, in return for the money he and his townsmen delivered to his majesty. During his last mayoralty, Canynge formed the merchants of Bristol into a guild, for mutual protection in regulating the prices of various articles of trade and for mutual help in misfortune, which although repugnant to modern economical policy, exercised at that time and for a long period after a beneficial influence on the commerce of the city. He spent much of his wealth on the restoration of the ancient and noble church of St. Mary Redcliffe, and in 1467, his wife and children being all dead, "he gave up the world, and in all haste took orders upon him, and in the year following was made priest and sang his first mass at Our Lady of Redcliffe." It is said that Canynge was induced to take this step in consequence of a project of Edward IV. for finding him another wife, and exact-

ing a large sum of money for his matrimonial agency fee. In Canynge's time there was a large number of great merchants in Bristol, including Robert Sturmy, who lived in lordly style and had extensive dealings with the Levant, and the brothers Jay, a family that was famous in two generations. In a work written towards the close of the fifteenth century, we read that in 1480 "a ship of John Jay the younger, of 800 tons, and another, began their voyage from King's Road to the island of Brazil, to the west of Ireland, ploughing their way through the sea." The ships did not discover the "island," although they sailed the sea for nine months; but was this a veritable voyage of discovery, or is there some mistake in the record?

There seems to be no good reason for doubting that John Jay at this early date sent out ships in quest of a new field for trade on the other side of the Atlantic. The Spanish ambassador at the English Court informed his sovereign in a dispatch dated 1498, that "for the last seven years the people of Bristol have sent out every year two, three, or four light ships in search of the island of Brazil and the seven cities;" and if we accept this statement as correct, it proves that the merchants of this town were searching for the New World at least two years before Columbus made his first voyage of discovery. But whether this be so or not, there is no room for doubting that a Bristol merchant of Venetian birth, named John Cabot, landed on the American continent before either Columbus or Americo Vespuccio. On the 5th of March John Cabot obtained from Henry VII., for himself and his three sons, Sebastian, Ludovico, and Sanzio, letters patent for the discovery of new lands, and in May of the following year he sailed out of Bristol with two vessels manned by a crew of three hundred men, which he had equipped with the help of his brother merchants. On the 24th of June he sighted land, which he supposed to be Cathay, "the territory of the Great Khan," but which turned out to be Labrador. In 1498 Sebastian Cabot left Bristol with a small fleet, and after searching for a north-western passage to India, explored the North American coast as far as Chesapeake Bay. The Cabots made no profit out of these expeditions, but at a later period their townsmen established a trade with Newfoundland that largely contributed to the prosperity of Bristol. On the visit that he paid to Bristol in 1487, Henry VII. marked his sense of the wealth and luxury that prevailed in the city by imposing a fine on such of the citizens as possessed property to the value of £20, on the pretext that the ladies dressed in too gorgeous and costly robes. The kings of England in those times resorted to peculiar methods of raising money.

MUSEUMS: THEIR CONSTRUCTION, ARRANGEMENT, AND MANAGEMENT.

BY SAMUEL HIGHLEY, F.G.S.

IX.—NATIONAL MUSEUMS (*continued*).

FROM what has been stated in previous articles it will be seen that the severance of the natural history from the antiquarian and bibliothecal collections of the British Museum will afford ample space for the time being, in the Bloomsbury building, for the development of the collections illustrative of *human history*, which should include specimens from the Tower armouries (the Meyrick collection being lost to the nation), Woolwich Arsenal, and Indian Museums. An extension of the National Gallery building would allow of the sculpture and pictorial art treasures being arranged in such manner as would best illustrate *Art*, and extend a sound knowledge of its principles among the people. *Practical Art* and *Economic Science* should find a place in their recognised home at the South Kensington Museum, in association with a teaching staff at the Science and Art Schools, while *Natural History* in its purely scientific aspects would find ample space for its full development according to modern ideas on the site now secured for the New Museum, to the south of the International Exhibition. Were the Economic Collections of the Kew Museum brought into association with the Museum of Practical Geology and the Food Collections of South Kensington, the Botanic Gardens at Kew would afford the collection of living plants desired by the memorialists of 1858; and it might be a question whether Government should not assist the Zoological Society with an annual grant, on the condition that the living animals should be grouped in more systematic order, and that that powerful aid to a knowledge of the habits of the invertebrata, the aquarium, should be re-organised, according to the latest experience, as developed at the Crystal Palace by that enthusiastic practical naturalist, Mr. Alford Lloyd, for in its present condition the aquarium house is a disgrace to the gardens of the Zoological Society.

I shall devote the remainder of this article on our science, art, and antiquarian collections, to a description of what the arrangement and management of a "National Museum of Natural History" ought to be, taken as a typical model open to modification according to the requirements of any given locality. It should comprise two separate buildings. One should be devoted to an elementary series forming an epitome of the leading principles of natural history, so constructed that it would provide for the general public being admitted not only during the hours of the day, but in the evening, for the benefit of the working classes and others engaged in business during the day. The other building would be devoted to the scientific or classified collections, and should be constructed so as to provide for the convenience of the general public, and the special requirements of students and scientific naturalists between the hours of ten and four. The two buildings should be sufficiently isolated, to provide against the destruction of the Scientific Museum, should a fire by any accident arise in the Elementary Museum. It would therefore be better to place the Elementary Museum at one end, rather than in the middle of the buildings, as proposed in Professor Owen's plans of 1859 and 1862; for though such a disposition may appear more symmetrical from an architectural aspect, in the event of a fire occurring in a central structure—the Elementary Museum being the only part where artificial illumination should be admissible—the destructive element would literally be provided with two strings to its bow, and the difficulty of confining a conflagration to its narrowest limits would be materially increased. The smaller building might be called the "Index Museum," or as Professor Owen considers a circular structure would be the most convenient form, as it "admits of the most economic and effective supervision" for an introductory series, the "Rotunda of Elementary Natural History" would provide a designation that would perfectly define its aims.

Estimate of Space.—On the first announcement of Professor Owen's scheme for a new Museum for the British Natural History Collections, much misconception prevailed, and even prevails to the present day, as to his real ideas on the subject, which may have arisen from misstatements of his views, similar to that made by Mr. Gregory when he announced in Parliament that a gallery of 850 feet in length was proposed to be devoted to whales. The truth was, that 850 feet was specified in the plan of 1859 as the entire length of the "Mammalian Gallery," but the veriest schoolboy ought to know that the single *order* Cetacea does not constitute the entire *class* Mammalia. Yet this gross misrepresentation led to Lord Palmerston's protest against the admission of whales into our National Museum, and making the quaint suggestion for the excision of the cetaceans out of the scheme of Nature. Now that science is being taught in our great public schools, such as Eton, Rugby, Marlborough, Winchester, and the masters are desirous of teaching it still more extensively on the soundest basis that our scientific educationists can indicate and practical experience establish, we may hope in future days to be saved from such lamentable displays of ignorance on the most elementary conceptions of the aims of the naturalist, under the roof that covers "the collective wisdom" of our country, by those who would patronisingly pat an Owen or a Huxley on the back as "men fond of beetles." Professor Owen's scheme has been regarded as "extravagant" both as to idea and cost, if carried into execution; but when the keepers of the several departments came to make estimates of space for their individual requirements, it was found that their demands exceeded those originally made by Professor Owen in 1859.

It will be found that Professor Owen always has spoken in his printed reports and works as to the necessity of the curator being guided by "the principle of selection" as to what specimens were best suited for public display, though he enforces the necessity for the skins and skeletons of all large animals being arranged in the public galleries, as unwieldy specimens could thus be more conveniently examined than if kept packed in boxes, etc., in the store-rooms or studies; for though boxes,

drawers, etc., may be a convenient and practical arrangement for specimens of birds, bats, and "such small deer," the system does not hold good for bulky or pachydermatous animals, as common sense indicates. On referring to the tabular form given at page 320, under the column headed "Estimate of New Museum," it will be seen, that according to the returns of the keepers of the several departments, based on the data laid down by Professor Owen, previously defined, a gallery length of at least 7,400 feet by an average width of 50 feet, together with an area of about 300 square feet for an Index Museum, is essential for the proper display of any National Collection of Natural History; or an entire area of 322,100 square feet, equal to about seven and a quarter acres, and add, as Professor Owen says in his Report of 1862, "for architectural requirements, for light, access, galleries, halls, symmetry, and ornament,* say three acres, and the whole would call for a building of two storeys upon about five and a-half acres of ground."† This, says Professor Owen, in his edition of 1862,‡ "is scarcely one-sixth the size of the Exhibition Building of 1862, for the arrangement and display of the samples of industrial products of the present generation." "One mile of galleries stored with examples of creative skill may leave the traverser somewhat wearied, but thousands gladly court the greater fatigue of six miles of gallery stored with the works of industry of all nations."

Professor Huxley, in his examination before the British Museum Parliamentary Committee,§ stated that he considered six such rooms as the Ornithological Gallery in the British Museum (which is 300 feet long by 45 feet wide), "with appropriate offices," would afford ample space not only for the existing zoological collections, but also for future additions for fifty years to come. This would only amount to a gallery length of 1,800 feet, or 2,600 feet less in length than estimated by the officers of the British Museum. By reduplication at the ends of the rooms, the absolute length of wall-cases (having a depth of 3 feet) in the Ornithological Gallery equals 900 feet, and the floor-space allows of two rows of table-cases 10 feet long by 4 feet 7 inches wide, with an allowance of 3 feet space between the cases. Such a Zoological Museum (*without the appropriate offices!*) would not cover more than 2 acres of ground. As an illustration of the ratio of specimens required for public exhibition on the typical system, Professor Huxley considered that 1,500 species would be a very large allowance for the needful illustration of ornithology as to form, colour, and structure, and that the male, female, and young, different ages or varieties of the same animal need only be exhibited, where any law, fact, or considerable truth could be illustrated. "Every *fact* of variation should be properly illustrated, but every variety, say of the class of birds, should not be exhibited in the public galleries." The estimate of that practical curator, Professor Agassiz, for the Museum of Comparative Zoology of the State of Massachusetts, not only confirms, but exceeds that made by Professor Owen, as for the illustration of zoology solely, he required and secured "an oblong square of about five acres," on which galleries having a collective length of 6,000 feet by 50 feet wide have been built. We may therefore assume that the estimate for space for the New Museum of General Natural History is not founded on extravagant ideas or an unsound basis, when two such eminent naturalists as Professors Owen and Agassiz, who have devoted the greater part of their lives to the details of Museum arrangements, independently arrive at such a close approximation to the same conclusion; and I believe another practical curator, Professor Flower, the Conservator of the Museum of the Royal College of Surgeons, also considers the space specified in Professor Owen's Report essential for the proper elaboration of the National Museum of a great, wealthy, and intellectual country. Now that the desired ten acres of ground has been acquired, Mr. Waterhouse's plans approved, and £35,000 voted for the erection of the Museum, it is to be hoped the building will be speedily completed. It is to be regretted that the debate of 1860 had the effect of postponing the decision of Government on such an important question for a period of twelve years.

* In an article contributed to the *Gardener's Chronicle* (page 749, vol. for 1858) Dr. Hooker suggests the advantage of a grass-plot being laid round a Museum, as "it not only cools and moistens the impending atmosphere, but mechanically retains the dust swept off surrounding objects by surface currents."

MINING AND QUARRYING.—XXV.

BY GEORGE GLADSTONE, F.C.S.

LEAD (*continued*).

ASSAYING—SMELTING—THEORY—SMELTING IN REVERBERATORY FURNACES AT ONE OPERATION—CALCINERS—FLOWING FURNACES—THE ORE HEARTH—SLAG HEARTH.

In North Wales a flat iron bason with a lip is used, and if the ores are rich they are reduced in this without the addition of any flux whatever, but if poor a little carbonate of soda is added. The bason is covered with a close-fitting iron lid, and then put into an open forge for five minutes. By that time the greater portion of the metal is separated, and a scum, or slurry (as it is there called), is found to cover the surface. This is pushed to the back of the bason, and as soon as the slurry has sufficiently solidified the lead is poured out into a mould. The slag is then re-heated for about an equal time, to free any metal that may have become mechanically suspended by it, and this is then poured out as before. The sum of these two meltings will give with great exactness the quantity of metal in the ore.

If earthen crucibles are used, some small pieces of iron, or wrought-iron nails, are put into the crucible, care being taken that they reach to the bottom, or else some of the sulphide may escape decomposition. All the pieces of iron must be withdrawn before the contents of the crucible are allowed to cool, or they will become fixed in the lead.

Any silver that may be present in the ore, will be found in the button of lead weighed by the assayer, so that the result must not be understood to represent the per-centage of pure metal, but of the argentiferous lead. In a small sample, such as 10 oz., which is a common quantity to be assayed at a time, the silver will only be represented by a fractional quantity, as 0·1 per cent. of silver is equal to a yield of $32\frac{2}{3}$ ounces to the ton. The same remark will apply to the gold; but it scarcely ever happens that it amounts to an appreciable quantity, even in an assay balance of the most delicate construction. Sulphide of antimony, which is not an uncommon ingredient of lead ores, will in like manner affect the result of the assay. If copper is present, about one-third will probably find its way into the metal, the remainder being retained in the slag. Iron will not affect the assay at all, as the whole of it will pass into the slag. Zinc and arsenic, being both very volatile substances, will not interfere with the calculations of the assayer.

At many of the great lead mines, such as those of Mr. W. B. Beaumont, at Allenheads, the reduction-works are on the spot, and form part of the same establishment, so that the ores obtained from them do not come upon the market; but where the ores have to be sold to smelters, this is generally done by ticket, upon the same plan that tin and copper ores are sold in Cornwall and Swansea. The argentiferous ores, which term includes all those which contain sufficient silver to cover the cost of separation, are of course assayed for both metals, and fetch a corresponding price. Anything above from two to three ounces of silver to the ton will repay the cost of desilverisation.

The smelting of lead is a comparatively simple process theoretically, but it will be seen from the following descriptions that in practical operation there are a great many details which call for the exercise of ingenuity, and which also involve a very heavy outlay for plant.

The theory of the process consists in converting the ore, which is the sulphide of lead (PbS), into either the oxide (PbO) or the sulphate ($PbSO_4$); and then fusing either or both these with a quantity of the unchanged ore in certain proportions which will yield metallic lead (Pb) and sulphurous acid (SO_2).

The following formulæ will show what relative proportions will give the best result; that is, will liberate the whole of the lead in the ingredients. No other proportions will be found to fulfil this condition:—

2 of oxide to 1 of sulphide ($2PbO + PbS = 3Pb + SO_2$).

1 of sulphate to 1 of sulphide ($PbSO_4 + PbS = 2Pb + 2SO_2$).

1 of sulphate and 2 of oxide to 2 of sulphide ($PbSO_4 + 2PbO + 2PbS = 5Pb + 3SO_2$).

In practice, of course, exact results like these cannot be at-

tained: firstly, because none of the ingredients are perfectly pure; secondly, because there is always more or less reaction between them and the materials of which the furnace is composed; and thirdly, because lead is easily volatilised, and a considerable portion of the metal passes away in the fumes. Owing to these unavoidable sources of error, it is found that there is nearly always an excess of the oxide and sulphate, and, therefore, that the proportion of lead represented by the undecomposed portion of them is left unreduced.

Almost all the lead works in this country are conducted upon the principle of this double reaction; but there are different modes of carrying it out, which will have to be noticed separately. At many of the Continental establishments, especially where the ore consists largely of silicates, the lead is reduced by the direct action of metallic iron—an application on a large scale of the principle described above for the assay of lead ores.

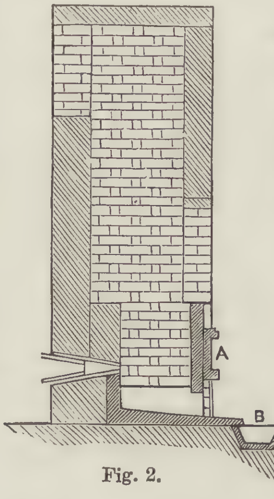

Fig. 2.

To return to the English practice. There are two kinds of furnaces used—the reverberatory and the blast furnace. The use of the latter, called the "ore hearth," is almost confined to the northern counties and to Scotland.

The reader will ere this be so familiar with the ordinary arrangements of the former that a lengthened description will be unnecessary. One reverberatory furnace may be made to yield the metallic lead from the dressed ore at a single operation; but in some works the calcining of the ore and the subsequent reduction of the metal are conducted separately in their respective furnaces.

The entire operation, according to the first plan, is accomplished in 4½ to 5 hours. The hearth of the furnace is made to slope down from each end and the back, to the centre of the front side, which part is connected by a pipe with a bason for the molten metal outside the furnace, similar to that used in the smelting of tin. The sole or hearth is made of old slag broken up, and heated sufficiently to enable it to be beaten down into a solid mass. The ore is supplied through a hopper in the roof, and there are usually three working doors on each side of the furnace through which the furnace-man and his attendant work the charge.

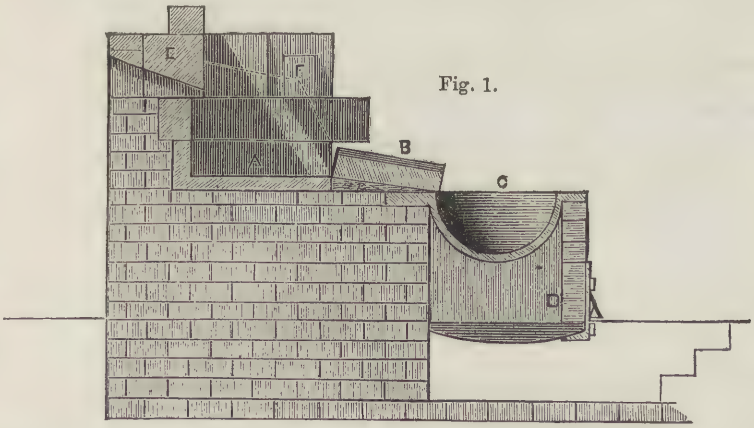

Fig. 1.

The temperature of the furnace is only moderate when the charge, say 20 cwt., of ore is introduced through the hopper. The assistant immediately spreads it evenly with his rake over the hearth. Then the furnace-man skims off the slags resulting from the previous charge, which overlie the lead in the bason outside, and throws them into the furnace by the working door furthest removed from the fire. The metal from these slags soon runs down and flows through the pipe into the bason. A second skimming takes place, and the slag is thrown into the furnace as before. While the assistant at the back is attending to the present charge, the furnace-man ladles the lead from the preceding one out of the bason and pours it into the pig-moulds. At the end of two hours, during which time the temperature of the furnace has always been kept at only a dull red heat, and a plentiful supply of air has been admitted by the working doors, the roasting or calcination of the ore is complete, and the second process, or smelting, begins. In this the fire is increased and the doors closed, so that in half an hour the furnace will be got up to a bright red heat, and the lead will be found flowing down towards the middle. The slags are then raked up to the ends and spread out, and some quicklime is thrown in upon the lead. The charge is then well worked by both the smelter and his assistant for about half an hour. The furnace is next allowed to cool down a little, after which the process just described is repeated twice, the temperature each time being raised rather higher than on the preceding. The tap-hole is then pierced, and the lead is allowed to run out into the bason. The slag which remains behind upon the sole of the furnace is poorer in quality than that which flows with the lead into the bason, and is raked out by the assistant and put on one side for subsequent treatment by a separate process.

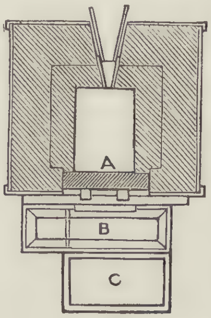

Fig. 3.

The result will probably be about 15 to 16 cwt. of metal, as it is usual at most works to mix the rich and poor ores together, so as to make a fair average quality of material. This plan has not only the advantage of rendering the working of the furnace regular, but the poor ores serve as a flux to the richer, and so render the use of an artificial one unnecessary. From 1 to 2 cwt. of lime is used to make the slags drier or less fusible, and the coal consumed for each charge will be about 10 cwt.

During the calcination the free admission of air causes the partial oxidation of the sulphide, so that the contents of the furnace at the close of that stage of the process will more or less closely agree with one or other of the formulæ given above, and contain all the elements for the double decomposition represented in those equations.

In Cornwall and some other parts, the calciner and the flowing furnace are separate. They are both made on the reverberatory principle. The sole of the former is flat, and there is no special feature connected with it to call for particular remark. That of the flowing furnace is hollowed towards the part opposite the channel through which the lead flows into the bason. The rich and poor ores are mixed together prior to calcination, so as to yield a mixture containing from 65 to 70 per cent. of metal. The roasting then proceeds gradually for about eighteen hours; the charge is raked over every hour, and a little lime is added from time to time to prevent the ore from clotting. The calcined ore is spread evenly over the hearth of the flowing furnace, and then the doors are closed and the heat got up for two or three hours, by which time the furnace will be ready to be tapped. This having been done, some lime is then thrown over the slag, and a little scrap iron introduced; the furnace-doors are again closed, and the temperature raised still higher. At the second running the lead will be succeeded by a regulus, which is usually tolerably rich in copper, and is sold to the smelters of that metal; the slag is then allowed to run into a pit at the side, and is so free from metal as not to be worth further manipulation.

The "ore hearth" is of quite another construction, and the principal fuel consumed in it is peat. Hence its suitability for the northern parts of the kingdom, where peat is the cheapest fuel. The construction of this (which is sometimes also called the Scotch furnace) may be understood from the accompanying diagram (Fig. 1), which represents a section from back to front merely of the working part. Above the upper line is carried a hood for collecting the heated fumes, and the flues by which they are carried off to the condensing chambers. The hearth-bottom itself is represented by A, the work-stone by B, in the centre of which is a groove for carrying any lead which flows over into the bason C. This last is kept warm by a small fire at D; E is called the pipe-stone, as it contains the funnel-shaped aperture which holds the twyer; and F the forestone, which extends across the front of the furnace, and which can be raised somewhat if a full charge should be worked, in which case the contents will reach as high as the dotted line.

In most cases it is found desirable to calcine the ores before reducing them by this process, though some qualities may work very well without this preliminary operation. A smelting shift, as it is termed, lasts from twelve to fifteen hours, and is worked by two men. When the ore-hearth is ready for work, the hearth-bottom A is already full of melted lead and brouse, the latter being the local name applied to a mixture of half-reduced ore and slag. A little coal is first sprinkled over the surface, and then the peat is built up in the form indicated by the dotted line; some peats already ignited are placed in front of the nozzle of the twyer, and the blast is immediately turned on. When the whole of the fuel is properly ignited, some brouse is thrown in on the top behind the fore-stone F. As soon as the lead begins to flow, the workman thrusts his poker into the hearth-bottom and stirs it up, which causes some of the contents to fall upon the workstone; any grey slag that may be mixed with it is separated and put on one side for future treatment, and the brouse (which has become further oxidised during its short exposure to the air while on the work-stone) is shovelled up and returned to the hearth along with some fresh ore. At each stirring of the contents, which is now repeated every five minutes, the assistant places a fresh peat in front of the twyer, and re-arranges the rest, so that the blast may be evenly distributed throughout. When the receiving-pot is sufficiently full of lead, the one man keeps the surface skimmed while the other ladles the lead out into the pig-moulds. The metal produced by this process is usually very pure, as the temperature employed is too low to reduce any of the other metals there may be in the ore, except the silver, which always comes over with the lead.

Whether the reverberatory or the blast furnace be used, it will be seen from the foregoing descriptions that there are certain slags, the grey or furnace slags, which are put on one side to be treated separately. These consist principally of the oxide of lead with occasionally a little both of the sulphate and sulphide, and a large proportion of earthy ingredients, such as silica, baryta, lime, etc. When a sufficient quantity of these slags have been accumulated they are reduced in another kind of blast-furnace called the slag-hearth.

Figs. 2 and 3 will give the elevation in section, and a horizontal plan of this furnace on the level of the twyer. The construction of it will be very readily understood from the drawings. The slags which have to be reduced in this hearth seldom contain so much as 35 per cent. of lead, and are altogether more refractory in their composition, so that a much greater heat is required; and a mixture of coke and peat is selected as the fuel in the north of England.

About one and a-half to two hours are employed in getting the furnace up to a sufficient temperature, when the grey slag mixed with a little brouse is thrown in. After a sufficient time has elapsed to admit of the lead having begun to separate, the furnace-man makes a hole with a pointed iron rod in the clay stopping immediately below the fore-stone A, and the slag then runs out over the lead through B into the slag-pit C. The lead trough, it will be seen, is divided into two compartments, which communicate with one another by a little hole at the bottom of the iron plate which separates them. The larger compartment is filled up with spongy cinders, which act as a filter, the lead percolating through them and passing on to the smaller compartment, while the slag flows on to C. At the close of the operation, the clay stopping is all removed, and the imperfectly reduced slag remaining on the floor of the hearth (which is called slag-hearth brouse) is raked out and put on one side for use in the next shift. Slag lead is rarely so pure in quality as the metal yielded by the regular processes, as it is necessary to employ a temperature which will reduce the iron and other metals that may be in the slags.

In the foregoing descriptions we have purposely omitted all reference to the arrangements for the collection of the fumes arising from the expulsion of the sulphur, and more particularly from the partial volatilisation of the lead itself. It will be remembered from the description given of copper smelting (Article XX.), that the sulphurous acid evolved is destructive to all vegetation; but beyond this the lead salts are all highly poisonous, and if they were allowed to escape into the air from a short chimney, the water and all the herbage and plants around would become so affected by them as to be unfit either for human or animal food. A large quantity of lead would in such case also be irrecoverably lost. The arrangements for the collection of this lead must be reserved for another article.

BUILDERS' QUANTITIES AND MEASUREMENTS.—XVI.

BY E. WYNDHAM TARN, M.A.

We now resume the dimensions of work done by the plumber, zinc-worker, gas-fitter, glazier, painter and decorator, and paper-hanger commenced in our last paper.

GLAZIER.

4)	4 8 3 4	62 3	Glazing with 2nds crown, in squares 14″ × 10″.
2)	6 0 3 0	36 0	Ditto best, ditto, ditto, 18″ × 12″.
	6 6 3 0	19 6	Ditto best British sheet, ditto 39″ × 18″.
	6 6 3 0	19 6	Polishing ditto.
	7 0 10 6	73 6	Glazing with best Brit. plate, in sqrs. 7 ft. × 3 ft. 6, ½ in. thick.
	4 0 2 6	10 0	Ditto, ditto, in sqrs. 48″×15″.
	7 0 3 6	24 6	Extra bendg. plate glass.
	4 6 3 0	13 6	Glazg. with rough plate, in sqrs. 27″ × 18″.
6)	8 0 2 0	96 0	Glazing in lead quarries, with tinted cathedral, copper ties, and cementg. into stonewrk.
	3 0 2 0	6 0	Hacking out old glass.

No. 8 doz. sqrs. cleaned.
„ 4 glass tiles, 20″ × 10″.

PAINTER AND DECORATOR.

12)	6 8 3 6	280 0	Knottg. primg., and 4 oils.
4)	6 8 3 6	93 4	Grd. wainscot and 2ce. varnd.
	7 0 5 0	35 0	4 oils skylight.

2)	48 0 9 0	864 0	4 oils and flat to plaster, find. ash green.
2)	15 0 2 6	75 0	3 oils to balusters.
5)	48 0	240 0	4 oils skirting.
2)	48 0	96 0	Skirtg. grd. w., and 2ce. varnd.
	34 0	34 0	3 oils cuttg. to stairs for carpets.
	40 0	40 0	4 oils staff bead.
	16 0	16 0	2 oils edge of shelf.
2)	15 0	30 0	3 oils strings.

No. 4 sash frames 4 oils b. s., 6 ft. by 4 ft.

Having completed the series of imaginary dimensions for the plumber's work, etc. etc., we now proceed to form an abstract of them as before. This abstract might have been disposed across the page, so as to exhibit the whole of the work required in the different branches specified, in one table. For convenience' sake, however, it has been found advisable to present the work of the plumber, zinc-fitter, gas-fitter, and glazier in one abstract, and that of the painter and paperhanger in another.

NOTABLE INVENTIONS AND INVENTORS.

XXX.—ISAMBARD KINGDOM BRUNEL.

BY JOHN TIMBS.

This great and original engineer was the only son of Sir Isambard Mark Brunel, and was born at Portsmouth in 1806. As Normandy was the birthplace of both his parents (his mother being a Miss Kingdom, of Rouen), his choice of a school, the college of Henri Quatre, is reasonably explained. He was, as it were, born an engineer, and those who recollect him as a boy will remember how rapidly, almost instinctively, he entered into and identified himself with the plans and pursuits of his father. The son was very early remarkable for his power of mental calculation, and for his rapidity and accuracy as a draughtsman. Nor was this power confined to mechanical drawing, for he thus early evinced a love of art and artistic feeling which characterised him through life. His father watched these early indications, and his education was directed to qualify him for the profession in which he afterwards became distinguished. At the age of fourteen he was placed under the care of Mr. Masson, before he entered the college at Caen, where he remained two years. He there completed a sound, practical education, and learned to observe and investigate facts, to generalise them, and from such inductions to deduce sound rules for practical conduct.

From Caen Brunel returned to England, and commenced his professional career as his father's assistant in the Thames Tunnel works. The energy and ability he displayed in mastering the physical difficulties in this great scientific struggle are duly chronicled in its records; and it has been shown that at this time the anxiety and fatigue he underwent, and an accident he met with, led to future weakness and illness. In one of the irruptions the rush of the water carried him up the shaft. In his descent in a diving-bell to examine the breach made by the irruption the bell was lowered about thirty feet, to the mouth of the opening; but the breach was too narrow to allow it to go lower, that the shield and other works, which lay eight or ten feet deeper, might be examined from the bell. Mr. Brunel, therefore, took hold of the rope, and dived below the bell for the purpose. After he had remained under water about two minutes, his companion in the bell became alarmed, and gave a signal which caused Brunel to rise, when he was surprised to find how much time had elapsed—a circumstance accounted for by the condensation of the air in the bell, from which his lungs were supplied by the pressure of a column of water nearly thirty feet high, which would condense the air into nearly one-half of its usual bulk. Upon a similarly trying occasion Brunel, being an expert swimmer, saved the lives of several workmen at the risk of his own. He was welcomed with a hearty and respectful cheer by the workmen, who crowded round him and wept like children as they affectionately grasped his hand; and the wives of the men he had saved fell on their knees before him, imploring blessings upon him; others cut little pieces from his coat, which they long treasured as relics.

Brunel at an early age possessed the advantage of being able to express or draw clearly and accurately whatever he had matured in his own trained mind. He could also work out with his own hands, if he pleased, the models of his own designs, whether in wood or iron. As a mere workman he would have excelled. Even at this period steam navigation occupied his mind, for he made the model of a boat, and worked it with locomotive contrivances of his own. Everything he did with all his might and strength; and the same energy, thoughtfulness, and accuracy, the same thorough conception and mastery of whatever he undertook, distinguished him in all minor things. ("Stories of Inventors and Discoverers," 1860.)

After the suspension of the Thames Tunnel works, Mr. Brunel became employed on his own account at various works. At Bristol and Sunderland he constructed docks, and he designed a suspension bridge across the Avon at Clifton. When a railway was contemplated between London and Bristol, and a company formed, Brunel was appointed their engineer; and curious it is to read the report of a lecture delivered at Bristol, in the year 1833, by John Britton, the antiquary, upon this means for reviving "the commerce of the west." Brunel's earliest works were on the Bristol and Gloucestershire, the Merthyr and Cardiff, and several colliery tramways, when his mind was first turned to the construction of railways. He was appointed engineer of the Great Western Railway Company, being then only about twenty-eight years of age, but skilful and ingenious, and anxious to strike out an entirely new course of railway engineering. From the great proportion of passenger traffic expected it was proposed to travel at a higher speed upon this line than had been attained upon any other railway. With this view the permanent way was to be peculiarly laid, principally in fixing the gauge at seven feet, a much greater width than had hitherto been adopted, and by which greater steadiness could be ensured than otherwise was consistent with high speed. "The directors seem early to have had misgivings as to the expediency of the change introduced by their engineer; and in 1838, while the line was still under construction, they invited several engineers of eminence to advise with them on the subject. Robert Stephenson and James Walker declined to do so; but Nicholas Wood and John Hawkshaw consented. Both sent in reports which concurred in recommending the adoption of the *narrow* or established gauge, in place of the *broad* or exceptional

one. Mr. Hawkshaw clearly pointed out that the existing gauge had originated in experience, and that the men whose practical knowledge of railways had been greatest saw the least occasion for its alteration; that three-fourths of England was being traversed by the narrow gauge, and it would be a great evil if the Great Western district were to be isolated from all the great lines in its neighbourhood; that nothing was to be gained by increasing the width of the gauge, while much might be lost by the unnecessary expenditure of capital in the first place, and by driving traffic in other directions in the next; and under these circumstances he strongly urged that, as only twenty-two miles of the railway had been laid down at the date of his report, that portion should forthwith be converted into narrow gauge, and the remainder executed of the same width. Mr. Hawkshaw's recommendations were of no avail. Mr. Brunel, Mr. Babbage, and Mr. Russell Gurney opposed their adoption by the company: genius, science, and eloquence carried the day. Mr. Brunel assured the shareholders that the broad gauge was the best gauge, and that the Great Western 'could have no connection with any other of the main lines of railway.' On a division the shareholders endorsed the recommendations of their engineer, and the controversy was for a time put an end to by the completion of the Great Western as a broad-gauge railway, which was so novel that it was called the Grand Experimental Railway; while it rendered Brunel famous as a railway engineer.

"Years passed, and railways of a different gauge met Mr. Brunel's line at many points. Mr. Brunel himself was the engineer of various lines of narrow gauge, thereby admitting its practical sufficiency for railway traffic. The *break of gauge* eventually came to be viewed in the light of a public calamity. The intervention of Parliament was even called for, and a Royal Commission was appointed to take evidence and report on the subject, which they did in 1846. But it was too late to remedy the evil. While an actual saving of capital would have been effected by the adoption of Mr. Hawkshaw's recommendation eight years before, it was now found that the alteration of the Great Western lines from the broad to the narrow gauge would cost upwards of a million sterling. How was this amount to be raised? By the shareholders, or by the public? The question was, indeed, felt to be surrounded with difficulty; and all that the commission did was to recommend the future restriction of the broad gauge lines to their own district. Since that time something has been done to remedy the original evil: the mixed gauge—that is, the narrow gauge with the broad—has been adopted, and gradually extended."

Among the Great Western constructions are the viaduct at Hanwell; the Maidenhead Bridge, which has the flattest arch ever attempted in brickwork; and the Box Tunnel, which at the date of its construction was the longest in the world. The excavation through the solid rock of the latter was satisfactorily accomplished under the direction of Mr. Brunel. This tunnel, which is ventilated by six shafts, varying from 70 to 300 feet in depth, is 3,173 yards in length. It pierces through Box Hill, between Chippenham and Bath, part of which is 400 feet above the level of the railway. The number of bricks used in its construction was 50,000,000; a ton of gunpowder and a ton of candles were consumed every week for two years and a half; and 1,000 men and 250 horses were kept constantly employed.

The tubular bridge over the Tamar, together with the similar bridge over the Wye, the "bowstring girder bridge" at Chepstow, are imposing monuments of Mr. Brunel's boldness and skill. The principle upon which these bridges were planned has been much criticised, but the works executed undoubtedly possess great strength and durability. The foundations of these bridges, under the customary modes adopted with such works, would have been extremely difficult of execution; but Mr. Brunel's ready appreciation of the merits of new discoveries enabled him to take full advantage of the pneumatic process, by a modification of which he established the foundation of the principal pier of the Saltash Bridge, at a depth of water and soft mud at which no works of the kind had been previously founded. It consists of nineteen spans, seventeen wider than the widest arches of old Westminster Bridge; while the other two, resting on a cast-iron pier of four columns, cross the whole stream of the Tamar, at a leap of upwards of 900 feet, or a greater distance than the breadth of the Thames at Westminster. The total length of the structure from end to end is 2,240 feet; its height from foundation to summit is 260 feet, or more than 50 feet higher than the London Monument. The main pier in the centre of the river, on which the great spans rest, has its foundation on solid rock, under some 70 feet of sea-water, with 20 feet of mud and concrete gravel. This was built on the coffer-dam principle. An immense wrought-iron cylinder of boiler plate, 100 feet high and 37 feet in diameter, and weighing upwards of 300 tons, was made and sunk exactly on the spot whence the masonry was to rise; then the water was pumped out and the air forced in; the men descended, and, working as in a gigantic diving-bell at the bottom of the river, cleared out the mud and gravel, until the rock was reached and hewn into form to support the cylinder evenly all round. Powerful steam air-pumps were necessary to keep the labourers supplied below; and they worked at an atmospheric pressure of upwards of 35 lbs. to the inch. On this massive pile, built in the cylinder, the iron columns for the centre pier are raised. Until these ponderous masses were cast, metal works of such dimensions were seldom dreamt of. There are four octagonal columns 10 feet in diameter, 100 feet high, and 150 tons weight. These columns stand 10 feet apart from each other, in the centre of the granite, and are bound together with a massive lattice-work of wrought iron. The great spans, each of which has one end resting on two of these columns, are made on the principle of a double bow; the lower one is of chains, carrying the roadway; the upper is a tube of wrought iron, to which the lower is attached by powerful supports. Thus, a great weight on the lower bow only tends to give additional support by strengthening the upper, and *vice versâ;* each, in fact, counteracts the effect of the other. Each arched tube is elliptical in form, and made throughout of inch boiler-plate, with inside wrought-iron diaphragms, with tie-rods and angle-irons. The pressure on the centre pier foundation is more than eight tons to the foot; the whole work involved six years' toil, anxiety, and peril. The Chepstow Bridge has a span of 306 feet, besides three side spans of 100 feet each.

TECHNICAL DRAWING.—LXXIII.

DRAWING FOR BRICKLAYERS.

In addition to the positions already mentioned, brick arches are also used under the following circumstances:—

When the whole or part of a front is to be covered with cement, straight arches are sometimes built rough in the following manner:—At the key or crown of the arch fragments of bricks are laid, cut to the form of the letter V. All the others are whole bricks, parallel sided, but diverging inwards in contrary directions, and cut at top and bottom only to the splay. This can scarcely be said to carry out the arch principle, and is not by any means to be recommended. Inverted arches are generally used in bad or doubtful foundations, and often even in good foundations, immediately under the apertures of the doors and windows. These may either be segmental, semi-circular, or parabolic.

In storehouses, stables, etc., where much light is not required, semi-circular openings are sometimes made arched at top, with a sill at the bottom.

In the basement storey of buildings small circular apertures, technically termed "bull's-eyes," are sometimes made, which are arched all round, so as to possess the properties both of common and inverted arches. These, however, seldom exceed three feet in diameter.

Rough arches are often used to support the flues of chimneys, whenever it is required to change the direction of those flues, in order that those belonging to distant fireplaces may be brought up in the same shaft at the top of the house.

Arches for coal-cellars, etc., are often built opposite to the basement storey of houses, beyond the area, so as to extend below the pavement of the street. These arches are commonly semi-circular, one brick thick, not exceeding nine feet in span, and having pier walls of one and a half or two bricks in thickness—that is, when there is a continued range of them; they being supported at the extreme ends by abutments of greater thickness when necessary.

In plan the pier walls of such arches usually serve to support horizontal arches, forming the extreme ends of the same vaults, which are thus enabled to resist the pressure of earth of the

street or external ground. Arches of this description may be seen in the side walls of the Metropolitan Railway.

DRAINS AND SEWERS.

The purpose of these lessons precludes our entering further into this subject than to describe some of the forms of drains used for carrying off sewerage, and our illustrations must necessarily be limited to such as are constructed of bricks to the exclusion of drain-pipes formed of earthenware.

From every water-pipe carrying off rain-water from the roof of a building, as well as from every sink and water-closet, a small drain leads into a greater one, the former of which is called a branch drain, whilst the latter is called the principal drain of the building. The latter likewise receives the water from all the areas, and also often from the grounds in the immediate vicinity of the building, which for this purpose is levelled at a gentle slope, and has surface-drains or gutters leading to iron gratings over the main drains by which the water descends after rain.

Branch drains when built of brickwork are of three kinds:—

1. Flat at the bottom, with perpendicular sides and arched at the top, like the section of a small gallery. This kind of drain is built of various sizes, from 9 to 24 inches wide. In the first, three courses of bricks would be employed, the walls and arch being $4\frac{1}{2}$ inches thick; in the latter the walls would, as a rule, consist of eight courses, the custom being to make the height to the springing correspond with the width. The arch, as explained in a former lesson, would be formed of two concentric rings, $4\frac{1}{2}$ inches each.

2. The barrel or circular drain. The smallest size used is 9 inches in diameter, which is built with a 4-inch arch. This size is considered sufficient for carrying off clean water.

Barrel, or, as they are sometimes called, gun-barrel drains, are the best in exposed situations, because of their strength; but as, unless by some special construction, there is no mode of cleaning them without breaking them up if they are too long to be raked, they should not be employed except with a considerable fall and a frequent or constant stream of water through them, as from a pump, trough, rain-water tank, etc. They are constructed on a barrelled centre, which the bricklayer drags on as he advances with his work, finishing as he goes.

In this, as in all small arched forms when built of the rough bricks, the joints must necessarily open very wide at the extrados or outer ring, for the reasons previously stated. Hence in the drains at the Ordnance Barracks at Chatham the bricks were ordered to be cut and gauged. When this is not done, pieces of broken bricks, tiles, etc., should be put between the bricks at the outer ends of the joints instead of using all cement or mortar.

In barrel drains of larger diameter, the circular arch is formed of several $4\frac{1}{2}$-inch concentric rings of brickwork. The slope of a drain for clean water may be from $1\frac{1}{2}$ to 2 inches in 10 feet: the slope for a drain carrying down other sewerage should be from 2 to 3 inches in 10 feet, where such a slope can be commanded. The barrel form is that generally adopted for small drains, for which there seems to be good reasons, as the circle is the most compact and strongest form, and gives greater velocity, or, as it is termed, a sharper run to the water than a flat-bottomed drain of the same width.

All sewers, in fact, which are intended to convey anything more than water should either be cylindrical, or be built with concave bottoms, although the sides be parallel and the covering horizontal. The concave channel keeps the stream more together, and better enables it to carry its impurities along with it; whereas a flat-bottomed drain offers a large surface for the particles of soil to attach themselves to; and further, the stream of water being more scattered is less efficient in force.

Drains, in places where it may be necessary to open them at any time, should be somewhat of the form of the letter U, semicircular at bottom, and raised for a few courses above the inverted arch; the whole being covered with a flat stone. The obvious advantage of this arrangement is that the drains may be opened and examined without materially deranging the work; whereas the small drains constructed wholly of brickwork cannot be thus examined without taking the upper part of the arch to pieces.

In all small drains, except those for clean water only, it is necessary to have cesspools considerably larger and some feet deeper than the drain or drains to which they belong.

These cesspools being covered by a stone or iron plate, or sometimes by a grating, receive the sand or earth washed down, and thus prevent the drains from being choked up; and when the cesspools themselves are nearly full, which should be ascertained by the persons in charge of the building, they must be emptied out by removing the stone or iron covering, which is replaced after the clearing is effected. Besides these cesspools, it is usual to form much smaller ones of a different description, usually termed "stink-traps," to prevent offensive smells from passing along the whole extent of a drain. They are made by forming part of the bottom of a drain at a lower level, so that water must necessarily stand in it at all times, although the body of the drain may be occasionally dry.

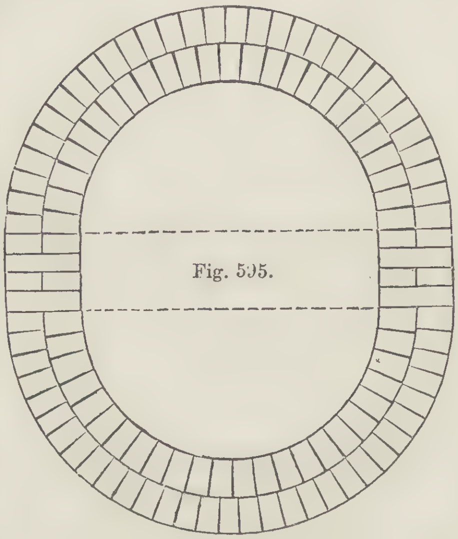

Fig. 595.

Into the little pool of water thus formed a vertical stone or plate of iron is fixed from above, the under part of which enters lower than the surface of the water. This arrangement, without impeding the regular course of water in the drain, which finds its level after entering beneath this stone or plate, prevents in a very great measure the passage of foul air.

These traps are now made of iron or earthenware, and should be well studied by the bricklayer, so that he may understand their action.

Care should be taken in arranging the small drains of a building that nothing but the clean water drains shall have any possible communication with the tanks or cisterns for receiving rain-water from the roofs when such are used.

When the principal drain of a building is within a few feet of the surface, it may be formed of bricks or earthenware pipes large enough to carry off with ease the greatest quantity of water that can come from the branch and surface drains.

This arrangement is not, however, always practicable. In every building having a basement storey it becomes a necessity that the bottom of the drain should be below the level of the area. In this case, but more especially where the drains pass under pavements, roads, walls, etc., which cannot conveniently be disturbed, it is proper to make them large enough for a man to go through and examine any part of it. Drains of this description are termed sewers or culverts, to distinguish them from the smaller kinds before described. The smallest sized opening in which a man can well move by stooping is one of $2\frac{1}{2}$ feet in width by $3\frac{1}{2}$ feet in height.

Such sewers may be elliptical in section, oval, or egg-shaped—*i.e.*, wider at top than bottom—or they may have vertical sides with semicircles or arcs at top and bottom.

Fig. 595 is a section of a drain of the kind last mentioned. In this example it will be seen that the walls of the drain are one brick in thickness, the upper and lower arches being formed of two $4\frac{1}{2}$-inch rings. These are formed of bricks laid on edge, and are not rubbed to the splay, which is not deemed necessary in arches of this character and span.

THE LATHE.—X.

By Henry Northcott.

LIGHT HAND-TOOL LATHES (*continued*).

Fig. 31 is another example of a light hand-tool lathe with slide-rest attached, as made by Messrs. Cunliffe and Croom, of Manchester. This lathe also is a good example of its kind, well and substantially made, and possessing one or two features that have not been yet illustrated in any of the lathes of which engravings have been given. The driving-shaft has outside cranks, which are connected to the treadle by chains. The shaft itself is turned throughout its length, and instead of being hung between the points of two centre-pointed screws with lock-nuts, or supported in solid bearings, it is arranged to run upon friction rollers. There are three of these small rollers at each bearing. Two of them are placed underneath the shaft to form the proper bearing, and the third is placed over the shaft to keep it in place and prevent it rising. The bearings of the shaft are thus formed by six of these rollers or pulleys, and these pulleys are caused to rotate slowly by frictional contact with the shaft when the latter is put in motion. The object of this arrangement is the reduction of friction. By it and the use of chains—which also have a rolling motion—the crank-shaft may be rotated with great ease. When the inertia of the heavy fly-pulley is overcome, and the shaft put into rapid rotation, the rotation will continue for a long time after the primary moving force of the foot has been withdrawn from the treadle-board.

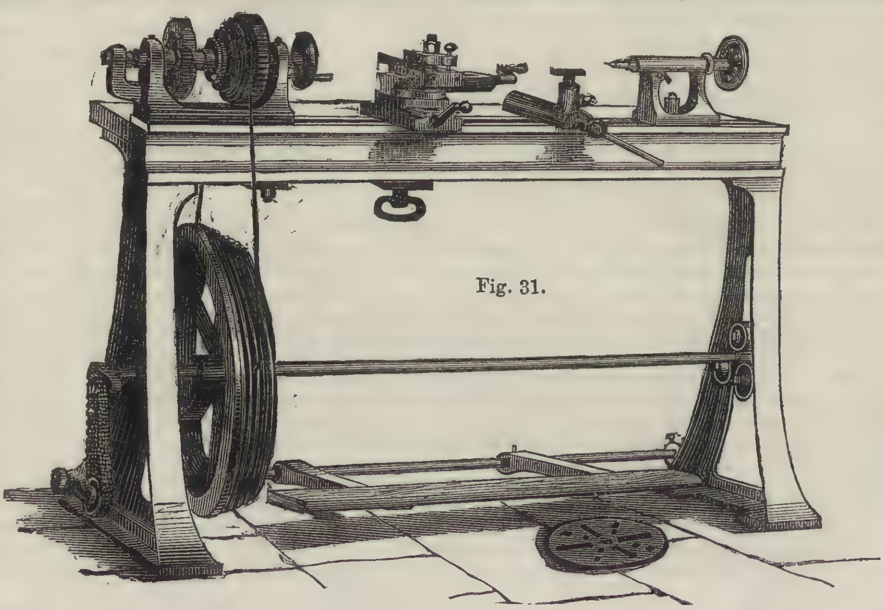

Fig. 31.

The slide-rest is of the same general construction as some of those already illustrated, and it is fastened down upon the lathe-bed in the same manner as in the previous examples—namely, by means of a bolt fastened to the bottom of the rest, and passing down between the slabs of the lathe-bed, with a suitably shaped hand-nut underneath. Generally the hand-tool rest is fastened down in the same manner, but in the present example another mode is adopted. It will be noticed that there is no handle underneath this hand-tool rest, but a lever is shown attached to a spindle projecting from the front of the rest. This spindle, after passing through a bearing formed by the metal of the rest, is made excentric, and the excentric portion goes through a circular eye upon the holding-down bolt. By raising the end of the lever shown in front, the centre of the excentric portion of the spindle is shifted downwards towards the bolt, which is thus loosened, so as to allow of the rest being moved along the lathe-bed. By forcing the end of the lever downwards, the centre of the excentric is raised, and the bolt is tightened up so as to fix the rest firmly upon the bed, as is necessary when the rest is to be used. This is a somewhat neater plan than the other, and it is occasionally applied to the shifting headstock also. Its chief advantage is its not interfering with the transverse ties, or stiffening pieces which generally connect the two slabs of the lathe-bed. In long beds these connecting webs are very necessary to keep the two slabs in position, and to stiffen them. The through-bolt with the handle underneath evidently interferes with the movement of the rest along the bed if the transverse ties are used. For short lathe-beds one kind of fastening is as convenient as the other, but the long bolt with the hand-nut under is evidently inadmissible in certain cases, whereas the short bolt and excentric can always be applied. It will not be necessary to describe any other lathes of this kind, as there is a very strong family likeness amongst them, although some details are differently worked out according to the fancy or opinion of the maker. Some have back-gearing, and some have not; some have outside cranks, and some have inside cranks; some are fitted with slide-rests, and some are not so fitted. But however the crank-shaft may be arranged, it should run easily and truly. All the power absorbed in driving the crank-shaft, lathe-spindle, and other mechanism is not only so much power exerted without producing any useful effect, but the power thus abstracted is actually employed in wearing out the lathe mechanism. It is very necessary, therefore, that every means should be taken to reduce friction, not only by correctly proportioning the bearing surfaces and fitting the lathe with proper lubricating apparatus, but by keeping them well oiled and free from dust, grit, and hardened oil. For the proportions of the lathe and means for lubrication the lathe-maker is responsible, but for the remainder the lathe-user is alone responsible. By using good oil, and not too much of it, and keeping the bearings clean, a good lathe will give satisfaction and continue in good order for a lifetime. But a careless turner may ruin his lathe in a few months. Turners should always bear in mind that all the force required, otherwise than to cut the material, is worse than wasted; and

that the physical exertion and fatigue corresponding to this, is being employed in destroying the lathe.

It is very advisable also that the rotating parts of a lathe should be accurately balanced, and this is especially the case with light lathes, which are driven at a high velocity. The driving-wheel is sometimes purposely made heavier on one side so as to overbalance the weight of the treadle and connecting gear, and prevent the crank stopping on the centres. In this case a greater evil is obviated than is introduced, as the driving-wheel does not run at a very great velocity. But the driving-arm of the dog-plate, or the connecting bolt for the double gearing, when unbalanced, will in fast-running lathes cause considerable vibration of the whole lathe, and render the production of good work a matter of impossibility.

Fig. 27 (Vol. III., p. 313) shows the kind of hand-lathe chiefly employed by engineers, and these are driven from overhead in the manner already explained. Sometimes, where many are used, they are mounted several upon one long iron bed, instead of on separate beds as in the figure. The counter-shafting is also placed in a line overhead, and the belt-shifting levers are generally brought down and connected with a long horizontal rod placed in front of the lathe-bed, so as to be within reach of the workman, wherever he may be standing at his work. In the early days of mechanical engineering all the work had to be turned in hand-lathes, and turning was often a very tiresome and laborious occupation. But now the hand-lathe is reduced to a very subordinate position in the workshop, being chiefly employed in preparing work for self-acting lathes, and in completing the shape of such odd and inaccessible corners as the self-acting lathes cannot so conveniently operate upon. The old school of millwright hand-turners is now very nearly extinct, but I have heard members of it say that those who attend to self-acting lathes are not turners at all, and even maintain that the work they produced in their youths was equal both in quality and quantity to that produced by the aid of the self-acting lathe. Neither of these statements will bear much investigation, but I have worked with and known hand-turners, not only in wood but in metals, who could run a self-acting turner a very close race in certain classes of light turning which are now almost exclusively executed in self-acting lathes.

The hand-lathe is adapted to plain turning in any material. The materials chiefly used are woods of various kinds, iron and brass, and not only does each of these substances require different tools and different treatment, but each material varies so much in texture and density as to require corresponding variation in the means employed in working it. Wood, for instance, may be obtained of very different densities. Some of it is readily indented, and may almost be cut by the finger-nail; other varieties are almost as hard and quite as difficult to turn as some of the metals. The tools suitable for cutting the softer varieties of woods would be greatly damaged if used upon some of the hard woods, and if the hard-wood turning tools were employed upon soft woods the result would be equally unsatisfactory, although in this case the tools would have the best of the encounter. Iron, again, if of good quality, is comparatively soft, and some varieties are so soft that they may be acted upon by tools which would produce a fair result even upon soft woods. Other sorts of iron are much less tractable, and cast iron requires quite different treatment to that suitable for soft wrought iron. Steel, if well annealed, is as soft and as easily turned as good wrought iron. If improperly annealed it may require much the same tools and treatment as cast iron, or it may be so intractable as to be a most difficult and unsatisfactory substance to deal with. Hardened steel, or steel that has been made red hot and suddenly cooled by immersion in cold water, is quite invulnerable so far as cutting is concerned, although it may be shaped by other means.

Brass also exhibits very similar properties. As a rule it may be turned in much the same way as good cast iron; but whereas soft brass may be ripped off with ease and rapidity, hard brass is very nearly as intractable as hardened or partially hardened steel. Ivory and some other materials of similar texture chiefly used for ornamental work are operated upon by tools of much the same character as some of the hard woods.

Copper, lead, and zinc are not much employed for turned articles. They are easily turned with the tools suitable for wrought iron, and require no very distinctive treatment.

The softer fibrous woods require very keen tools, with a cutting edge formed with a very acute angle. For the denser woods the angle must be much more obtuse, although the cutting edge should still be kept keen and well sharpened. As a general rule, the softer the material the more acute should be the angle of the cutting tool.

Then again, not only must the cutting tool be adapted to the nature of the material it is required to operate upon, but the speed of cutting must be similarly varied. The soft wood may be driven at a very high velocity whilst being turned, and within certain limits the faster the speed the smoother and more satisfactory does the tool cut. For iron and well-annealed steel the speed must be considerably reduced. The surface to be cut should not pass the tool's point at a much greater velocity than eighteen feet in a minute. Cast iron is usually driven somewhat slower than this, and brass and lead rather faster. The harder the material the slower must it be driven past the cutting tool. The operator soon gets to know how fast he can advantageously drive his work, as if the speed be too great his tools rapidly lose their cutting edge, and if the excessive speed be continued the temper of the tool is injured, owing to the great heat developed by the friction caused by the tool's rubbing against the work instead of cutting it. An experienced turner can tell at a glance whether the speed is correct for the material he wishes to cut, but the beginner requires to exercise a good deal of care if he wishes to keep his tools in proper order.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXXIII.—NICHOLAS COPERNICUS.

BY JAMES GRANT.

In Vol. II. of The Technical Educator it has been shown how Galileo, in the sixteenth century, was the first who taught physics to speak the language of truth and reason; but it was a little before his time that Nicholas Copernicus discovered the true system of the world, and invented that method of astronomy which still bears his name.

He was born on the 10th of January, 1472, in the quaint old town of Thorn (in Polish Prussia), which twenty years before had revolted against the tyranny of the Teutonic knights, and been incorporated with the kingdom of Poland. He was taught Latin and Greek at home, but afterwards was sent to Cracow, to study philosophy and physic at that famous old university which had been began by Casimir the Great, and finished by Udislaus Jagello. In his twenty-third year he set out for Italy. His genius had now turned to mathematics, which he studied in all its various branches; thus he stayed for a time in Bohemia for the sake of being with the celebrated astronomer, Dominicus Maria, whose society he cultivated, less as a learner, than as an assistant to him in making his observations. From Bohemia he proceeded to Rome, where he speedily won a reputation that was considered no way inferior to that of the famous Regiomontanus; and his name became so famous, that he was chosen professor of mathematics, which he taught for a long time with great applause, during the stormy period when Pope Alexander VI. occupied the chair of St. Peter.

In the year 1500 he made some important astronomical observations at Rome, and on returning to his own country he began to apply his vast knowledge in mathematics to correct the system of astronomy which then prevailed. He set himself to collect all the books which had been written by philosophers and astronomers—no easy objects of acquisition in the first years of the sixteenth century—and to examine all the various hypotheses they had invented for the solution of the celestial phenomena, seeking thereby if a more symmetrical order and constitution of the parts of the world could not be discovered. Of all the hypotheses of the ancients, none pleased him so well as the Pythagorean, which made the sun the centre of the system, with the earth and planets revolving round him in their own orbits.

Many of the ancients, he found, had maintained this idea; particularly Ecphantus, Seleucus, Aristarchus, Philolaus, Cleonthes Samius, Nicetas, Heraclides Ponticus, Plato, and, lastly, Pythagoras. Archimedes also, in his book of the number of the grains of sand, had maintained the Pythagorean system, but until the days of Nicholas Copernicus it was dropped and forgotten. After long and profound contemplation, and after

many calculations, the learned Pole removed some of the obscurities of the old system and improved it. These discoveries and improvements he embodied in a work on astronomy, the publication of which, knowing the perils that then surrounded those who dared to broach new opinions, he with great prudence suppressed, until he found a powerful lover of astronomy to protect him in the person of Pope Paul III., a learned, bountiful, and magnificent prelate—the same who boldly cited Henry VIII. of England to appear before the College of Cardinals, there "to answer for his adultery and other crimes."

In this system none of the celestial bodies shine with their own native light, save the sun; so that all the planets, both primary and secondary, are opaque bodies, that have no other light but that which they receive from the sun, and reflect back towards the earth and other planets. This is most evident from the moon; for only that side of her is observed to shine, which is directly opposed to the sun; while the other side which is turned from the sun is quite dark, except so far as it is illuminated by reflection from the earth. We see her, indeed, more or less illuminated in proportion as more or less of the surface on which the light of the sun is shed is turned towards the earth, as is evident on watching her through her various phases. Thus at the full she appears all illuminated, and at the change all dark. The same phenomena are observable in Venus and Mercury, which show all the phases of the moon, and sometimes appear like a black spot upon the luminous body of the sun. Mars likewise appears gibbous when near the quadratures of the sun. The satellites of Jupiter are eclipsed when they are behind his body, being then lost in his shadow; they likewise cast their shadows on the body of Jupiter. In Saturn the shadow of the ring upon his body proves his opacity; while the weakness of the light of those planets which are remote from the sun shows that it is not innate, but borrowed.

All the planetary bodies, Copernicus maintained, were nearly spherical, and that all of them had a rotation round their axis. These motions are found by means of certain spots upon their surfaces, which fix the time of their rotation. In some planets, from the absence of such indications, the times of their revolution have not yet been found. That they are spherical bodies appears from the slow motion of the spots near their edges, and their swifter motion near the middle. Likewise the line separating the illuminated part from the dark is always elliptical, which proves their form to be spherical.

Such was the system of Copernicus, who so fully revived that of Pythagoras, and thus inaugurated a new and important epoch in the history of astronomy, which we may justly reckon the most ancient science in the world, for Josephus tells us that Seth erected two pillars, one of stone and the other brick, whereon were graven the principles of that science.

In the dedication of his labours to Pope Paul III., Copernicus tells his holiness, that "he had suffered the fruit of his labours to ripen, not nine years only, but four times nine."

At length he committed the care of the impression to two friends named Schoner and Osiander in a distant city, where the work was printed in 1543, under the title of "De Revolutionibus Orbium Cœlestium," and the author, then residing at Frauenburg, a little town on the shores of the Haff, not far from Kœnigsberg, received a copy of it but a few hours before his death, which occurred on the 24th of May in the same year.

He resided in a house near the cathedral (of which he was a canon), and in the latter, a handsome building on a height overlooking the town and the Haff, he was buried; and there are still preserved, besides his tomb—a simple tablet bearing a globe—some curiosities and relics, such as crucifixes, and other things which belonged to him.

Within the enclosure of the cathedral is a well furnished with water by an aqueduct and hydraulic pumps constructed by him. The machinery of these pumps has, of course, long since disappeared; but a model of it is still preserved in the cathedral, and is supposed to have been imitated in the water-works at Marly. The tower which contained it stands near the cathedral, and is called the *Kunst Thurm.*

Besides supplying the Domberg (or cathedral hill) with water, he introduced it into the town of Frauenburg, by collecting from the neighbouring streams a current of water sufficient to turn a corn-mill, an advantage which its inhabitants did not previously enjoy. On the southern wall of the *Kunst Thurm* there is still traceable the following inscription to the memory of Copernicus:—

> "Hic patienter aquæ sursum properare coactæ,
> Ne careat sitiens incola montis ope.
> Quod Natura negat, tribuit Copernicus arte;
> Unum pro cunctis fama loquatur opus."

Few works that the world has seen have destroyed more riveted and deeply-rooted errors, or have established more important truths, than the great book of Copernicus. His noble theory, now so well known as the Copernican system, was at first coldly received, or utterly rejected; but the labours of future astronomers at length obtained for it complete triumph. Copernicus was also the first who demonstrated the double orbit of the moon—her menstrual motion about the earth, and her annual about the sun. Nor did this great man stop here; for after laying a solid foundation of the celestial physics, he began the superstructure, by surmising a principle of attraction to be inherent in all matter.

Copernicus also wrote a tract on trigonometry, and has also, as we have shown at Frauenburg, exhibited tokens of the versatility of his talents. He was very familiar with the Greek and Latin languages, and was acknowledged to have considerable skill as a painter.

In 1616, when Paul V. occupied the pontifical chair, seven inquisitors passed a decree at Rome, declaring that the opinions of Copernicus, as demonstrated by Galileo, were *not only heretical in faith, but absurd in philosophy.* "This sentence," says Voltaire, "against an opinion which has since been so variously confirmed, is a pregnant testimony of the force of prejudice. It should be a lesson to those who have nothing but power on their side, to be silent when philosophy speaks, and not to attempt to determine points which do not fall under their jurisdiction."

Galileo, as we have shown in his memoir, was condemned by the same severe tribunal to do penance in prison, and to retract on his bended knees! And it is a curious fact, and perhaps not generally known, that the Papal excommunication of Copernicus for publishing his "System of the Revolution of the Heavenly Bodies" was not revoked until 1821!

His name is still borne by an astronomical instrument invented by Whiston, to show the motion and phenomena of the planets, both primary and secondary. It is founded upon the Copernican system, and therefore is called by his name.

FARMING AND FARMING ECONOMY.—XV

By Professor WRIGHTSON, Royal Agricultural College, Cirencester.

BREEDS OF CATTLE (*continued*).

HEREFORDS—DEVONS—SUSSEX—LONG-HORNS—NORFOLK AND SUFFOLK—WELSH BREEDS—GALLOWAYS—ANGUS OR ABERDEEN—WEST HIGHLANDERS—AYRSHIRES—IRISH CATTLE.

To give a minute and graphic description of an animal is by no means easy, and in the remarks which follow we shall endeavour to give only a general idea as to the appearance, character, distribution, and history of the remaining races of British cattle.

Hereford Cattle are principally found in the south-west of England, and, according to the late Mr. H. H. Dixon, few counties south of Shropshire are without them. They are to be seen grazing on the rich marshes of the eastern counties, and have pushed their way into Surrey on the south-east, and Cornwall on the south-west. They are seldom seen in the north of England, and we only know of two herds in Scotland. They have met with supporters in Ireland, and a considerable export trade exists in breeding animals to Jamaica, Canada, the United States of America, and Australia. Although four varieties of Hereford cattle are described—the red with white faces, the red with mottled faces, the light greys, and the dark greys—the first is the most ordinary type. They are all large and imposing in appearance, and are of a fine red colour, broken with white upon the breast, face, mane, ridge of back, end of tail, and occasionally on the feet. Their fattening propensity at mature age is quite equal to that of Short-horns. Doubt has, however, often been thrown upon their flesh-producing powers at from two to three years old. That this is founded on fact is, however, questionable. But in order to throw light upon an important question, we abstract the following table from the *Agricultural Gazette* of December 17th, 1870,

where not only the average weight and ages of Short-horns and Herefords are given as obtained at the Islington show of that year, but also the average weights of Devon and Sussex cattle. The result obtained by the scales was as follows for oxen :—

OXEN.	No. of Class.	Average Age.		Average Live Weight.		
		yrs.	mths.	cwt.	qrs.	lbs.
Devons	7	2	4	10	0	20
Herefords ...	6	2	4½	14	1	13
Short-horns ...	4	2	4	15	3	0
Devons	8	3	2	13	2	22
Herefords ...	4	3	0	15	3	1
Short-horns ...	5	2	11¾	17	0	18
Sussex	4	2	9	15	0	6
Devons	8	4	1¼	16	0	26
Herefords ...	13	4	0¼	19	2	23
Short-horns ...	9	3	10½	18	3	10
Sussex	7	3	10¼	19	0	12

Lord Scudamore, who died in 1671, is recorded as having introduced red cows with white faces from Flanders, and from these, the calf in question, as well as others—for we can hardly give credit to the assertion that all the "white faces" are descendants of one bull—may have derived their colours. The Herefords, like the Short-horns, have a history. Their improvement was due to the labours of the Messrs. Tomkins, Weyman, Yeoman, Tully, and Hewer, from about the year 1766. Since then the breed has been carefully kept up, and the pedigrees of pure-bred animals have been preserved in a Herd Book commenced in 1845 by Mr. Eyton, and continued since 1857 by Mr. Duckham, of Baysham Court, Ross.

The *Devon Cattle* form a well-defined race of uniform red colour, and of smaller size than Short-horns or Herefords. They are supposed by competent naturalists to be nearly allied to the modern type of *Bos primigenius*, seen in Chillingham Park, and therefore claim a direct descent from the ancient bovine inhabitants of the British forest. The breed is divided into the smaller and more symmetrical, mossy-coated, North Devon, and the larger, straight-haired cattle of the fertile vale of Taunton Deane. The breed has not extended widely in this

AYRSHIRE COW.

while the comparison of the cows by weighing presented these adjoined results :—

Cows.	No. of Class.	Average Age.		Average Live Weight.		
		yrs.	mths.	cwt.	qrs.	lbs.
Devons ...	4	3	1¾	13	3	14
Herefords ...	5	3	4½	14	0	8
Short-horns ...	10	3	1¾	16	0	12
Sussex... ...	8	3	5	14	3	0
Devons ...	4	6	11¾	12	1	19
Herefords ...	6	6	6	16	2	5
Short-horns ...	6	7	8½	18	1	23
Sussex... ...	4	6	4	15	2	24

Mr. Duckham, editor of the "Hereford Herd Book," contests for the superiority of his favourite breed, and informs us through the columns of the before-named paper (May 21st, 1870) that at the Christmas meeting, 1868, the average weight of the Hereford steers not exceeding 2 years 6 months old was 10 st. 3 lbs. more than that of the Short-horns; whilst in the class not exceeding 3 years and 3 months old he is compelled to admit that the Short-horns exceeded the Herefords by an average of 5 stones (14 lbs. to the stone).

The beef of Hereford cattle is of fine marbled appearance, and of excellent quality, but the cows are poor milkers. The race is said to have been of uniform reddish-brown colour until the appearance of a white-faced bull calf about the middle of last century, from which the present Herefords are descended.

country, and is for the most part in the hands of a less wealthy class of men than the short-horn. Captain Tanner Davy, their historian, and the editor of the "Devon Herd Book," however, assures us that they have found a home in many counties of the United Kingdom, as well as in Mexico, Jamaica, Canada, Australia, France, and the United States. The general colour of the Devon cattle is red broken with white upon or near the udder only. The skin is of an orange-yellow colour, as is seen around the eyes and inside the ears. The horns are of medium length, and of fine waxy colour. The general form is light and graceful, but scarcely so good in the posterior as in the anterior portion of the body. The cows are famous rather for the richness than for the abundance of their milk. The Devon oxen are better adapted for the yoke than any other British race, and a pair of bullocks will plough in double harness, as the writer has himself seen. The *Sussex* cattle are very nearly allied to the Devons. They are stronger and coarser in head and horn, and larger in frame, but in all other points are identical with the Devons.

The *Long-horns* are chiefly interesting as a race which, after having been improved by the breeder's art, and introduced as the leading breed into almost every English county, has succumbed to a powerful rival whose very name appears to have been coined in a spirit of opposition—the Short-horn. These cattle originally were found by Bakewell in the fertile vale of Craven, in the West Riding of Yorkshire and eastern portion of Lancashire. Mr. Welby and Mr. Webster, of Canley, both obtained their stocks from Sir Thomas Gresley, of Drakelow

House, and this strain of blood subsequently came into the hands of the famous Leicestershire breeder, who, keeping in view the importance of beauty and utility of form, muscular development, and fattening qualities, brought out the new Leicesters, which soon became the favourite cattle of their day. They are thus described by Youatt. The fore-end long and light almost to elegance; neck thin; chap, or under side of jaw, clean; the head long, fine, and tapering. Horns varying according to sex; in the bull from fifteen to twenty-four inches, and in the cow and steer from thirty to forty-two inches in length; the horns turning down almost parallel with the cheeks, and in some cases turning inwards so as to require cutting, to prevent them from piercing the face of the animal. The colour, white along the back, and brindled brown and black on the sides. The Long-horns were imported into Ireland by Lord Massereene, the Marquis of Donegal, and Mr. Lesley, of Lesley Hill, and did much to improve and modify the native breeds of cattle there. They were also naturalised in Anglesea, where their descendants, still preserving the most characteristic traits of the breed, are yet to be found. Long-horns are still to be seen in the Midlands, and we may especially mention Mr. Chapman's herd at Upton, Warwickshire, as preserving the blood of the renowned bull "Twopenny."

Norfolk and Suffolk possess an excellent breed of polled, red cattle, supposed to have been derived from the polled Galloway cattle which have for long been favourites with the eastern counties' graziers. These animals are of uniform red colour, and are excellent milkers.

HEREFORD COW.

WEST HIGHLAND COW.

WELSH CATTLE.

Pembrokes.—These cattle are closely allied to the aboriginal cattle of this country; the White Forest breed, by mere change of colour, becoming similar to the modern Pembrokes (*Lowe*). The colour is black, broken upon and about the udder with white; the horns are fine, tapering, turned up at the points, and tipped with black; the skin is of a deep orange colour, sometimes approaching to black, as is seen on the naked portions of the body. The Pembroke may be looked upon as the type of all the mountain breeds of Wales, although he often appears as an unimproved and inferior type.

The Glamorgans have been crossed with the Herefords, to

which they now bear a strong resemblance. The cattle of Anglesea retain the appearance of the Long-horn, with which they were crossed during the dominance of that race.

SCOTCH BREEDS OF CATTLE.

Scotland is rich in native races, many of which are very distinctive. Among them one of the most important is the *Galloway* breed, named after a district which forms the termination of a range of hills stretching from St. Abb's Head, on the east coast, to the North Irish Channel. It comprises Wigton and Kirkcudbright, and a portion of Ayr and Dumfries.

The Galloway cattle are black and hornless (polled), and on account of this last-named peculiarity, as well as their fattening properties, are great favourites with graziers, especially in Norfolk and Suffolk. The Galloway cattle are peculiar for a wonderful compactness of form, great length, uniform breadth from the shoulder to the rump, heavy well-fleshed thighs, and deep well-sprung ribs. They are not a large breed, but will often attain to heavy weights. Closely resembling the Galloway is the *polled* or *clodded Angus* or *black Aberdeenshire* race. They are higher on their legs, and altogether larger and somewhat less closely grown beasts than the last, with scarcely so much coat. They are black, occasionally broken with a little white near the udder; hornless; characterised by great length and great width across the shoulder-tops, continued backwards by well-sprung ribs, and good loins without prominent hook-bones. The hair is short and glossy, and the skin soft and thick. Such is a general description taken by the writer from prize animals exhibited last year at the Highland and Agricultural Society's Show at Perth.

The *West Highland Cattle* or *Kyloes* form a well-marked race occupying all the mountainous region after which they are named. They are small in size; have horns turning more or less upward at the points; short muscular limbs, and are thickly covered with hair. Their muzzle is usually black; the hair on the neck (mane) is long; their colour varies from mouse, or even silver grey, to reddish brown and black; they are hardier than any other race of British cattle, and their size varies according to the richness or poverty of the district in which they occur. The finest specimens are found in parts of Argyleshire and in some of the Hebrides, as in Skye.

Ayrshire Cattle are famous as dairy stock. Colonel Fullerton, in "The Husbandry of Ayrshire, 1793," says that Mr. Bruce, a gentleman of long experience, dates their origin to cows introduced by the Earl of Marchmont, who succeeded to his title in 1724, and died in 1740. The varied colour and other peculiarities point to the Holderness breed (the immediate progenitor of the improved short-horn) as probably the original stock which was crossed with the native breed, giving as the result the Ayrshires. These cattle are rather small in size, varying in colour from white with a little red, to red with a little white, and again from a fawn colour broken with white, to almost black and white.

The typical Ayrshire cow is formed for milk. Her long fine head and upturned horns are succeeded by a thin neck, no great depth of bosom, shoulder-tops and crops narrow, ribs well sprung, and great breadth over the hips. Again, looking at the broadside of the animal, the depth should gradually increase backwards towards the flanks, giving what is termed the wedge form. This is much insisted on by all Ayrshire breeders, and it signifies the gradual thickening of the animal from the set-on of the head, where the neck is light, to the base of the neck, the breast, the girth, and the still greater depth at the flank. This gradual deepening contrasts with the heavy fore-end of the short-horn, and indicates milking, rather than feeding properties. Milk is indeed their speciality. The cows will give five gallons per day for two or three months, three gallons for three months, and one and a-half gallons for four months. Mr. Aiton rates the annual yield of milk at 1,000 gallons, but Mr. Ranken considers from 700 to 850 gallons as rather more than an average cow will give.

IRISH CATTLE.

The droves of Irish cattle brought over to our fairs in such large numbers every year have rendered these hardy and useful animals familiar to the eyes of Englishmen. The late Professor Lowe says the native breeds of Irish cattle may be divided into those of the mountains, moors, and bogs, and those of the richer plains with intermixed breeds resulting from the union of different races. Among the most distinctive of these mountain cattle is the Kerry breed, good alike for milk and for beef. The *Kerry* cow, as figured in Professor Lowe's "Domestic Animals," is of a yellowish-red colour broken with white on the bosom, belly, and udder; the hair is abundant, and forms a tuft midway between the throat and dewlaps; the fore-quarters are light, and the whole frame of the animal indicates a disposition to produce milk rather than flesh; the neck is thin, the head fine and light; the horns white, tipped with black, and growing upwards. The Irish cattle have been modified by both the long-horn and the short-horn, and owing to the importation of the latter breed during late years, the general character of the Irish cattle has been much improved. Many pure-bred herds of short-horns also are to be found in Ireland, and this breed seems destined to spread over all the fertile portions of the country, as it has already done both in England and Scotland.

NOTABLE INVENTIONS AND INVENTORS.

XXXI.—ISAMBARD KINGDOM BRUNEL (*continued*).

BY JOHN TIMBS.

THE sea-wall of the South Devon Railway was another of Brunel's great works. On this line he adopted the plan which had been previously tried on the London and Croydon railway—namely, of propelling the carriages by atmospheric pressure; but this proved unsuccessful, and the loss exceeded half a million of money. Still, he entertained a strong opinion that this power would be found hereafter capable of adoption for locomotive purposes.

Next, Brunel devised an iron-plated armed war-ship, capable of withstanding the fire of the Sebastopol forts. It was in connection with the interests of the Great Western Railway that Brunel first conceived the building of a steam-ship to run between England and America. The vessel was built accordingly; its power and tonnage was about double that of the largest ship afloat at the time of her construction; it was propelled by paddle-wheels, and named the *Great Western*. Next, Brunel designed and built the *Great Britain* steam-ship, the result, as regards magnitude, of a few years' experience in iron ship-building, and more than double the tonnage of the *Great Western*. Brunel's foresight in extending the use of iron in the construction of ships was very remarkable. While others hesitated, he saw that it was the only material in which a very great increase of dimensions could be safely extended. The very accident which befell the *Great Britain* upon the rocks in Dundrum Bay showed the skill he had then attained in the adaptation of iron to the purposes of ship-building. The means taken, under Brunel's immediate direction, to protect the stupendous vessel from the injury of winds and waves attracted deserved attention, and they proved successful, for the vessel was again floated. Nor must it be forgotten that Mr. Brunel was the first man of eminence in his profession who perceived the capabilities of the screw as a propeller. From his experiments on a small scale in the *Archimedes* he saw his way clearly to the introduction of that method of propulsion which he afterwards adopted in the *Great Britain*. He next persuaded the Admiralty Board to give it a trial in Her Majesty's Navy, under his direction. He was much thwarted in this trial, but the *Rattler*, subsequently placed at his disposal, and fitted with engine and screw, by Maudslay and Field, was a complete success, and was the first screw-ship which the British Navy possessed.

Brunel built for the metropolis an elegant suspension bridge, from Hungerford Market to Belvidere Road, Lambeth—a fine specimen of mechanical skill. It consisted of two lofty brick piers or towers, in the Italian style, 58 feet above the road, and built in brickwork and cement, connected by inverted arches at the bottom, and built on the natural bed of the river, without piles. For the foundation of the abutments piles, 26 feet long, were driven in an inclined direction. In the upper part of these towers four chains passed over rollers, so as to equalise the strain; they carried the roadway seven feet higher than the crown of the centre arch of Waterloo Bridge, with single suspension rods, the chains being secured in tunnels at the abutments to iron girders, embedded in brickwork and cement.

There were three spans, the central one between the piers being 110 feet wider than the Menai Bridge, and second only to the span of the wire suspension bridge, which is 900 feet. Brunel's bridge was built without any scaffolding but a few ropes, consequently without impediment to the navigation of the river; the cost was £110,000. The bridge was taken down in 1863, and the chains were carried to Clifton for the suspension bridge erecting there. In November, 1843, the bridge was sold to the original proprietors for the sum of £226,000, but only the first instalment was paid, and the purchase was thus void. The height above the piers was 21½ feet. Thus was gained additional height for the river traffic and a graceful curve, with the appearance of swagging prevented.

During the Russian war Brunel fitted up the Renikoi hospital on the Dardanelles. He laid on a special supply of water from the adjacent hills, and constructed short lines of railway with easy carriages, to facilitate the removal of the wounded from the landing-place to the different wards.

In the year 1851, prepared by experience and much personal devotion to steam navigation, Mr. Brunel began to work out the idea he had long entertained, that to make long voyages economically and speedily by steam required the vessels to be large enough to carry the coal for the entire voyage, and unless the facilities for obtaining coal were very great at the outport, for the return voyage also; and that vessels much larger than any built could be navigated with great advantage from the mere effects of size. Hence originated the *Great Eastern.* "The mere idea of a ship of a capacity six or eight times that of anything afloat had doubtless occurred to many an enthusiastic schemer; but Mr. Brunel gave shape to his idea by preparing plans, and otherwise convincing himself of its practicability. As an example of naval construction the *Great Eastern* is, unquestionably, the work of Mr. Scott Russell; yet Mr. Brunel's services were hardly of less importance, and every one at all conversant with the organisation of an establishment devoted to the construction of steam-vessels is aware that the duties of the naval architect and builder and those of the engineer are each clearly defined, and in no way conflicting; and certain it is that Mr. Brunel's name will be indelibly associated with the *history* of the *Great Eastern,* as long as that shall survive."

The success of this stupendous work, in a practical point of view, is admitted, as well as the strength and stability of the construction of the vessel. The difficulties attendant on the launching of the ship in 1858 at one time seemed insurmountable. To a friend, who despondingly expressed his fears that the huge ship would never reach the water, Brunel quietly replied, "Oh, she shall move; she must!" He never for a moment despaired of success. His health, however, had long been impaired by over-exertion, and his death was hastened by the fatigue and mental strain caused by his efforts to superintend the completion of the great ship. By a coincidence, as it would appear, Mr. Brunel went on board the great ship for the last time on the day when it could be said she was ready for sea. If not so in every detail, she was, as a whole, essentially completed, although still untried. On that day, the 5th of September, Mr. Brunel was stricken down by paralysis, from which he never recovered. He sank until the evening of the 15th of September, when he passed away, still young, and upon the completion of the greatest work of his life.

In the Patents' Museum, South Kensington, is a model of the Leviathan Steamship, as it was first called, constructed on the wave principle and lines of Mr. Scott Russell, for the Eastern Steam Navigation Company. The following are the principal details:—Length, 680 feet; breadth, 83 feet; depth, 58 feet; tonnage, 23,000 tons; nominal horse-power of paddlewheel engines (Scott Russell and Co.), 1,000 horse-power; nominal horse-power of screw engines (Watt and Co.), 1,600 horse-power; draught of water (light), 18 feet; draught of water (laded), 28 feet.

Mr. Brunel died at his paternal house at Westminster. He was a Fellow of the Royal Society, having been elected at the early age of twenty-six. He was the President of the Institution of Civil Engineers, and Vice-President of the Society of Arts; a Fellow of the Astronomical, Geographical, and Geological Societies, and a Chevalier of the Legion of Honour. "He lived and died with a scientific reputation, bounded only by the limits of the civilised world. He has left too many monuments of himself, raised both on land and sea, to permit of his being soon forgotten."

In the *Quarterly Review* is the following estimate of Mr. Brunel's talents, which, it will be seen, differs from that of other authorities:—"Notwithstanding Mr. Brunel's great engineering skill, it is to be doubted whether he possessed much of the genius of an original inventor. He took up a principle already established, and pushed it farther, exhibiting in a striking light the development of which the ideas of others were capable. His ruling idea was magnitude: he had an ambition to make everything bigger than he had found it. Thus, he found the railway gauge 4 feet 8½ inches, and he increased it to 7 feet, thereby involving wider tunnels, more expensive works, and a heavier equipment in working stock. So in the atmospheric railway, he found the tube in use on the Dalkey Railway 15 inches in diameter, and on the South Devon line he doubled it. Then in steam-ships the *Great Western* was nearly double the power and tonnage of any previous steamer; the *Great Britain,* which followed, was double the tonnage of the *Great Western;* and the *Great Eastern* exceeded in size all that the most imaginative ship-builder had conceived to be possible. It was a race of bigness run against himself as well as others. But in the case of the *Great Eastern* steam-ship, as of the Great Western Railway, it is not probable that Mr. Brunel's example will be followed; for it is now pretty well understood that ships, like railways, may be *too big*—at least, for those who own them. Notwithstanding the want of success which attended Mr. Brunel's principal undertaking, he was well supported throughout by the moneyed interest. The shareholders in the Great Western Railway not only readily found the capital which he required to carry out his splendid ideas with reference to that line, but they presented him with a handsome testimonial in acknowledgment of his genius. Though the *Great Western* steam-ship proved commercially a failure, he had no difficulty in finding capitalists to enable him to build the *Great Britain* at a still greater sacrifice, and still again to project and bring to completion his magnificent idea of the *Great Eastern* steam-ship."

It may be interesting to abridge from the *Quarterly Review,* No. 223, already referred to, the following singular incidents of Mr. Brunel's personal history:—"He had more perilous escapes from violent death than fall to the lot of most men. He had two narrow escapes from drowning by the river suddenly bursting in on the Thames Tunnel works. During the Great Western Railway inspection he was one day riding a pony rapidly down Box Hill, when the animal stumbled and fell, pitching the engineer on his head. He was taken up for dead, but eventually recovered. One day, when driving an engine through the Box Tunnel, he discerned some light object standing on the same line of road along which his engine was travelling. He turned on the full steam, and dashed the object (a contractor's truck) into a thousand pieces. When on board the *Great Western* steam-ship he fell down a hatchway into the hold, and was nearly killed. But the most extraordinary accident which befell him was, in showing a sleight-of-hand to his children, his swallowing a half-sovereign, which dropped into his windpipe, remained there for six weeks, when it was removed through an incision in the windpipe by Sir Benjamin Brodie and Mr. S. Key; his body was inverted, and after a few coughs the coin dropped into his mouth. Mr. Brunel afterwards used to say, that the moment when he heard the gold piece strike against his upper front teeth was, perhaps, the most exquisite in his whole life."

SANITARY ENGINEERING.—XXIII.

ON THE CONSTRUCTION OF SEWERS AND SUBWAYS.

THE literature of sewer-building is so voluminous, extending to many volumes octavo in our public libraries, that anything approaching a complete analysis of the question is entirely beyond our limits. We shall content ourselves, therefore, in the present paper by stating a few general principles, and giving the details of the methods which are now generally adopted in some of the most important undertakings of the day. In our two preceding papers we dealt with house drainage (No. XXI.) and the ventilation of house drains (No. XXII.), and we now come to the next branch of our subject, *i.e.,* the commo

sewer—common as receiving the collected drainage of a street or district, and therefore common to all. The subject in itself is no new one, as it had received attention in early Roman times; and the remains of the Cloaca Maxima in Rome itself are still visible, a most excellent example of ancient masonry.

The question that first arises is as to the material to be employed. For small drains stone-ware pipes are now in universal use; but as these increase in size they increase in expense, and, except in special instances, are not to be obtained of a greater diameter than two feet, and the difficulty of manufacturing them to these dimensions renders brickwork the more economical material. There is also this point to be considered—that it is very desirable in extensive systems of sewerage that there should be a possibility of access from without throughout the sewer itself, so that in case of any obstruction, or failure in construction, it should be possible to get at it for removal or repair without opening the ground above or breaking up the course of the sewer itself. With a pipe-drain even of two feet diameter this is impossible, as the size must be sufficient to allow a man to pass, and we may take the minimum size as 3 feet 6 inches high by 2 feet 3 inches wide, the size now usually adopted by the Commissioners of Sewers of the City of London. We may take the opportunity here to thank Mr. Haywood, their engineer, for affording us this information of detail, and also for allowing us to publish the illustrations of the Holborn viaduct to which we shall presently refer. We may mention, as a matter of practice in the same district, that a 12-inch drain-pipe is now the largest size used; 15-inch pipes were used until quite lately, but their use has been discontinued.

We give in Fig. 53 a section of a form of sewer very generally used—showing the lower portion of the section as an "invert block"—specially burnt for the purpose in stone-ware, the upper portion being built of brickwork in cement. This section does not apply to any particular locality, but has been very generally used. The sketch shows the side entrance of a drain protected by a stone-ware trap to prevent flooding by storm-waters. The materials, of course, vary in different localities; we here only remark that they should be as much as possible non-absorbent. Soft, commonly called place bricks, should never be used, but the many recent improvements in the harder class of manufacture of late years place a large selection of materials at the command of the engineer. If possible, the internal surface of the sewer should be faced with glazed bricks, which are now readily obtainable in many parts of the country.

Fig. 54 represents a form of invert somewhat similar to the last, which was used in the sewers of the Holborn Valley district, to which we shall have occasion further to allude. A is the bottom surface of the sewer, C C is the stone-ware invert, B B B the brickwork; the whole laid upon the concrete foundation shown in the section.

A section of the form shown in Fig. 55 has been strongly advocated, and denominated self-flushing, as the lower channel, A, from its narrowness, is supposed to be more readily cleansed by the flow of water than the plain oval section, and it is probable that in dry districts which have not an abundant water-supply it may be adopted with advantage. Many other peculiarities of section are adopted by different engineers. We do not, however, further allude to these, but confine ourselves to authentic examples of sewers now extensively in use, and proceed to give a series of sections with which we have been furnished from the office of Mr. Bazalgette, the engineer to the Metropolitan Board, representing various sizes of sewers in daily course of construction in different parts of the London district; giving, also, calculated data as to size and quantity of material. These are shown in section in Figs. 56, 57, 58, 59, and 60; they run from No. 1, the largest, to No. 5, the smallest, and the quantities are expressed in decimals.

It may be as well to point out to any artisan who may be studying these papers, and who may require some instruction in the details of the mode of drawing the sections of these figures, that the intersection of the dotted lines meeting in an acute angle to the right or left of the diagram as the case may be, indicates the centre from which the arcs forming the sides of the sewer are to be struck. Further information will be found in "Technical Drawing" (page 15), where the entire operation of drawing the figure called an oval is fully and clearly explained.

The following gives the quantity of brickwork per foot-run in each of the sections of sewers, Nos. 1, 2, 3, 4, and 5, exhibited in Figs. 56, 57, 58, 59, and 60. The inverts of Nos. 1, 2, 3, 4, are in cement blocks; the sides in sound stocks in mortar in Old English bond. In No. 5 the bricks are all laid in cement, and the invert is a stoneware block. All of these sewers are bedded in concrete, as shown in the diagrams, up to the springing of the arch, unless the ground be sound and excavated to the exact form of the invert.

The particular size of sewer to be adopted in any particular locality must, of course, be determined by an infinite variety of circumstances, all of which are, however, a matter of calculation, and are readily ascertained by the experienced engineer.

We give in Fig. 61 (*a*, *b*, *c*), a section and plan of the side entrance to a sewer, published by the same authorities, showing how access may be obtained at any required points, and also in Fig. 62 (*a*, *b*, *c*) the details of a bell-mouth junction, which further elucidates the remarks we made in a previous paper on the junctions of drain-pipes, that these should never be made at right angles, but always in curves gradually coinciding with the sewer line in the direction of its current.

We may here point out that in the various sections of sewers shown concrete in certain proportions is provided. This is not in all cases necessary, and especially in the case of smaller sewers it may occasionally be dispensed with, when, however, the foundation is reliable—of good sound gravel or clay; but if the sewer has to pass through what is called "made ground"—*i.e.*, ground which has been disturbed and filled in again—a much larger concrete foundation should be provided than that shown in the sections; and we here remark that one of the most treacherous foundations is a piece of ground in which clay and gravel occur in alternate layers—a formation not uncommon in the neighbourhood of London, especially on the southern side. A bed of gravel, perhaps, on the side of a hill, intersected at intervals by narrow layers of clay, is apt to be very troublesome when opened for sewers or foundations, as the gravel seems to slide over the clay, and constant slipping is the consequence. In marshy land or soft sand it may also be desirable to extend the width of the concrete foundation considerably to prevent the risk of subsidence.

The question of sewer construction leads necessarily to that of the method of dealing with the sewage, and the details of flushing gates, penstocks, pumping stations, and many other similar requirements; but as these are subjects rather for the mechanical than the sanitary engineer, we shall not attempt to treat them in detail. We may mention, however, for the benefit of those of our readers who are in a position to avail themselves of the opportunity, that the whole of the contract drawings for the Metropolitan Main Drainage have been presented by Mr. Bazalgette to the library of the Institution of Civil Engineers, and may be there inspected by any one interested in the details of one of the greatest, if not the greatest, sanitary undertakings of modern times.

We conclude the present paper by a short notice of subways, in which may be contained, within one accessible passage, the gas mains, the telegraph wires, the water mains, and the sewers, accessible at all times for the purpose of inspection, alteration, or repair. We need hardly point out the great advantages of their adoption in all great metropolitan centres,

where the wealth and extent of the community render their introduction possible; but as the limits of our paper are nearly reached, we conclude it with a reference to two diagrams (Figs. 63, 64), showing two sections of portions of the Holborn Viaduct district, and clearly indicating the general arrangement. The larger section, that of the Holborn Viaduct (shown in Fig. 63), is no doubt exceptional from its extreme height; but we prefer illustrating, by this sketch in our present paper, a large undertaking recently carried out in all its details with thorough success, to laying before our readers drawings which, though perhaps more generally applicable to ordinary circumstances, have never been actually carried out in practice. It will be evident that, did our space allow, we might refer to many of our previous papers on gas, water supply, drainage, traps, and other points alluded to in the course of our present series; but the sections with which Mr. Haywood has favoured us are so clear in themselves, that if our previous papers have been read the drawings will easily explain themselves.

Our next paper will deal with the question of the ventilation of sewers, when we shall have again to acknowledge our obligation to the same authority.

GREAT MANUFACTURES OF LITTLE THINGS.—IX.

NAILS.

BY CHARLES HIBBS.

When Hutton, the historian of Birmingham, first approached the town he was afterwards to describe with so much humour and graphic power, he "was surprised at the prodigious number of blacksmiths' shops upon the road; and could not conceive how a country, though populous, could support so many people of the same occupation. In some of these shops," he goes on to say, "I observed one or more females wielding the hammer with all the grace of their sex. Struck with the novelty, I inquired, 'Whether the ladies in this country shod horses?' but was answered with a smile, 'They are nailers.'" At the time Hutton writes of, it is probable that the nail-making industry was carried on under conditions very similar to those which prevail in Belgium and some parts of France at this day, where a semi-agricultural population, occupying small holdings in the neighbourhood of the large towns, and deriving part of their subsistence from the soil, fill up their long hours of leisure by working at their own homes at some mechanical occupation, in which all the family can join. Cultivating a large patch of garden ground, or perhaps a small dairy farm, the Staffordshire nailer, and his wife, and his sons and daughters, used up all their spare moments in the nail-shop behind the house; and on the market day the good wife, clad probably in a man's flannel jacket over her looped-up gown, would trudge beside the donkey-cart to the nearest market town, perhaps eight or ten miles distant, and there dispose of her butter, and take the week's work of the family to the nail warehouse, where it was weighed in and paid for, and a fresh supply of nail rods given out for the next week. They were a hardy and laborious people, much given, it must be owned, to deep potations of ale, and lamentably ignorant; the children being put to the nail-block as soon as they were able to grasp a hammer, and even before that time they were made useful in blowing the bellows. In the course of time, as the district became honeycombed with coal-mines, the market gardens and the dairy farms were swept away, but the nail industry remained, and became the sole support of many a family. At one period it was computed that 60,000 persons were earning their subsistence at nail-making, and, as times were, their wages were fairly good. Large contracts for tea-chest nails came annually from the East India Dock Company; the Admiralty took between 600 and 700 tons a year; a large trade was done with Canada and the United States; and with the home demand these were generally sufficient to keep the nailer in constant work the whole year round. He had his seasons of holiday, during which it would have been sacrilege to strike a blow. The most notable of these was the wake, when, like the Dane at Yule, he

"gorged upon the half-dressed steer,
Caroused in seas of sable beer;"

and made merry, in his uncouth way, with bull-baiting, and such barbarous sports, the whole week through, to pinch for it a fortnight after. When work was going on briskly there was many a less cheerful scene than that presented by the nail district, comprising Dudley, Darlaston, West Bromwich, Oldbury, Rowley, Tipton, Bilston, and Wednesbury on the one side, and Stourbridge, with the adjacent district, known by the euphonious title of the Lye-waste, on the other. On a murk winter's night, when the sky was all aglow with the fires from the blast-furnaces, and the lurid flame, invisible by day, of some ignited pit mound, the music of the nailing hammers might be heard all the country round. From the little huts or sheds, dotted here and there upon the broken landscape with an utter absence of order or convenience, as though the mighty geological operations underneath had shaken them into the most unlikely places, the gleam of the hearth-fires would shine from the open shutters, and the merry songs of the workers, male and female, sung at the very topmost pitch of their voices, might be heard a mile away. Up to ten or eleven o'clock at night would these sounds continue—no uncommon circumstance in a district where labour never seems to rest, but where the roaring furnaces and the great rolling wheels go on unceasingly, day and night. Through the open loop-hole the whole art and mystery of nail-making could be witnessed by any passer-by. The nailer would have the ends of three or four rods in the fire, and taking out the one which had been in longest, after a pull or two at the bellows to bring it to a welding heat, he would taper down the point upon his anvil, at the same time making a shoulder for the head. He would then hold it over a chisel or cutting-punch, stuck upright at the side of his anvil, and, giving it one tap with his hammer, cut it halfway through; an iron stop in front of the punch giving him the exact gauge for the length. He would then turn down the point of the half-severed nail into a steel instrument called a *bore* (the top of which formed a mould for the head), and twist it off, and then, with a few smart blows, he would beat it down until the head was spread out sufficiently, and assumed the required shape, the nail just turning from red to black as he gave it the finishing tap. As his rods got too short, he would weld or "shut" two of them together, and put a new rod in the fire, and so on, with the regularity of clock-work, probably in a thousand nails not once varying the number of blows upon each. A great feat in the trade was making nails so minute as to be scarcely perceptible with the naked eye. A quantity were shown at the Exhibition of 1851, which, being put upon clean white paper, looked like so many grains of dust; but which, when examined through a microscope, appeared well-formed and perfect nails, each with the marks of seven distinct blows upon the head. A veteran nailer was attached to his hammer as a cricketer to a favourite bat: its haft was made to suit him, and he could work with no other; but with it he could perform wonders. Hutton, the historian before mentioned, said that the hammermen of Staffordshire were so skilful that he verily believed they could forge images upon the anvil.

Nail rods were produced by rolling iron, in the first place, into plates of the proper thickness, and afterwards passing these under *slitting* rollers, which split them into long square rods. Odd pieces of this material may be seen in the nail district serving various purposes, not the least frequent of which is that of tying the parts of a pig-stye together. There are various qualities and sizes, to suit the different varieties of nails, the best being used for making horse-nails, which require to be exceedingly tough and fibrous to admit of being driven into the hoof without breaking. Old horse-nails were at one time used extensively in the manufacture of the best gun-barrels, partly because the iron of which they were composed was of known good quality, and partly, it was supposed, from some additional property of toughness they acquired in the horse's hoof. It is probable, however, that the only advantage so derived was a guarantee that they were real horse-nails, and that they had stood the test of use—a guarantee which modern fraudful ingenuity has rendered valueless, for sham horse-nails, not to be distinguished from real, have been thrown in large quantities upon the market. Wheelwrights require good nails; so do hurdle-makers. There are as many as 3,000 different kinds of nails distinguishable by name—such as clasp, clout, and counter-clout; rose, dog, brads, tacks, etc. "A ten-pound

rose" would signify a rose-nail, of which a thousand would weigh ten pounds. Each locality produces its own special kinds; and a factor who would deal in all descriptions of nails must draw his supplies from widely separated places.

The first account of nail-making machinery occurs in the Patent Records of 1790, when one John Clifford obtained a patent for rolling them. He had a pair of rolls, cut all round with a series of nail moulds or matrices, heads and tails together, one-half of the impression in each roll, so that the rod came out converted into a string of nails, which required to be separated by cutting nippers. This plan was, of course, only available for the larger sizes, though he described it in his specification as "an entire new mode of manufacturing nails of every kind by machinery, never before made use of for that purpose." The same inventor afterwards took out a patent for punching nails from plates of iron, which was rolled taper for the purpose, having a thick side and a thin one. A punch and die, having the same taper, cut out spikes from these plates, and the heads were afterwards "upset," as the term goes, by another operation. This was coming nearer to the present method.

Guppy's patent, in 1796, was for cutting nails from plates by means of passing them under a roller having two cutters fixed at two opposite parts of its circumference. Underneath the roller was a movable piece called a vibrator, fitted with a die, which came in its motion under the cutters, and enabled them to cut off a piece the shape of a long thin wedge from the plate. This was then conveyed, by what the specification describes as "a chain calculated for the purpose," to a vice, which tightened up as it received it, held it while three taps of a hammer were given to it to upset the head, and afterwards opened out and let it fall; the whole being effected by one revolution of a wheel. This must have been a somewhat ingenious machine.

Visitors to the Workmen's International Exhibition of 1870 will have seen, among the machinery in motion, the modern process of nail-cutting. A girl sits in front of a press worked by steam, holding a strip of iron in a pair of long pliers, the handles of which are tightened up to retain it firmly; and turning it over rapidly at each stroke, a continuous stream of well-shaped nails falls from the machine, the head of one being formed from the point of the next, and *vice versâ*. The formation of the die and punch is somewhat peculiar. In the bed of the press is cut a square oblong hole, in which a punch of the same shape works, filling it exactly, and forming a solid block of steel, rising and falling with the motion of the press. The punch never rises entirely out of the hole, but on its under side is cut a step, the shape of the nail to be produced, and the girl inserts the strip of sheet-iron under this step as it clears itself from the hole, pressing the end of the strip against the solid part, and the sharp edges of the step cut off the nail. This arrangement causes the machine to work rigidly, and avoids bending the nail. Those small tacks called sparrowbills, which are much used by shoemakers, and have no projecting head, are most easily cut by this process; while sprigs, which have a head projecting to one side, are also formed with great neatness and regularity. On putting two of these together, head to point, it will be found that they fit into each other with extreme nicety. More complex machines there are, one of which we shall presently attempt to describe, which avoid this alternate process by a feeding apparatus which vibrates from side to side; while others, which make nails of different shape, have a supplementary contrivance for forming the head. There are few kinds of nails which cannot now be formed by machinery, and the trade in them is enormous, though probably not nearly so many hands are employed as in the best days of the hand-made nail-trade.

The revolution in the nail manufacture was completed by the introduction of an elaborate automaton machine, patented by Messrs. Ledsam and Jones, in 1827. A massive rigid framework, in shape like the skeleton of an oblong table, sustained, in the first place, a shaft working underneath, with a crank in its centre, which gave motion to the upper machinery, and was itself set in motion by a band-pulley at the end of the frame. On the top of the table were two massive slides, working in grooves, moving horizontally opposite ways from the centre. Motion was communicated to them from the crank by means of a rod and a toggle or knee-joint, which it is necessary to pause and describe. It consisted of two separate arms or levers, hinged together at one end, and the other ends hinged to the two sliders. When the crank-rod was connected at one end to the crank itself, and at the other end to the central hinge of this knee-joint, of course every revolution of the crank would cause the knee alternately to bend and straighten, and by consequence cause the sliders to move backwards and forwards. When it was at the upper part of its revolution the knee would be bent upwards, and when it was at the lower part it would be bent downwards; while at the middle part the knee would be perfectly straight. The nature of the motion gave almost irresistible impetus to the sliders, especially at the moment when the knee-joint was assuming the straight position. The reader has seen the very common children's toy, a box of wooden soldiers, with a slight jointed framework on which they can be stuck, and which elongates and contracts by moving the ends which are held in the fingers; this is simply a combination of toggle-joints. The sliders were fitted with cutters of rhomboidal shape, which could be fixed and taken out at pleasure, and were held firmly in their position by screws. As the sliders moved in their grooves, the sharp front edges of the cutters passed immediately under the corresponding edges of two other cutters, fixed rigidly in a position overhanging the frame. So far the cutting part of the machinery; what remained constituted the feeding apparatus. Hung to the frame we have described was a second oscillating frame, enclosing and overhanging it, which derived its motion from an excentric fixed on the crank-shaft. Through grooves in the upper part of this frame the strips of iron to be cut descended gradually to the level of the cutters, being held upright by means of rods depending from a beam overhead. A holder received the upper end of the strip, and this holder could be so fixed upon the depending rod as to slide down it by its own gravity, being weighted sufficiently for that purpose, and to allow of the strip of iron falling at a sufficient rate of speed as it was cut away. The business of the oscillating frame was to present the strip to the cutters at such an angle as to allow of a perfect nail being cut off, and the only attention which the machine required was the putting in of fresh strips, as the old ones were cut to the stump. Not the least ingenious part of the machine was the excentric, which could be adjusted to suit every size of nail by a screw, the head of which could be reached with a spanner.

Nails which required to be headed after they were cut, were subject to a defect arising from the extreme squeeze which was required to be given to them to hold them sufficiently tight for the head to be formed when cold. To obviate this a manufacturer, named Kingham, patented an improved machine in 1868, the object of which is thus set forth in his specification:—"The ordinary machine-cut nail is so griped while being headed that it is pressed out of shape, being of different form and often smaller immediately under the head than at a short distance below it; while the nail made by my improved machine is griped by dies so made and operated that the symmetry of the nail is preserved, or, in fact, improved; the shank being pyramidal, and thus suited for boat-building and other purposes."

The history of the hand-made nail trade since the introduction of machinery is a sad record of strife and disaster; abject poverty on the part of the workers, and often cruel oppression on the part of the employers. The numbers engaged have dwindled from 60,000 to less than 20,000, and the wages of those left in almost the same proportion. He is a clever nailer who can earn 12s. a week; and the labour of the whole family scarcely suffices to keep body and soul together. The Factory Act is inoperative in these districts, the work being done still at the nailers' own homes, which makes legal inspection and supervision practically impossible, and the poor untaught children are put to work at the very earliest age, for the sake of the few pence they are able to earn, thus bringing up another generation to cling hopelessly to a declining industry. Wages are largely paid in truck, in defiance of the law, and the number of respectable money-paying firms is constantly on the decline. The poor workman is often glad to exchange his morning's make of nails for a meal at the truck shop, or he is compelled to accept a little credit, from which moment the truck-master has him under his thumb. The cash-paying masters have often tried to put an end to the infamous truck system, but in vain; and the competition of the truck masters in the market compels them unwillingly to lower the wages of their work-people. To their honour be it said, they have not done so

without endeavouring on several occasions to make a public stand against it. At a meeting of nail-masters held in 1842, the following resolution was passed :—

"That, although this meeting is informed that some masters have been reducing wages for some time past, it is the opinion of this meeting that wages, as already fixed by the masters, are low enough, and they entreat those masters to give the full amount of wages, thereby preventing that distress which must otherwise follow such practices."

No trade has suffered so much from strikes; and a memorable one which took place shortly after the meeting referred to, led to the military being called out and the Riot Act read. Seldom has a strike resulted in anything but a further reduction; and the prospects of the future trade may be estimated, when it is stated that some descriptions of machine-made nails can be sold for one-fifth of the price of those that are hand-made, although the price of these last is not one-half of what it was.

Still it is supposed that there will always be a demand for some kinds of hand-made nails, and there are some which cannot be produced of sufficient quality in any other way. Among these are horse-nails, and in this branch wages were even greatly advanced during the period we speak of. It has been found impossible to get the requisite amount of toughness otherwise than by working the metal under the hammer, and this being the case, workmen are able to command a fair remuneration for their labour. Still the trade gives employment to comparatively few.

Copper nails, or nails cast from a mixture of copper with some cheaper alloy, are much used in ship-building, and especially for fastening on the sheathing to the bottoms of vessels. It was found that when the heads were left rough the ship's bottom fouled much faster than usual, and that a barnacle was sticking to every nail. The heads of these nails have, therefore, to be turned and smoothed in a lathe.

CAPITAL AND LABOUR.—II.

By J. E. Thorold Rogers, M.A., Tooke Professor of Economic Science.

POSITION OF THE QUESTION IN ENGLAND (*continued*).

It is very unfortunate that the hopes to which we drew attention at the close of our first paper on this important subject have been raised, for assuredly they will not and they cannot be gratified. A government is never, except for very short periods, in advance of the opinions entertained by those whose affairs it administers. No reform in the ways or habits of any society can ever be achieved except by those powers which lie within society itself, and which may be aroused or strengthened by the presence of those occasions on which they can be exercised, and by the heads and hands of those who understand and wield them.

In England the case has been very different. Here the habit of spontaneous agency, of self-government, of association, of combined action is so strong and so familiar, that no sensible person in this country expects that a government should do more than take away hindrances to such combination and association—should attempt anything beyond giving as much liberty as is consistent with order and quiet. English people, therefore, rarely expect that the government under which they live should take in hand the settling of their condition by finding employment for unoccupied hands, still less that it should re-distribute the wealth which the various individuals of which society is composed have collected. In other words, they expect, provided only that action is free and law is fair, that the condition of each person, and his share in the general product of labour, will be settled by competition, or arrangement, or contract.

Unfortunately, law has not, in times past at least, been at all fair. For nearly five hundred years the English law, though it put no hindrance in the way of employers, so as to prevent them from making the best bargains they could, put very serious hindrances in the way of labourers. The beginning of this system was the occurrence of a sudden scarcity of labour, and a consequent rise in its price. In order if possible to check the rise, laws were enacted forbidding employers to give, and labourers to receive, more than the wages which prevailed before the scarcity occurred. In time a different expedient was adopted in order to attain the same end. The magistrates were empowered to fix the rates of wages at their quarter-sessions. In other words, the employers of labour were allowed to determine by law what they might choose to pay their workmen, and the workmen were obliged to be content with the allowance which was made them. At the same time any association of workmen, which had for its object the discovery and employment of means by which the rate of wages might be heightened, was *strictly prohibited* and *severely punished*.

It is one of the consequences of an unwise or unfair law—those two words being in legislation almost synonymous—that the evil it does lasts long after its abrogation. The fact that this legislation was directed against the workmen, and that it stood in the way of attempts on their part to better their condition, left permanent feelings of suspicion and distrust in the minds of the labourers—of suspicion and alarm in the minds of the employers. There is no country in the world which has witnessed so many disputes and bickerings as England has in its various industries. Sometimes they took the form of riots and machine-burning, sometimes of strikes and lock-outs. On the whole, perhaps, the rate of wages earned by skilled artisans is greater, and the hours of labour are shorter, than in any European country, not indeed that the former are too great, or the latter too light. But there is no other European country in which there have been so many bitter and angry disputes between employer and workman.

Another reason why the relations of labour and capital (using the words in their popular meaning as denoting the bargains between employer and workman) have occupied so much space in social and economical philosophy, is the fact that the line between employer and workman is drawn with far greater strictness in England than it is elsewhere. In one kind of industry the line is seldom overpassed by the workman. It is very rarely the case that an agricultural labourer succeeds in becoming a tenant-farmer. In other industries it constantly happens that the workman tries to become an employer, or at least to work on his own account. This is particularly the case in those callings which are very widely distributed, and for which there is consequently a very general demand, such as the building trades. But in several callings it is seldom the case that the workman in England rises to be an employer. He is apt to remain permanently in his condition.

The case is very different in other countries. In Germany, for example, the workman on his own account is the rule, the capitalist employer and the hired labourer the exception. England is the country of large capitals, custom, and much more law, assisting in the aggregation of wealth, and discouraging its distribution. Now whatever the word capital may mean, it always means wealth employed actively for the purpose of obtaining income or profit, as the case may be; and therefore, where large capitals exist, there always will be a tendency towards stereotyping the two classes of employers and workmen. Of course if the habit of association were to spring up among workmen, the capitals which many men could collect, as has been proved in certain co-operative undertakings, may become far in excess of the largest capital possessed by private proprietors.

There is one advantage, however, which the English law has given the labourer at all times. It has considered his wages as a secured debt. In other words, if the employer becomes bankrupt or insolvent, his labourers have a claim to be paid in full, before any part of his effects can be distributed among his other creditors. It is probable that the origin of this custom is to be found in those times in which the payment of labour was generally made by granting the occupation of land, or *vice versâ*, where the occupier of land paid labour in liquidation of his rent. But whether this be the cause of the custom, or it be assigned to some feeling of humanity, the practice has a defence, in the fact that the labourer, in so far as he advances his labour to his employer—as he generally does—has disposed of his whole property or capital to one man, and therefore would be put in a disadvantageous position by the side of any other creditor, who may be supposed to have lent only a portion, and a small portion, of his capital to his debtor.

There are, then, several reasons which may account for the prominence which the relations of labour and capital possess in the theory of English social life. Some of these reasons are derived from the freedom which characterises contracts and associations in this country, some are the consequences of our

law, some are derived from the peculiarities of our trade and manufactures.

PROFITS OF CAPITAL.

My reader will see that in the foregoing remarks I have used the words capital and capitalist to represent the resources and the function of the employer. But I have done so under protest. The workman, in so far as he possesses the strength and the skill necessary for the work which he undertakes, and in so far as he lends his labour to the employer, before he receives his wages, is just as effectually a capitalist as the employer is who hires him. Familiar usage, and the necessity of making a distinction between the two principal agents in most productive actions, render it convenient to speak of the employer as a capitalist, and the artisan as the workman, though both possess capital, and both do work.

The remuneration which the work of the capitalist obtains is called profit. It must not be imagined, however, that all that which he is enabled to appropriate as his share is paid him for the work which he does. He may employ the property of others, and pay interest for the loan. Now, interest is the reward which a man obtains for allowing another to use his property. In so far as the employer has property of his own, so he will expect and get interest for his property, as certainly as though he borrowed the property of other people; in just the same way as a man who cultivates his own land, receives, so to speak, rent from himself. The amount of interest which a person can get for the use of his property depends entirely on the quantity of property which can be lent, and the uses which borrowers can put such property to. If the property be scanty, and the desire to use it keen, the rate of interest is high. If, on the other hand, the property is abundant, and the wish to use it slight, the rate will be low. In neither case is it necessary that the profit of the employer should follow the rise and fall in the rate of interest. At the present moment, the rate of profit in many callings is very high, but the rate of interest is exceptionally low.

Again, part of the remuneration which the capitalist receives is security against risk. Business is ordinarily conducted in such a manner as that no loss occurs in the great majority of transactions; but no business is free from risks. Apart from the chance that a purchaser may be insolvent, and therefore be unable to pay his debts, there are risks that the manufacturer may have produced more than the market requires, or than the public fancies, or have offered something which nobody cares to purchase, or have made a loss in the purchase of his materials, or have made some other miscalculation. These chances are so numerous and so serious that it is not too much to say, that they who prosper in life generally do so, because they have contrived either by skill or good fortune to escape some of these losses which others, not so intelligent nor so fortunate, have suffered. In such a case, the former gets an advantage from the losses of the latter. Business is calculated on the average of profit and loss, and the man who individually incurs the least loss, gets most profit.

Take out of the quantity which the employer of labour appropriates, that which he receives as interest on his property, and that which he lays by as a security against risk, and the residue is gained by him, because he gives pains and trouble, or, in other words, labour, to the calling in which he is engaged. It will be seen, therefore, that there is no economical difference between the true profits of the employer and the wages of the workman. Both are payments for work done, and both are made because work is done. Both are wages; and sometimes persons have spoken of the "wages of superintendence," as part of the profits of the employer. In reality, if the exposition given above is intelligible, profits are wages in disguise.

The distinction and similarity between profits and wages are no mere verbal limitations. It is wholly essential to a right understanding of the relations which subsist between labour and capital, that the resemblance between profits and wages should be recognised, for by this fact we are able to discover what there is at the bottom of all those struggles between labourer and capitalist, which are so constantly observed and commented on, but so little understood. In brief, these struggles generally consist in an attempt on the part of the employer to increase his rate of wages, and a similar endeavour on the part of the workman to increase his.

It is commonly said that profits tend to an equality. This statement is very imperfectly true. Interest not only tends to an equality, but, if the securities are equally good, actually makes an equality. Risks are not an equality, but an average. It is only because that part of what is called profits, which is really interest, and that part which is half insurance appear to be, and to a great extent are, equal in most callings, that this error of the tendency of profits to an equality has arisen. Wages do not tend to an equality, even when they are the wages of workmen; for they vary not only by reason of time and place, but much more by the comparative skill of the workman. Still more, however, do the wages of employers vary, because the skill of different employers varies exceedingly. One employer makes a fortune, another hardly gets a living. It is absurd to say that their profits are equal, or even tend to equality.

There are two ways in which greater profit, in the sense which I have assigned to this word, is made. One of them is by lessening cost; the other is by multiplying transactions. Different kinds of business give very different opportunities for these two sources of increased profit. It will be clear to every one how powerfully manufacturing profit is affected by the first of these processes. A piece of woollen cloth is woven at the present day for a tenth of the cost which was incurred a century ago. By a discovery that woollen rags could be used over again, the saving of cost in the manufacture is assisted by a saving of cost in the material. Now, as long as any lessening in the cost is the property of one man, it becomes his profit, and his only. As soon as it belongs to all other manufacturers, either the public will get the advantage, in the lowering of prices, or the labourer will share the boon in the increase of his wages. It will be plain, however, that the intelligence which lessens cost is a kind of labour, and a very important kind too.

It will be easy to illustrate the other manner in which the individual increases his profit. The labour of a stockbroker consists in purchasing securities on behalf of his customers, he receiving a fee in the form of a per-centage on the purchase or sale of the security. The business of the broker is to get as many of these commissions as he can; there is no limit to his power of doing such business. If a single broker kept clerks enough, he could buy and sell every pound's worth of the stocks and shares which change hands in the market. His function is to be known and to be trusted.

This leads me to point out what is meant by good-will. There are some kinds of business in which the connection between the trader or workman and his customer is so valuable, that if it be judiciously transferred, it will sell at a very great price. Instances of such a kind are the business of a banker in good repute, or an attorney who has what is called a good family connection. In both these cases considerable advantage is gained out of ordinary routine transactions, over which a general supervision on the part of the manager is all that is necessary. Of course the basis of this connection is a reputation for integrity and good faith.

The profits of trader and manufacturer are always highest in those countries which are rapidly growing in wealth. But they are highest in such countries, because the wages of all labour are high, provided of course that the labour is useful, and therefore in demand. Now this result occurs in the most marked manner when the business of such countries is brisk, and the resources are great. In no countries are profits higher than in such newly-settled regions as possess abundant land, the produce of which can be easily brought into the markets of those countries where population is abundant, and land fully occupied. Similarly, in a country like our own, where there are extraordinary opportunities for obtaining that increase of profit which comes from very numerous transactions on commission, large fortunes are made from that kind of business in which such commissions can be indefinitely extended.

BUILDERS' QUANTITIES AND MEASUREMENTS.—XVII.

BY E. WYNDHAM TARN, M.A.

BRINGING INTO BILL.

We now come to the last operation to be performed by the measuring surveyor, and the one for which all the previous

operations are only preparations; this is called bringing all the measurements into bill, and is performed by taking the several items *seriatim* from the abstract, and entering them in proper order on ruled bill-paper, so that the prices per yard, foot, rod, or each, can be attached to them, and the work priced out.

The following order should generally be observed in bringing into bill. Cubed articles to be placed first in each trade, then the superficials, then the runs, and lastly the numbers. It is also usual to begin with low-priced articles, and enter them in increasing order. These rules will be best explained by presenting our readers with a detailed bill of all the items contained in the abstracts previously given under the several trades.

BILL OF QUANTITIES.

EXCAVATOR.

YDS.	FT.	
74	5	Cube, digging in clay, 1 throw, and carting 1 mile
$28\frac{1}{2}$	0	„ ditto, ditto, 2 throws, part filled in and rammed, part wheeled two runs
$77\frac{1}{4}$	0	Ditto, ditto, in gravel, 2 throws, filling in and ramming
12	8	Supl., clay puddling to vaults
$180\frac{1}{2}$	0	„ levelling earth, average depth 12 in.
$41\frac{1}{4}$	0	Run, planking and strutting to trenches, 7 ft. 6 in. deep, 2 ft. 3 in. wide

WELL-SINKER.

FT.	
25	Run, digging and steining (dry) to well, 3 ft. diameter in the clear, gravel soil
10	„ ditto, ditto, in mortar to cesspool, 6 ft. diameter in the clear, clay soil
40	„ boring through sandstone rock, with a 3-in. auger

Carried to summary . . £

BRICKLAYER.

YDS.		
$15\frac{3}{4}$		Cube, concrete in foundations, composed of 1 part lime to 6 parts ballast
$49\frac{1}{2}$		Supl., 6 in. concrete floor composed as above
$2\frac{1}{2}$		„ ditto, 1 part Portland cement, and 8 parts ballast
$21\frac{1}{4}$		„ ditto
		„ ditto in 9 in. walls, with use of apparatus
FT.		
23		Cube, stock brickwork in mortar to copper
RODS.	FT.	
12	160	Supl., reduced stock brickwork in mortar
	195	„ ditto, fence walls
YDS.		
34		„ brick nogging to partitions
$89\frac{3}{4}$		„ Malm facing
112		„ tuck pointing
231		„ flat joint pointing
$99\frac{1}{2}$		„ $\frac{1}{2}$-in. tile paving in cement
$7\frac{1}{2}$		„ 1 brick vaulting in mortar
4		„ brick on edge, paving in sand and grouted
FT.	IN.	
86	1	„ Asphalte
76	8	„ Malm cutter arch
20	5	„ cutting to splay
18	0	„ $\frac{1}{2}$ brick trimmer arch
31	0	Run, chamfer to brickwork
32	0	„ double tile creasing
65	0	„ extra to brick on edge coping in cement
22	6	„ cutting chase for rain-water pipe
60	0	„ 6 in. glazed ware socket-pipe drain, and jointing in cement
YDS.		
376		„ iron hooping as bond, $1\frac{1}{2}'' \times \frac{1}{16}''$
		Number—
		6 flues cored
		6 chimney pots, and setting in cement
		1 range setting
		5 stoves ditto
		12 sash-frames and door-cases, bedded and pointed
		8 air-bricks
		3 6-in. junctions to drains
		2 ditto bends ditto
		1 ditto syphon-trap ditto

Carried to summary . . £

TECHNICAL DRAWING.—LXXIV.

DRAWING FOR BRICKLAYERS (*continued*).

We purpose in the present lesson giving some further illustrations of drawing.

Fig. 596 is a section of a drain of the oval form.

Before drawing this, it will be well that the student should be reminded that the difference between an ellipse and an oval is, that the former is equally curved at both ends, whilst the latter has the one end larger than the other, similar, in fact, to the form of an egg, and hence its name (from *ovum*, an egg). The following figure (Fig. 597) from "Practical Geometry applied to Linear Drawing" is here repeated in order to save trouble of reference:—

To construct an oval, the width A B being given. Bisect A B by the line C D, cutting A B in E. From E, with the radius E A, draw a circle cutting C D in F. From A and B draw lines through F, and produce them indefinitely. From A and B, with radius A B, draw arcs cutting the last two lines in G and H. From F, with radius F G, describe the arc G H, to meet the arcs A G and B H, which will complete the oval.

Now in Fig. 597 it will be observed that only the width is given, whilst the depth at D is found by the radius of the arc drawn from F.

In Fig. 596, however, the height of the drain, as well as the width, is given.

In this drain the span is 3 feet and the height 4 feet 6

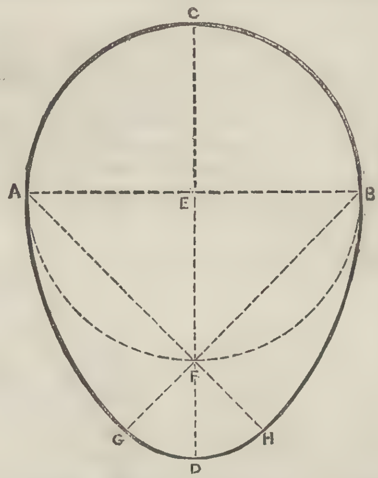

Fig. 597.

inches. The upper arch is a semicircle of 18 inches radius, and the lower curve is the third portion of a circle of $10\frac{3}{4}$ inches radius, the centre of which is of course set off on the centre line at the distance of the radius from the bottom. These two curves are united by arcs struck with a radius of 4 feet $10\frac{3}{8}$ inches, the centre being on the springing line produced.

The upper arch in this example is formed of two $4\frac{1}{2}$-inch rings, with occasional whole bricks laid as headers, or bricks of a wedge-like form purposely moulded.

The sides of the drain are worked as rough arches in whole and half brick, the half brick being of course half in appearance only, the whole brick lying in the direction of the drain.

The lower arch is formed of bricks purposely moulded to the form, by which means the closest possible joint is obtained in that part of the drain through which the sewage is passing, and which should therefore be rendered absolutely impervious to water.

In relation to bricks purposely moulded as superseding rubbed bricks, we extract the following passage from Mr. Gilbert Redgrave's official report on this section of manufactures in the International Exhibition of 1871:—

"Much as we admire it, we cannot help considering rubbed brickwork to be false in principle. There is no doubt that rubbing has been resorted to in some of the most beautiful work which we possess, and we must admit the new buildings at South Kensington are most excellent examples of the judicious employment of red bricks. But we are convinced that as bricks are necessarily moulded in the process of manufacture, it is a mistake to tamper

with and shape them after they have left the kiln. It is really doing the work twice over to cut them into fantastic shapes when they might have received these forms in a quarter of the time while the clay was in a plastic state."

The following example (Fig. 598) is a section of the principal drain at King's Mews Barracks, near Charing Cross.

It is 2 feet 6 inches wide by 4 feet 9 inches high in the clear. The sides are straight for nearly three feet in height, and are one and a-half brick thick. The arch at top is a segment approaching to a semicircle, and at bottom a flat segment-arch is used. These arches are one brick thick. The foundation is level, and small buttresses (not shown in the figure) are added at intervals. In concluding this section it may be observed that all drains should be well considered before a building is commenced, and they should be amongst the first things executed. The ground for the foundation should be levelled according to the proper slope, and carefully examined before the brickwork is begun. A drain should never be made to turn abruptly in any part of its course when it is possible to avoid it, and for the same reason it is best that the branch drains should not enter the principal drains at right angles, but should, when possible, be slanted a little, so as to favour the direction in which the water is to flow. It is, of course, proper to make the branch drains somewhat higher than the principal drains, to prevent the greater body of water in the latter from flowing up into the former and choking them.

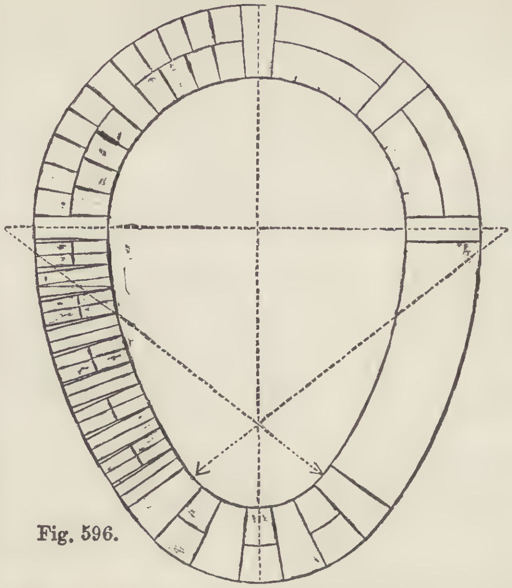

Fig. 596.

PLAN DRAWING.

The various kinds of drawings used in the erection of buildings are by most people classed under one general name, "plans."

This massing together of all the drawings is, however, wrong technically. The drawings consist of plans, elevations, sections, and working drawings. These have been already fully explained in "Building Construction," and need, therefore, be only briefly alluded to in this place. The plans, it will be remembered, are classed as—

1. Block plans: showing the mere outlines of the buildings, and their position in relation to the surrounding objects.

2. Excavation plans: showing the shape of the trenches to be dug for the foundations, cellars, underground kitchens, etc.

3. Basement plans: showing the foundations and works up to the level of the ground, or, as it is called, the ground line.

4. Floor plans: including (1) the ground-floor plan; (2) the chamber plans, showing the disposition of the different rooms, which are not always arranged as on the ground floor; but, of course, the main walls necessarily cause the general apportionment to be the same; other divisions are accomplished by means of partitions; and (3) the attic plan, showing how the garrets or attics are arranged.

5. Roof plans: showing the manner in which the roofs are disposed, so as to secure the fall required, that rain may at once pass off by the gutters and spouts.

Plans resemble the appearance of any object viewed from a height above it. They represent not only the piece of ground occupied, but the space it overhangs as well. This has been fully demonstrated in "Projection," in which the principle of projecting elevations from the plans has been fully worked out.

Plans, therefore, do not convey any notion as to the *appearance* of a building, but as to its *reality*. They do not show how the building looks, but how its different apartments are arranged. Nor are plans associated in the mind with what may have been seen; for, of course, a true view of a roof, such as would be given in a roof plan, could only be obtained from a point above it, looking immediately downwards.

Ground plans or foundation plans of buildings or other works do not give any just notion of the appearance of the object represented, because when a building is finished, it is impossible from any point of view whatever to see the various walls and foundations in the manner in which they must be represented in the ground plan, the whole of these parts being hidden by the very building reared upon them.

In fact, the ground plan of any finished building is, properly speaking, a section through the various walls; the only difference between it and a common section consisting in this: that the common section is taken vertically, whereas the actual section of a building which is exhibited in any ground plan of it is supposed to be taken *horizontally*. Thus, if the student can imagine a house cut through horizontally, immediately on the line of the first floor—that is, on the level of the top of the first flight of stairs—and the whole part above this cut including the floor to be removed, a drawing made of the edges of the walls, of the floors, and stairs they include, would be the plan of the ground floor.

Since, then, the elevations must be entirely dependent on the plans, the utmost care must be exercised by the student, not only in the design, but in copying such sets of drawings, since they must correspond with each other with the utmost degree of accuracy.

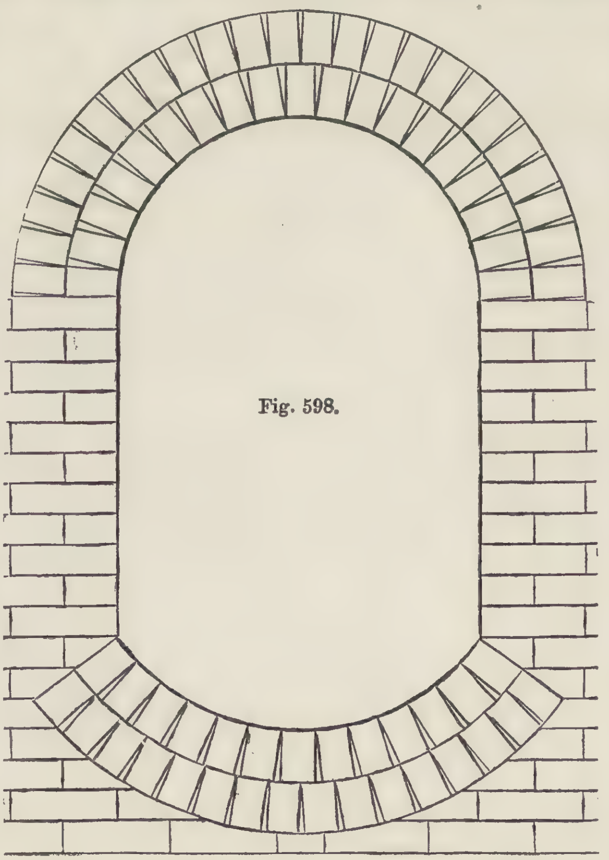

Fig. 598.

MINING AND QUARRYING.—XXVI.

BY GEORGE GLADSTONE, F.C.S.

LEAD (*continued*).

LEAD FUME—COMPOSITION—VALUE OF FUME—MODE OF COLLECTION—REDUCTION—SOFTENING OF LEAD—TREATMENT OF DROSS—NAPLES YELLOW—CHARACTERISTICS OF PURE LEAD.

In the last article the objectionable character of the waste gases from the lead-smelting works was briefly referred to. Those who have passed through the Swansea valley will have been impressed with the utter absence of any vegetation, which is due to the sulphurous acid evolved in the course of copper-smelting; but the destruction of all plant life is the only serious objection to the presence of copper works. It is not so with those where lead ores are treated: were they to be as near Swansea as the copper works are, and were the same low chimneys to be used, the town would be absolutely uninhabitable. The whole of the population would soon present symptoms of lead-poisoning.

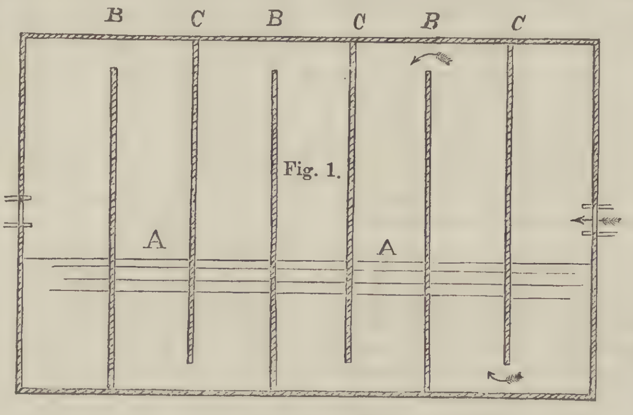

Fig. 1.

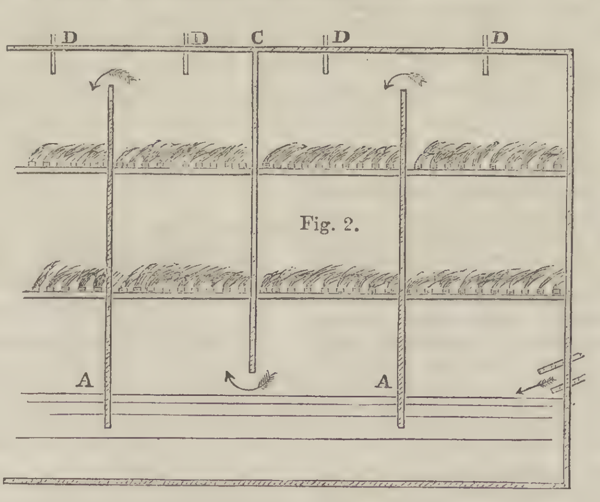

Fig. 2.

It is the lead fume, as it is technically called, which must be prevented from passing into the atmosphere; the sulphurous acid gives no trouble to the lead-smelter. The lead fume, moreover, is of very considerable value, too great to allow of its being lost. In composition it varies somewhat, but the principal ingredient is always sulphate of lead, the proportion of which will range from 65 to 85 per cent. There is usually some oxide and sulphide of lead as well, the rest consisting of silica, lime, alumina, etc. As it comes away from the furnace it most probably consists of sulphide and oxide of lead, but as large quantities of sulphurous acid are being evolved at the same time, the latter combines with the lead salts above named, and converts them into the sulphate.

The fume when given off from the furnace appears as a dense white smoke, which gradually deposits a fine powder varying in colour from white to grey; but even after passing through all the arrangements made for its collection a sufficient quantity usually passes up the chimney to render it a characteristic feature of a lead-smelting establishment.

For this reason the chimney-stack is generally removed to a considerable distance from the works, and if possible to some piece of mountain or waste land. Thus the great chimneys of Mr. Beaumont's works at Allenheads form a conspicuous feature in the landscape for many miles round, being erected on the very summit of the high moorlands which rise above the works. The lofty chimneys of Pembrey, situated on the waste lands close upon the shore, form in like manner, with their dense white smoke, an equally conspicuous object from any part of Carmarthen Bay.

The fume has usually, however, a considerable journey to perform before it reaches the exit into the open air. At Allenheads, for instance, the aggregate length of the flues is about 9 miles, one of them alone measuring more than 2½ miles. They are carried horizontally, or nearly so, for a considerable distance, and then rise with the hill until they reach the chimneys on the top. The flues are built of masonry, and are 8 feet high by 6 wide. Doorways are made at intervals, which are opened on the occasions when the flues are cleaned out; and on one of these occasions the quantity of lead fume which was collected from them yielded no less than 800 tons of metallic lead. The value of lead saved by this means at these works alone amounts to about £10,000 per annum.

Sometimes large chambers are placed at intervals along the line of flues with the object of aiding the deposition of the fume by reducing the strength of the draught; but the fume appears to be in so very finely divided a state that they exercise no perceptible influence upon the quantity of deposit, which seems most readily arrested by friction against the sides of the flue. This opinion is supported by the fact which has been frequently noticed, that those parts of the flue which may be wet from the percolation of water do not contain so large a deposit of fume as those where the masonry or brickwork is quite dry.

The first cost of flues of such enormous length, and the constant expenditure incurred in keeping them in repair, form no inconsiderable items; and various arrangements have been devised for artificially throwing down the fume, and so dispensing with the long flues. Some of them are found to work well, though the older plan still maintains its ground when the nature of the country is suitable; and in some cases a combination of the long flue and the condensing apparatus has been adopted with great advantage.

These artificial plans for condensing the fume almost always depend upon the agency of water applied in one way or another. They are called after the names of the inventors—Stagg's, Stokoe's, etc.; but it will not be necessary to go into all these in detail. In Stagg's condenser the fume is forced, by water or steam power, through water several times in succession, by making it pass through a chamber divided by horizontal partitions on the principle shown in the diagram (Fig. 1), in which A represents the level of the water, and B B B and C C C the two sets of partitions, the one set reaching nearly to the top, and the other nearly to the bottom below the surface of the water, so that the fume will have to take the course indicated by the arrows.

In Stokoe's condenser, on the contrary, the water scarcely reaches up to the partitions C C, etc., so that the fume does not actually pass through the water at the bottom of the chamber, but each division has two floors made of open woodwork, upon which fagots are laid, as shown in Fig. 2: streams of water pour down continuously from the pipes D D, which become broken into showers as they trickle through the fagots, presenting a large surface of water to the fume as it also passes through them. A fan-blast is of sufficient power to work this apparatus.

In others a layer of pebbles is substituted for the fagots, and again in others jets or showers of water are thrown at intervals into the condensing chambers. Some of them are said to do their work so thoroughly that no ill effects are produced by the smoke when it issues from the chimney.

The quantity of lead fume given off in the course of the smelting seems to vary very considerably; probably from differences in the nature of the ore, as well as in the treatment. The lead extracted from the fume frequently amounts to 7 per cent. of the total quantity of metal produced at the works, and sometimes even to more than this proportion.

As the fume when collected consists almost entirely of sulphate, it is generally smelted in a reverberatory furnace with the addition of some coal and about an equal quantity of scrap iron; but owing to the finely divided state of the fume it cannot be put into the furnace without being first agglomerated into lumps, which is done either by gentle heating until it just becomes soft, or by mixing it with lime paste.

The greater portion of the lead produced by the various processes already described is not of a quality fit for the manufacturer, and is termed hard lead, in contradistinction to the finished article known as soft lead.

The refining of the hard lead must now be described. This operation goes by various names, being sometimes called softening, and at other times calcining or improving. The hardness of the lead is due to impurities, amongst the most common of which is the presence of antimony and zinc; these metals form alloys with the lead, and so alter its character as to deprive it of some of its most valuable properties: they render it less manageable under the roller, diminish its power of resisting the action of the atmosphere, and interfere with the separation of the silver from the lead.

In order to get rid of these objectionable ingredients, the lead is melted in a reverberatory furnace with a shallow level hearth, and kept for some little time at a dull red heat, a good supply of atmospheric air being maintained throughout the operation. The dross, which consists of a mixture of the oxides of the various metals, including also some portion of the lead itself, is skimmed off as it accumulates on the surface, and the metal is tested from time to time to ascertain when it has arrived at a proper condition of softness. The right period is known by the peculiar iridescent and crystalline appearance of the surface of the test sample as it cools, which is easily recognised by an experienced workman. As soon as this point has been arrived at, which may be in the course of twelve hours, or on the other hand after three or four weeks if the lead has been very much contaminated, the whole of the dross is skimmed off, and the metal drawn from the furnace into a pot, from which it is again ladled into the pig-moulds.

In this, which is the ordinary process, the result is due entirely to the slow oxidation of the metals during the prolonged exposure in the furnace; but some manufacturers have preferred to add nitrate of soda, caustic lime, common salt, and other ingredients which assist in the separation of the impurities.

The dross skimmed from the surface of the lead during the softening, contains a large proportion of oxide of lead; and this is again reduced in either a reverberatory or blast furnace, some coal, and occasionally also a little soda ash, being mixed with the charge. This will yield a lead still harder, or in other words still more full of impurities, than that from which the dross itself was derived; but it may nevertheless be worth softening. This will yield a still inferior dross, which will no longer be of any value to the lead-smelter, though it may be turned to account by converting it into the antimoniate of lead, which is the pigment known to painters as Naples yellow. This product may be obtained by the simple calcination of the dross at a red heat; though the brilliance of the colour is said to be improved by the addition of a good quantity of common salt during the latter part of the process, or by subsequently exposing the calcined article to the action of acetic, hydrochloric, or sulphuric acid.

In the first article upon this subject, attention was drawn to the fact of this being the great lead-producing country of Europe; but it appears from the statistics compiled by the Government that the home consumption of this metal is somewhat in excess of the production. According to the official returns for the year 1868, the quantity used in this country was calculated at 78,000 tons, while the quantity derived from the ore raised within the United Kingdom was only 71,000 tons. The balance has to be made up by imports from abroad, either of the ore or of the metal itself. In the course of the twelvemonth a good deal of ore does come here from the Australian colonies and from foreign parts to be smelted; but although the produce of the country so nearly balances the home consumption, the total imports of the year above named amounted to 58,000 tons, and a large proportion of this was in the condition of pig-lead.

It seems anomalous that with all our advantages we should import such large quantities of the manufactured article, but the explanation will be found to lie in the fact that the pig-lead imported is the hard lead, which is brought to this country to be softened and subsequently desilverised. This is now a regular branch of trade carried on to a large extent on the banks of the river Tyne. The principal source of supply of this hard lead is Spain, where, though the ore is exceedingly abundant, the smelting processes are carried on under certain disadvantages, the ores being poor in quality and refractory in character, while fuel is so scarce in the lead-mining districts that the coke used in the smelting has to be sent out from this country.

The softening and desilverisation of foreign leads is an industry of recent introduction; in the year 1844 only 213 tons of Spanish lead were imported into Newcastle for this purpose; in 1852 this had increased to 7,317 tons; in 1862 to 12,459; and each succeeding decennial period bids fair to show a considerable advance upon the last. The lead contains on an average about fifty ounces of silver to the ton.

Pure lead is of a bluish-grey colour with a bright metallic lustre, but this is soon lost on exposure to the air. It is very heavy, the specific gravity being 11·35; but on the other hand it is so soft that it can be readily scratched with one's finger-nail. It can easily be rolled out into thin sheets, and these may be bent to almost any extent without breaking. It melts at about 620° Fahrenheit, and as compared with other metals is a very bad conductor of heat.

The facility with which it can be rolled out into flat sheets, and also pressed into the shape of hollow tubes, coupled with its pliancy, have led to its very extensive application in these forms. Moreover, this mode of using lead was well understood long before the means of rolling zinc into plates was discovered, and though much more expensive than the latter, it will certainly hold its ground against its modern rival on account of the ease with which it can be manipulated by reason of its pliancy. The sheet lead used in covering the roofs of houses, in making gutters, and in lining cisterns, together with the lead piping for conveying the water to the various parts of our houses, are familiar objects in every plumber's shop. The mode by which pig-lead can be made to assume these forms must be considered in the next article.

MUSEUMS: THEIR CONSTRUCTION, ARRANGEMENT, AND MANAGEMENT.

BY SAMUEL HIGHLEY, F.G.S.

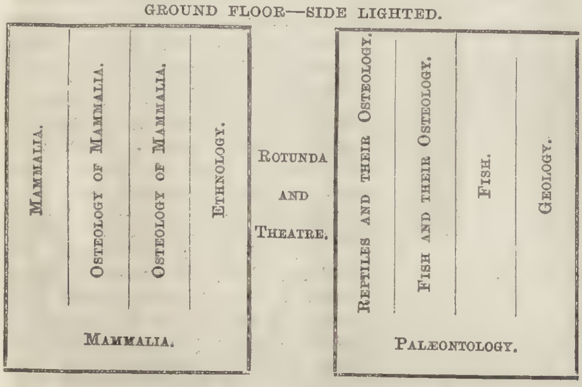
X.—NATIONAL MUSEUMS (*continued*).

6. *Construction.*—As affording a simpler type of construction, I prefer giving an ideal plan of a National Museum of Natural History, founded on the published views of Owen, Agassiz, Hooker, Sclater, Flower, Archer, Huxley, Wallace, etc., rather than the absolute designs of Mr. Waterhouse.

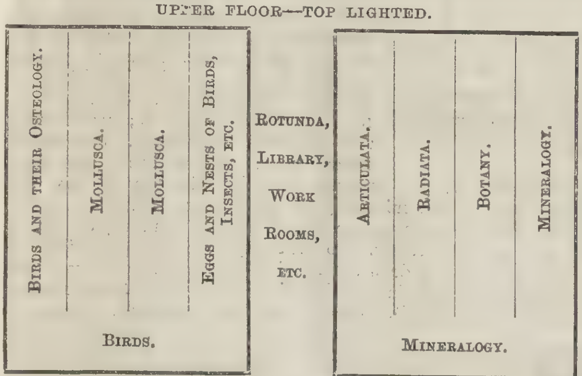
Before describing the complete building, it will be well to consider the leading ideas on the principles of construction that have suggested themselves to those naturalists who have given attention to the subject. First, as to date, is Professor Owen's plan of 1859, founded on the principles he had carried out in the construction of the new Hunterian Museum, built under his auspices during his conservatorship at the College of Surgeons, which answer the objects in view admirably—viz., the attainment of the perfect illumination of both wall and table cases by admitting daylight through windows placed in the angles formed between the walls and a flat roof, as shown at L in the section (Fig. 1). He considered that if space could not be given for the erection of the entire series of galleries on one floor, to allow of this principle of lighting being carried out, then light should be admitted by windows placed on each side of the lower galleries, immediately over the wall-cases, and to effect this he intersected the series of galleries with open courts 20 feet wide, as shown in the plan (Fig. 1). Professor Owen devoted the basement, B, to store-rooms, workshops for taxidermists, modellers, skeleton preparers, carpenters, etc. Over the basement he placed a range of galleries 30 feet high by 40 feet wide, with an average length of 150 feet, light being attained by the open courts referred to, C, C, of plan and section.

These side-lighted galleries he considered suited for the disposition of mammalia, reptiles, fish, ethnology, osteology, palæontology. Above the lower, he placed a second range of galleries, 25 feet high, lighted from the angles of the building, as at the College of Surgeons, which he deemed best fitted for the arrangement of birds, oology, mollusca, radiata, plants, minerals. The plan of 1862 consisted of a series of eight such galleries, 150 feet long, on each floor, with a rotunda for the lecture theatre, elementary collection, etc., in the centre, which were arranged thus:—

GROUND FLOOR—SIDE LIGHTED.



UPPER FLOOR—TOP LIGHTED.



In case of additional space being needed, the open courts could be covered in with arched glass roofs, at a height of 25 feet from the floor, so as not to interfere with the side windows of the lower galleries. Keeper's rooms and small studies were placed at the end of certain galleries, as indicated in K and S, in the plan (Fig. 1). It will be noted that the successive links in the chain of Nature are here arranged in broken or disconnected order, and that the requirements of the memorialists of 1858 are not complied with as to the direct blending of the osteological and palæontological with the recent specimens, or of the eggs, nests, etc., into the life-history groups of birds, insects, etc., though this is a matter of arrangement, not of building construction: the two subjects are so intimately connected that it will be advisable to call attention to it here.

Fig. 1—Section and Plan—gives a clear idea of Professor Owen's opinions on the construction of Natural History Museums.

Next we have Dr. Philip Lutley Sclater's* ideas (Fig. 2), as conveyed in a paper read before the British Association at Liverpool, September, 1870, entitled, "On Certain Principles to be Observed in the Establishment of a National Museum of Natural History." His plan is to arrange the building in the form of a hollow square, the external walls measuring some 600 feet by 400 feet, this external block being divided by a central wall or partition into two equal parts, the outer portion being devoted to the public galleries, the inner portion to the studies, keeper's and store-rooms, the centre of the hollow square being occupied by a circular building containing the library, having direct communication, by light iron galleries, with all the working-rooms, so that students of any department could obtain ready access to it and the lecture theatre. This museum might be of two, three, or four storeys, as the public galleries would be lighted by windows on the outer walls, and the studies, etc., by windows in the inner walls, the system of top lights being avoided. Dr. Sclater's plan of building will be readily understood on consulting Fig. 2. His system of arrangement must next be noted. Outside the partition that separates the studies from the galleries, he arranges a continuous line of wall-cases, for the display, in one unbroken series, of the "vertebrates, from the highest mammal to the lowest fish;" and so on, with the invertebrate, botanical, and mineralogical collections, or, as I suppose, in such manner as practical considerations might modify. The leading idea is that the fronts of these wall-cases should be hermetically glazed on the side exposed to the dusty atmosphere of the public galleries, and accessible only from the side next to the studies, to allow of any specimens required by students being removed from the cases containing the public series to the study-tables. This method had been previously suggested by Dr. Hooker, in a letter to the *Gardener's Chronicle*, as far back as 1858 (page 749 for that year); but as Dr. Sclater says, in a note to his paper, as published in *Nature*, for Oct. 6, 1870, "I can only, therefore, claim to be *an* (not *the*) original inventor of this method of arrangement." "These cases (says Dr. Hooker) should open from the back only, and then into smaller parallel side galleries, in which the naturalist might work undisturbed by the public." Further, he suggests that these cases should commence three feet above the floor, the space beneath being occupied by drawers, etc., opening into the back galleries, the space in the public galleries corresponding to the back of the drawers being utilised with diagrams, classifications, illustrative remarks for the instruction of the general public.

It will be observed that in Dr. Sclater's plan (Fig. 2) the wall-cases are reduplicated to obtain an extended range of wall-case in a gallery of limited length. Thus, as will be shown in Fig. 9, when in the ordinary way a wall-case would only present a frontage of 35 feet, by throwing out the cases 15 feet into the gallery, and doubling them on each other, a frontage of 95 feet may be obtained. To gain access to cases of this kind, it is necessary to provide a passage, at least 3 feet wide, nearly through the centre, to give access to the doors. It appears to me that the advantage gained by the hermetically closed fronts is to a great extent counteracted by the manner in which Dr. Sclater places these cases in the open public galleries, as the dust disturbed by the traffic would distribute itself over the top of the cases, and find access to the cases when the doors at the back were opened. It would be better to place these back close to the wall that separates the galleries from the studies, so that the backs of the cases formed the separating partition itself, and then it would be necessary to roof in the passages. This might be done by throwing a gallery over the projections, in a manner similar to that which may be seen at the Museum of Practical Geology, as indicated at G (Fig. 2); but the drawback therein experienced is the serious darkening of the cases at the end of each bay, and the increased difficulty of general supervision, as such covered recesses form covers for thieves and other objectionable characters, that, according to the evidence given before the Committee on Public Institutions,* must be provided against in our public galleries, especially those of great extent. The better plan would be to place the cases *at the end of the recesses*, under a beam or iron girder, stretching from pier to pier at 9 feet above the floor, of equal depth as such cases, say 3 feet, so as to bring the fronts flush with the upper part of the walls of the galleries, and the backs flush with the walls of the studies, then by roofing the projecting cases so as to cover the passages from the studies, the fronts would be really hermetically closed on the public side, and dust effectually excluded. My idea on this point is indicated at H (Fig. 2), and will be shown in detail in Figs. 7, 8. Dr. Wallace raises another objection to Dr. Sclater's plan, on the ground that the use of wall-cases on one side of a gallery for an entire museum is an expensive and wasteful principle of arrangement. The same might be said of devoting an equal width to the studies as to the public galleries, and on this point we might be guided

* Secretary to the Zoological Society of London.

* "Parliamentary Papers," Vol. XVI., 1860.

by Professor Maskelyne's opinion, that a depth of 25 feet from window to wall was essential for the instrumental requirements of the mineralogical private rooms.* Dr. Wallace raised other objections, but these were not associated with constructive details, and will be considered under the head of "Arrangements."

Typical Plan for National Museum of Natural History.—As Professor Owen's and Dr. Sclater's proposals embody the guiding ideas of British naturalists on museum construction, I will give the details of a plan that embraces the practical points of both systems. The main walls of the principal building would form a hollow parallelogram, as shown in Figs. 3 and 4. In elevation it would consist of a basement devoted to storage, workrooms, and workshops, wherein any operation *not requiring the use of fire or artificial light could be carried on.* The ground-floor would comprise the VERTEBRATE GALLERIES, 30 feet high by 50 feet wide, lighted by windows on the outer side, placed at 10 feet above the ground, and studies, store, and keeper's rooms, etc., running parallel with such galleries, in two tiers 15 feet high by 25 feet wide, lighted by windows looking out into the open court, with doors on the lower tier opening into the public galleries pertaining to the same CLASS of objects. The walls that separate the galleries from the studies being pierced to allow of wall-cases being employed in the manner shown in my next paper (Figs. 7, 8). All the lower tiers of studies would communicate one with the other by doors fixed in the walls that separate one CLASS from another, to give the student ready access from one CLASS to another. On the ground-floor a single-storeyed gallery, *lighted from above*, devoted to the proper display of birds, would intersect the open court. The upper floor would be arranged on the same principle, but be lighted entirely from above by angle windows. The galleries would be 25 feet high by 50 feet wide; the studies 10 feet high. This floor would be approached by wide staircases, S, S, at each end of the building, rising from the halls, H, H. Fig. 5 shows a section of the entire building, across B B, with the method of reflecting light into the windows of the basement, by means of white tiles placed at an angle. On entering at the main entrance, H, and turning to the left, the MAMMALIAN GALLERY (I.), 1,100 feet in length, would have to be traversed; then the AVIAN GALLERY (II.), 700 feet; the REPTILIAN (III.) and PISCEAN GALLERIES (IV.), with a united length of 1,100 feet; ascending to the upper floor the INVERTEBRATE GALLERY (V.), 950 feet long; next the Botanical Gallery (VI.), 200 feet long, with its Herbaria adjoining; then the Mineralogical Gallery (VII.), 500 feet; and the Gallery of Stratagraphical Geology (VIII.), 450 feet long, provides for the continuous survey of Nature from the mammal to the crystal, as required by the memorialists of 1858, and other naturalists. In front of this would stand the Rotunda, including on the ground-floor the theatre T, 76 feet in diameter. The galleries of Elementary Natural History and British Natural History are situated at E, E, and surround the circular building, to which light is admitted by side windows from the OPEN COURTS, C, C, C, C. The entrance-hall is at H, and at S are stairs leading to and from the upper floor, which contains the ethnological and geographical groups, arranged after the idea faintly indicated by the late Professor Edward Forbes at the Crystal Palace, in a domed rotunda, G, 150 feet in diameter, as required in Professor Owen's scheme, which also might contain, within the plane of the dome, as closely associated with geographical science, a large orrery, O, O, as in Fig. 6, which represents a section across A A. On each side of the rotunda are placed two blocks, the one on the right devoted to the reception-rooms and offices, D, of the director or superintendent, his secretary, etc.; and the private rooms, K, of the keepers of the zoological, botanical, mineralogical and geological departments; L, the lodge and apartments of the night guardian; and on the upper floor the library of general natural history, B. The left block is devoted to the lodge of the day guardian, L; refreshment rooms, R; guard-room and fireman's apartments, and watch-tower, F, F; and on the upper floor workshops, W, for purposes requiring the use of gas and fire; and M the mineralogical laboratory, lapidaries' room, etc. The lower rooms are lighted by side windows, the upper floors by angle lights. Covered ways for the protection of carriages on rainy days are provided between the wings of the two side buildings, indicated by the dotted lines between F and L and D and L (Fig. 3). Fig. 6, as we have remarked, represents a section across A A (Figs. 3 and 4).

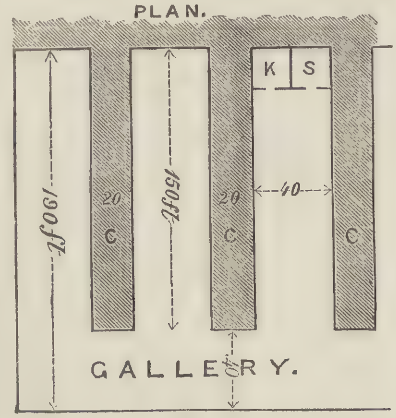


Fig. 1.

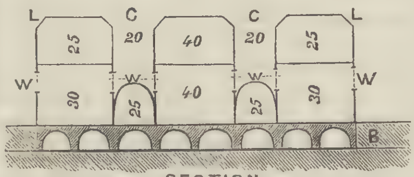

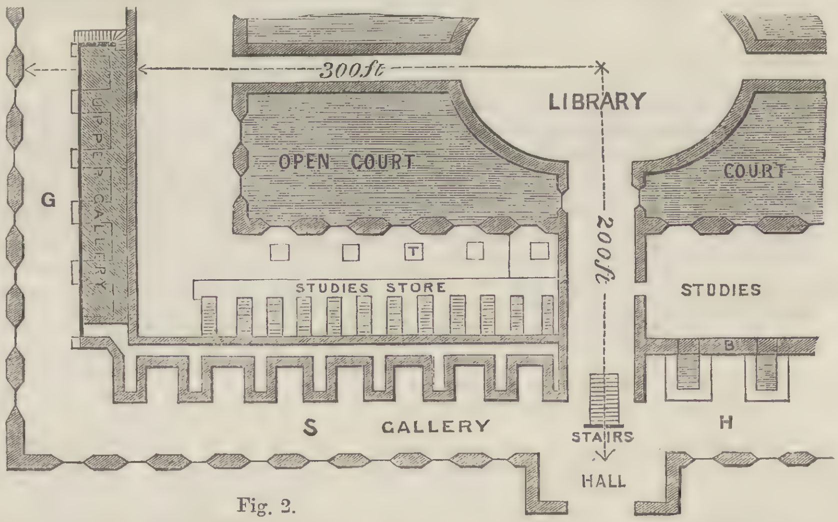

Fig. 2.

Provision against Fire.—At the present day houses for the keepers of certain departments are attached to the British Museum, but, as Professor Owen observes, "official residences, with servants, and especially with children, are elements of danger" to a national collection, he has not included space for such dwellings in his plans for a national museum. In connection with this observation, it may be stated that so greatly is risk from fire estimated by the present trustees of the British Museum, that though for years past Professor Maskelyne has urged the necessity for a small chemical laboratory, wherein the analysis of the minerals under his charge could be conducted, the trustees have uniformly declined to accede to that request, or allowed him, till within the last year or two, to temporarily rent, at small annual expense, an existing laboratory in the

* See "Committee on British Museum," Vol. XVI., 1860.

immediate neighbourhood, as one of their rules forbids a light or fire of any kind to be used within the walls of the museum, while another forbids any specimen to be removed from the building; so the keeper of the mineralogical collections has for many years been barred by the trustees from determining one of the most important characters of a mineral species or variety, though his scientific reputation was at stake on the matter of the correct naming of the specimens exhibited to the British public in their national museum.

The galleries of systematic natural history, as I have previously remarked, are planned for the perfect exclusion of artificial light and fire, provision being made for its being heated by hot-water systems, with isolated furnaces. The same rule would apply to the right-hand block, as containing the general library and the directors' and keepers' official documents, correspondence, official catalogues, etc. The left-hand block would be constructed with every provision against the extension of fire, should one occur, in laboratory, workshop, refreshment-rooms, or guardian's residences. The lecture theatre, the galleries of elementary natural history, of ethnology and geographical distribution, might be lighted by a gas system similar to that found to work so well in the South Kensington Museum. The supply-pipes should be arranged outside the building, with provision for instantaneously cutting off the supply by external main-taps. Gas properly arranged in a museum conduces to good ventilation, and causes less mischief than when there is less active ventilation, for on the gas being lighted at the South Kensington Museum on a hot summer's evening the temperature in the picture gallery has been decreased 2°, and the atmosphere of a crowded room at once materially improved.

In the Report of the Committee on Public Institutions previously cited, a curious result of some experiments on fugitive pigments is recorded. A series of sensitive tablets were prepared of uniform character, and distributed amongst certain public and private buildings. The most deteriorative effects were produced in the uninhabited National Gallery, the next worst place was an open country privy; the mischief at the former place being caused by the sulphuretted hydrogen emanating from the crowded visitors in a badly-ventilated gallery. The least effect was produced where perfect ventilation was attained by up-currents, caused by gas "sun-burners" placed in the roof of the building. The condensed gas lime-light apparatus, specially arranged for museum purposes, which has been described in this work in "Optical Instruments—Sources of Artificial light," may be advantageously and safely adopted in illuminating, as it presents the additional advantage of producing a light that exhibits *objects in their natural colours!*—a matter Dr. J. E. Gray considered unattainable by artificial illumination.

It will be noted that the rotunda and supplementary blocks are separated from each other, and this group isolated from the main building by a distance of 100 feet. Hydrants should be distributed around and within the buildings, not only for the purpose of providing against accident by fire, but also for keeping the external walls, courts, and surrounding grass-plots, pavement, etc., free from dust and smoke. The grass-plot, it is true, is not large in superficial area when compared with the great size and extent of the building, and its length makes it appear in the plan to be much narrower than it actually would be. It is, however, large enough for all practical purposes, and is, moreover, all that the space at command will allow, though the building itself would look better if it were larger.

SEATS OF INDUSTRY.—XXX.

BRISTOL (*continued*).

BY WILLIAM WATT WEBSTER.

AMONG the enterprising Bristol merchants who contributed to the fitting out of the expeditions of the Cabots, one of the most noteworthy was Robert Thorne, who claimed descent from Huldrich the Torn, uncle of Rollo, Duke of Normandy, and whose ancestors held the office of standard-bearers to the Norman house down to the conquest of England, and afterwards distinguished themselves in a variety of ways in this country. Several of his progenitors were cloth manufacturers and cloth merchants, and this would seem to have been Robert Thorne's chief trade, although at the same time he was an extensive dealer in white soap, which next to woollen cloth was the principal article manufactured in Bristol towards the close of the fifteenth and during the early part of the sixteenth centuries. Robert Thorne was appointed, along with fourteen others, to hold in commission the office of Admiral of England at Bristol in 1510, and in 1515 he was elected mayor. He represented Bristol in Parliament in 1523, and is supposed to have died a few years later, leaving his wealth to two sons, who also inherited much of their father's enterprise and public spirit. When Sebastian Cabot sailed with three ships and a caraval from Seville in 1526, on the voyage that resulted in the discovery of the river La Plata and the exploration of the adjoining districts, he carried with him the agents of various merchants whose ventures were estimated at a total of about 10,000 ducats, of which sum 1,400 ducats were contributed by Robert Thorne the younger and his partner in Seville. Returning to England in 1527, Robert Thorne the younger urged upon Henry VIII. the importance of prosecuting the work of discovery, especially towards the north, "the which," he argued in a letter to the king, "it seemeth to me, is only your charge and duty; because the situation of this your realm is thereunto the nearest and aptest of all other, and also for that you have already taken it in hand." In May of the same year "King Henry VIII. sent two fair ships well manned and victualled, having in them divers cunning men to seek strange regions," but the voyage was not prosperous. Robert Thorne the younger amassed great wealth, and his benefactions were liberal and wisely divided. Besides devoting a large sum of money to the rebuilding of Walthamstow church, supposed to have been originally erected by his ancestors in the eleventh century, and expending a smaller amount in founding a scholarship at the Merchant Taylors' school in London, this patriotic merchant bequeathed £300 for the purchase of a site for a grammar school at Bristol, £308 for the formation of a fund for buying corn and wood when they were cheap and selling them to the poor of Bristol at cost price when they were dear, and £500 which was to be lent in small amounts, interest free, to needy and deserving clothiers of the town. His brother Nicholas was also a benefactor of the Bristol Grammar School, and shared in the trading expeditions to the New World that laid the foundation of our colonial empire. Towards the end of the year 1534, it is recorded that King Henry "came disguised to Bristol, with certain gentlemen, to Master Thorne's house, and secretly viewed the city, which Master Thorne showed him; and he said to Master Thorne, 'This is now but the town of Bristol, but I will make it the city of Bristol.'" On the dissolution of the monasteries in 1540, Bristol, which till that date had been included in the diocese of Salisbury, was made the seat of a bishopric, and the conventual church of St. Augustine, which was saved from the Iconoclasts through Nicholas Thorne's intercession with the king, was made the cathedral. This merchant served Bristol in the capacity of member of Parliament in 1537, and as mayor in 1545. About the latter date Bristol furnished twelve ships for the war with France in which Henry VIII. was then engaged, the three largest vessels being the *Thorne* and the *Pratt*, each of 600 tons burden, and the *Gournay* of 400 tons, so called after the merchants at whose cost they had been built. The inscription on the magnificent tomb erected to the memory of Nicholas Thorne in St. Werburgh's describes him as "a famous and upright merchant, whose words were governed by truth, and whose deeds were ruled by justice and by virtue, whom the whole community of Bristol acknowledged as a munificent father; for by his bounty they were blessed."

During the reign of "Bloody Mary" three Protestant martyrs were burned at the stake at Bristol. Four ships were dispatched from the port in 1588 to join the fleet that was sent to oppose the Spanish Armada, and in 1574 Queen Elizabeth visited the city. When Sir Humphrey Gilbert asked the queen in the latter year to sanction an expedition of discovery and trade to the northern parts of America, "of all unfrequented places the only most fittest and most commodious for us to intermeddle withal," as he said, and "fatally reserved for England and for the honour of her Majesty," we find that "the city of Bristol very readily offered £1,000" out of the £4,000 required for the undertaking. The merchants of Bristol played a prominent part in the settlement of Virginia, and also in that of the more northern colonies. Three years after the issue of the patent for New England, which is dated 1620, James I. wrote to the authorities of Bristol and Exeter, requesting them "to move persons of quality to join in the advancement of that plantation, a work in which the public take great interest and likely to bring in good returns;" and Bristol readily complied with the request. Documentary evidence has been preserved of the early connection of many of the merchants of the city with America. A petition dated 1638, and signed by "Walter Barrett, Walter Sandy and Co. of Bristol, merchants," sets forth that "they have been many years settling a plantation in New England which was begun long before such multitudes of people went over; all they intend to send are regular people, neither factious nor vicious in religion; their plantation is apart from all others, and they desire to transport 180 persons; to provide victuals for furnishing the ships employed in the fishing trade upon that coast, for which they have built and made ready two ships." In 1651, "Lieutenant-Colonel Robert Yeomans and other merchants of Bristol, owners of the *Mary and Francis*," obtained permission from Cromwell's Council of State to accompany the fleet going to Barbadoes, "upon giving security to the value of the ship and goods that she does not depart from the fleet or trade with any in defection from the Commonwealth;" and in 1657 leave was given to Mr. Ellis, of Bristol, to send 1,000 dozens of shoes to the island of Barbadoes in January, and another 1,000 dozens in December. By a Commonwealth order of 1652, "liberty was given to Henry Hazard and Robert Yeomans, of the city of Bristol, merchants," to quote from Sainsbury's "Calendar of State Papers, Colonial Series," where the above particulars are also to be found, "to carry 200 Irishmen from any port in Ireland to the Caribbee islands!" It was from Bristol that William Penn sailed in 1682 for the New World. Being peculiarly affected in the controversy about ship-money, Bristol naturally espoused the cause of the Parliament in the Civil War, and was garrisoned by a body of the popular troops. It was besieged by Prince Rupert in 1643, and surrendered within three days through the treachery of the governor, Nathaniel Fiennes. For two years the royalists held the city, but it was assaulted and captured by Fairfax in 1645, when the castle was dismantled and the fortifications destroyed by order of the Parliament. After the restoration of Charles II., some of the inhabitants of Bristol would appear to have been affected by the reaction against Puritanism that then set in. There were two parties among the merchants of the city, and the strife was carried on with great warmth. After serving as Recorder of Bristol for twenty-one years, Sir Robert Atkins said in 1682, "I did all I could to join them together and unite them; for ever since they grew rich and full of trade and knighthood—too much sail and too little ballast—they have been miserably divided." The moral condition of the city at this period is described in the following terms by another citizen:—"Vice, profligacy, and a disregard of civil and moral obligations had entered the city and taken possession of her high places. The sacred fount of justice was polluted, her laws violated, and religion herself, in her holiness and her purity, was degraded to an instrument of cruelty, oppression, and wrong. In their abundance the people had forgotten the God they had acknowledged in their extremity. In their elevation, pride and the lust of power had supplanted the meekness and humility with which they were clothed in their adversity. They cared not to traffic with the bodies and souls of men, so that they supported their state and maintained their rule." The latter sentence of this heavy indictment refers to the share that Bristol merchants had in the African slave-trade, which was first added to the list of English trades by Sir John Hawkins, one of the famous Devonshire sailors of Queen Elizabeth's time, although it had been carried on upon an extensive scale by

the Spaniards and the Portuguese for more than a century previous to that date. Bristol was greatly enriched by its participation in the slave-trade, and continued to prosecute it with ardour till the suppression of the iniquity in 1807. Between the years 1795 and 1804, Bristol merchants shipped a total of 10,718 negroes from Africa to America and the West Indies.

Among the merchants who flourished in Bristol in the end of the seventeenth century, the most famous was Edward Colston, the last of a family that had been connected with the city since the year 1400, and several of whose members had filled important offices. It is chiefly as a philanthropist that Edward Colston is remembered. The first forty-five years of Colston's life were spent in London, but after the death of his father, which took place in 1681, he settled in Bristol, and carried on the business he had inherited, which consisted principally in sending ships to the West Indies with English goods, and bringing home sugar and other commodities. In 1689 he and his partners, Richard Beacham of London, Sir Thomas Day, and a Captain Nathaniel Wade, who had in his youth gone to New Jersey to form an ideal colony, and more recently had been implicated in Monmouth's rebellion, set up a sugar refinery at an old house known as the Mint, and in that year Colston took up his abode in the quaint house at Mortlake, still standing as a ruin, where Oliver Cromwell had lived before him. The benefactions of this merchant are too numerous to record. Every year he went through Whitechapel prison and the Marshalsea to empty his purse in freeing the most deserving debtors incarcerated for small sums, and in one case he sent £3,000 to liberate the poor debtors in Ludgate prison. He gave £20,000 to relieve the starving poor of the city of London in 1709, a year of famine, and in the following year he was returned as member of Parliament for Bristol, although he protested that he was too old to discharge the duties of that position, being then in his seventy-fourth year. Edward Colston's charities were so numerous and so munificent that they roused the jealousy of his brother citizens. In 1702, when he proposed to increase the number of Queen Elizabeth's Hospitallers from 50 to 100, the Bristol aldermen at first refused the gift, and denounced the institution as "a nursery for beggars and sloths, and rather a burden than a benefit to the place where they were bestowed," a criticism, however, that may not have been altogether devoid of truth. In 1707, Colston founded an hospital with school attached to it, in which about 100 boys are educated, maintained for seven years, and then apprenticed. He died at Mortlake in 1721, at the age of eighty-five.

When Queen Anne visited Bristol in the beginning of the eighteenth century, the splendour and cordiality of the reception she received made so great an impression on her that she said, "I never knew I was a queen till I went to Bristol." The charter of the city was confirmed by this sovereign. It was from Bristol that Dampier sailed on the voyage in which he fell in with Alexander Selkirk, the prototype of De Foe's "Robinson Crusoe." The history of the city throughout the eighteenth century is marked by few prominent incidents; but we may state that in 1761 Bristol contained nearly 100,000 inhabitants, and in 1799 there were twenty sugar refineries in the town, and no less than seventy full-sized vessels belonging to the port were engaged in the West India trade, sugar and negroes being then the staple articles of Bristol commerce. Serious bread riots took place in Bristol in 1753, and other disturbances broke out in connection with an agitation for the abolition of the bridge-toll in 1792. The most notable of the merchants of Bristol at that time were William Miles and his son Philip. In his interesting and elaborate work on "English Merchants," Mr. H. R. Fox Bourne gives the following account of the early history of William Miles:—"Somewhere near the year 1760—so the story goes—William Miles walked into Bristol with three-halfpence in his pocket, and a resolution to use his ready wit and his strong arms in advancing his then very slender fortunes. Taking the first porter's job he could meet with in the streets, he earned sixpence thereby. With fourpence he managed to buy food enough for the day, and to find some sort of lodging for the night. Next day he earned more, and earning each day more than he spent, he worked on as a street porter till he had saved a sum of £15. With that he apprenticed himself for three years to a carpenter and joiner, and during those three years he earned some more money and gained some further experience by doing evening work for a small ship-builder in the neighbourhood. He thus qualified himself, when his apprenticeship was over, for going out as a ship's carpenter in a Jamaica merchantman. While in Jamaica he applied his little savings in buying a cask or two of sugar, for which he was allowed free passage to Bristol, and while there he managed to sell at a considerable profit. With the proceeds he procured a little stock of such articles as he thought there was the best market for in Jamaica. So he went on, from each voyage earning more money, and enabling himself to carry on a larger traffic. Thus he came to be known on both sides of the Atlantic as a man of remarkable energy and honesty, and as soon as he had capital enough he settled down as a merchant in Bristol with certainty of success. So well did he succeed that in 1795, when his son Philip John, then twenty-one years of age, proposed to marry a daughter of the Dean of Lismore, he was rich enough to hand him a cheque for £100,000, and so, it was said, to remove the opposition of the aristocratic clergyman to association with the family of a self-made man." The son was a partner in his father's business, and carried it on after his father's death in 1805. Although he lived in princely style and spent his money freely, Philip Miles left personal property, at his death in 1848, valued at upwards of a million sterling. Conrad Finzel, a native of Frankfort, was an eminent Bristol merchant contemporary with the younger Miles, whose career was even more remarkable than that of the elder Miles. Flying from his native country to escape the conscription, Conrad made his way to London, where he found employment in a sugar refinery, and soon rose to be second boiler in the establishment, and which he left to become principal refiner in a sugar-house at Bristol. By 1836 he had earned and saved enough money to enable him to join with a partner in the working of a small refinery in Counterslip, on the site of which now stands the largest sugar refinery in the world, built in 1846 at a cost of £250,000, which yields 1,000 tons per week, and gives constant employment to more than fifty large West Indiamen. This establishment belongs to Messrs. Finzel, Son, and Co. Besides the profits of his own works, Conrad Finzel, during the latter years of his life, derived an income of about £10,000 a year from royalties paid to him by other refiners for the use of the vacuum pan and centrifugal vat for making crystals, which he had invented and patented. This merchant prince bestowed his means lavishly on charities of all sorts, and especially on the Orphan House established at Ashley Hill by his countryman, the Rev. George Müller, his gifts to which amounted during several years to £10,000 per annum. He persistently refused to accept any public function; and when elected as an alderman without his consent, he replied to the urgent entreaty of some of his fellow-citizens to serve the city in that capacity—"God gave me a faculty to be a good sugar-boiler, but no turn or talent to be a town-councillor." Conrad Finzel died at Wiesbaden in 1859, while on a visit to his native land.

PRINCIPLES OF DESIGN.—XXXI.

BY CHRISTOPHER DRESSER, PH.D., F.L.S., ETC.

STAINED GLASS.

In the Earthenware or Majolica Gallery of the South Kensington Museum a number of windows have been placed bearing subjects illustrative of the potter's art in various times, which are drawn in black on a plain light glass. Some of these are excellent, and most of them are well worth seeing.

Nearly twenty years since, when a comparatively young student at art, I was struck with the beauty of the frost on the window-pane such as we commonly see in winter on the glass of our sleeping-room windows, and was led to make sketches of some of the more beautiful forms. Ten years later I founded a style of window decoration on these sketches, and to this day I regard some of the patterns which I produced from these sketches as consistent and desirable enrichments for stained glass, and as my favourite works. Of these designs one was engraved (Fig. 143) in my last article. If this pane of glass be formed of a pale amber sheet of rich cathedral glass with the pattern drawn boldly in black, it will be such as I think satisfactory. Instead of the whole being formed of one piece of glass, the various parts may be differently tinted, and the whole leaded together, if colour is desired.

In the present chapter I engrave another design of a somewhat similar character, but consisting chiefly of curved parts (Fig. 146). Of the two I prefer the former and more simple treat-

ment, but when considered together, the two may give rise to a new style in domestic window glass.

In the last chapter I also gave an illustration of a bordering (Fig. 144), such as might be placed round a plain sheet of plate glass: this border would give colour and decorative effect, and its treatment I regard as correct. It is often desirable to form a window of small parts, or quarries, and if these are well managed very effective windows may be produced. These quarries may be enriched with conventionally treated plants, where the entire plant may be of one colour, and the background of another (old quarries are often met with bearing a flower, or a bird, or an animal, simply and conventionally drawn in outline on a pale green-grey glass, and having the figure filled with a yellow tint), or the flowers may be separated from the foliage by a third tint. Fig. 147 is an adaptation of the fuchsia, and Fig. 148 of the corn cockle (*Githago*), and in this last instance the leaves are arranged into the figure of the fleur-de-luce. Fig. 149 is only of floral character, but is not founded on any particular plant. Fig. 150 is after the type of the lotus bud. Fig. 151 is less floral in character, but retains a little of the vegetable type, while Figs. 152, 153, and 154 are wholly conventional in character.

Although I have occupied my space chiefly with illustrations, I may be excused for adding a few more remarks on art in glass painting, proceeding by saying, that if a window is placed in a very sunny situation, where it is intended to act in part as a blind, the introduction of a considerable amount of black, as in Figs. 147 and 149, is sometimes desirable, and certainly gives great force to the pattern.

To return for a while to Fig. 143, we have already remarked that the strong black lines of the pattern would look very effective when drawn on a pale amber-tinted sheet of cathedral glass. The effect of this may be ascertained approximately by drawing the design on a thin piece of lemon-coloured paper, and holding it up to the light, or even fixing it to a pane of glass. It must be remembered, however, that it will be impossible by this simple contrivance to gain anything more than an approximate idea of the actual appearance of the pattern when drawn on glass of the tint suggested, as the glass affords a transparent medium, while the paper is opaque, or partially so. The design may be applied in a variety of ways. It is suitable for a long, narrow, lancet-headed light, in which the pattern may be repeated thrice or four times, as shewn in the figure; the pointed pane at the top of the light being filled with the lower part of the design, which is confined by two curved lines springing from either side of the base, and meeting in a point a little above the actual centre of the drawing, as it is figured in the diagram. If the light be broad enough, the three or four sheets thus treated may be surrounded by a narrow border, in which, on a black ground, might be depicted amber leaves springing from a continuous stem running up the centre of the border, and turned alternately in opposite directions. Such a border would be in harmony with the central part of the window, the tints used for pattern and ground in the one being simply reversed in the other; but if it be preferred, there is no objection to the use of deeper and richer colour in the border, though, if this were done, the colour used should present a satisfactory contrast to the tint on which the pattern is delineated, as without strict attention to this, the effect produced will be far from pleasing to the eye. The same design may be used in sheets of glass placed side by side, as, for example, in the four window-panes frequently used to form the centre of a glazed door, and surrounded by panes of less width.

Fig. 146.

The border shown in Fig. 144 is adapted for the enrichment of a window, of which the centre is comparatively plain and simple in design, and devoid of much colour, as in the window shown in Fig. 145. Such a border presents a rich and beautiful effect when painted in three different tints of the same colour, the portion that is perfectly black in the design being painted in the darkest of the three tints—a tint, in short, approaching very nearly to black, or being the darkest possible shade of the colour used; while that which is white in the figure should be of a very light tint of the colour, and the part that is shaded of a tint forming as nearly as possible a mean between the darkest and lightest tint used. Another satisfactory mode of treating the design would be to allow the parts shown in black and white in the figure to be black and white in the painted copy as well, and to colour the shaded portions in any single tint forming a mean between black and white, that would be in harmony or pleasing contrast with the colours of the centre round which the border is disposed. The same mode of treatment will apply in an equal degree to the colouring of the figures given with the present chapter, and we may point out here, what may have already occurred to many of our readers, that a beautiful window may be formed out of Fig. 146 simply by repeating the design and border, so as to form a symmetrical pattern on either side of the central line, which, in case of a duplication of the design in this way, would be the line that now forms the boundary of the pattern on the right.

In forming designs for quarries, or small diamond-formed pieces of glass, similar to those shown in the opposite page, it is useful to search for plant-forms either common or peculiar to the neighbourhood in which the work is intended to be placed. In every district something worthy of conventional treatment may be found, and it is as right and necessary to use such forms for decorative art, whether in colour or carving, as it is wise in building to avail oneself of the building materials that the district yields.

BUILDERS' QUANTITIES AND MEASUREMENTS.—XVIII.

BY E. WYNDHAM TARN, M.A.

BILL OF QUANTITIES (*continued*).

TILER AND SLATER.

SQR.	FT.	
$10\frac{1}{3}$		Supl., plain-tiling, showing 4 in. on face, double fir laths and wrought nails .
$8\frac{4}{5}$		,, pantiling, 10 in. gauge, bedded in mortar and pointed . . . . . .
9	44	,, Countess slating, $2\frac{1}{2}$ in. lap, each slate with 2 $1\frac{1}{2}$-in. copper nails . . .
$9\frac{1}{4}$		,, asphalted felt, laid under slating .
FT.	IN.	
30	0	,, $\frac{3}{4}$-in. sawn slate shelf, planed . .
61	9	,, flat roof of 2 courses plain tiles in cement . . . . . .
28	0	Run, heading plain tiling to bargeboard .
28	0	,, ditto, pantiling, ditto . . . .
31	6	,, ornamental ridge tiling in cement . . .
28	0	,, cement filleting . . . . . .
45	0	,, hip and ridge tiles in cement to pantiling
45	0	,, sawn slate hip and ridge, fixed with white lead and copper screws . .
24	0	,, rounded nosing to $\frac{3}{4}$-in. slate shelf . .
		Number—
		2 hip-hooks and painting 3 oils . . . .
		Carried to summary . . . £

MASON.

FT.		Kentish Rag—
187	6	Cube stone in bondstones . . . . .
YDS.		
132		Supl., 24-in. rough random walling . .
$131\frac{1}{4}$		,, ditto coursed ditto . . . .
274		,, pointing in blue ash mortar . .
FT.		Portland Stone—
757	8	Cube stone rough . . . .
8	4	,, ditto landings . . . . . .
46	6	Supl., 3-in. balcony . . . . . .
93	7	,, sawing . . . .
614	10	,, plain bed . . . .
710	5	,, plain work . . . .
133	5	,, sunk ditto . . . .
371	11	,, moulded ditto . . . . . .
13	1	,, circular ditto . . . . . .
75	5	,, ditto sunk ditto . . . . .
11	10	,, ditto moulded ditto . . . .
39	0	Run, lintels 9″ × 9″, in 6 ft. 6 in. lengths .
17	10	,, groove for lead . . . . .
83	3	,, chamfer . . . .
7	6	,, cutting and pinning to landing . .
96	8	,, throating . . . .
6	0	,, joggle to 3-in. landing . . . .
		Numbers in Portland—
		2 carved capitals to design . . . .
		4 mitres to cornice, 27 in. girt . . .
		2 stopt ends to ditto . . . . .
		20 mortise holes . . . . . .
		30 holes for balusters . . . . .
		17 ends of steps, cut and pinned into wall .
		28 plugs . . . .
		30 slate dowells . . . . . .
		24 lbs. lead for running plugs . . .
YDS.		Yorkshire stone—
$12\frac{3}{4}$		Supl., $2\frac{1}{2}$-in. tooled paving . . . .
FT.		
58	6	,, 3-in. templates and core for cornice .
31	6	,, ditto rubbed hearths . . . .
11	3	,, 7-in. sink . . . .
26	0	Run, sill 9″ × 3″, weathered and throated .
51	0	,, coping, 12″ × 3″, ditto . . . .
43	0	,, cutting to edge of $2\frac{1}{2}$-in. paving . .
		Numbers in York—
		12 fair ends to sills . . . . .
		2 ditto coping . . . . . .
		1 rounded corner to 7-in. sink . . .
		1 rebated hole ditto . . . . .
YDS.		Pavior—
$41\frac{3}{4}$		Supl., Elland edge pitching in sand and grouted
FT.		
30	0	Run, granite curb, 12″ × 6″ . . . .
		Marble—
21	0	Supl., 2-in. polished slab . . . . .
15	2	,, 1-in. ditto . . . .
		Number—
		4 console chimney-pieces, value 10 gs., P. C.
		Carried to summary . . £

CARPENTER.

FT.		
36	0	Cube, fir, use and waste in shoring . .
32	8	,, ditto, bond, plates, etc. . . .
138	3	,, ditto in single joists . . . .
135	3	,, ditto, framed in trusses . . .
56	4	,, ditto, girders, sawn down, reversed and bolted . . . .
4	7	,, ditto, proper doorcase . . . .
0	9	,, oak, weathered sill . . . . .
113	9	Supl., centering to vaults and arches . .
135	0	,, bracketing to cornice . . . . .
481	6	,, planing fir . . . .
60	0	,, 1-in. deal gutter-board and bearers .
27	6	,, ditto, feather-edged louvre boarding .
23	5	,, $1\frac{1}{2}$-in. ridge piece. . . . .
SQR.	FT.	
5	88	,, $\frac{3}{4}$-in. battens, $3\frac{1}{2}$-in. wide, laid for Countess slates. . . . . .
2	41	,, ditto, $2\frac{1}{4}$-in. ditto, 10-in. apart, plugged to wall . . . . . .
3	60	,, 1-in. sound-boarding on two fillets. .
3	61	,, ditto, weather-boarding . . .
RODS.	FT.	
16	0	Run, 5 feet cleft oak pales, 2 arris rails, with oak posts 9 feet apart . . .
FT.		
265	0	,, 1-in. oak plank, 12-in. wide, to fence .
265	0	,, ditto, capping, ditto . . . .
49	0	,, tilting fillet . . . .
24	6	,, 2-in. ridge roll . . . . . .
24	0	,, herring-bone strutting . . . .
14	0	,, turning pieces $4\frac{1}{2}$ ins. wide . . .
21	6	,, $\frac{3}{4}$-in. deal arris gutter, 4 in. deep . .
10	3	,, ditto water-trunk, $4\frac{1}{2}$ in. square . .
12	6	,, circular head to window frame, glued in thicknesses, 5″ × 3″ . . . . .
		Numbers—
		1 shoe to water-trunk . . . . .
		2 joints, ditto . . . .
		1 hopper-head, ditto . . . . .
		6 blocks to purlins . . . . .
		24 wood bricks . . . .
		4 angle-pieces to bracketing of cornice 18 in. girt . . . .
		4 drips to gutter . . . . . .
		2 cesspools, ditto . . . . . .
		2 oak posts, 12″ × 12″, 5 feet high . .
		1 5-bar field gate, 9 feet wide, with sawn rails
SQR.	FT.	Sawyer—
1	96	Supl., sawing fir . . . .
0	240	Run, ditto, 6 in. oak rails . . . .
		Carried to summary . . £

JOINER AND IRONMONGER.

SQR.	FT.	
2	17	Supl., 2 cut white batten folding floor . .
1	87	,, $1\frac{1}{4}$ in. yellow ditto, straight joint, ditto
1	96	,, ditto, with iron tongues . . .
FT.		
15	9	,, deal-cased frames, oak sunk sills, $1\frac{1}{2}$ in. ovolo sashes, double hung with brass pulleys, white lines, and iron weights.
22	0	,, deal-cased frame, oak sunk and weathered sill, 2 in. deal lamb's-tongue sash, doublehung, brass pulleys, patent lines, and iron weights . .
29	3	,, ditto, 2 in. ovolo sash, ditto . .
35	9	,, solid oak rebated and moulded frame, 4″ × 3″, mullion and transom, mitred, beaded, and weathered sill, 2 in. lamb's-tongue casement, circular on plan, $\frac{1}{4}$-in. rise to the foot . .
7	0	,, 2 in. oak ovolo fanlight, circular head .
16	6	,, $1\frac{1}{4}$ in. deal 2 panel square door . .
16	6	,, ditto, 4 panel moulded and square ditto
17	11	,, $1\frac{1}{2}$ in. ditto, square ditto . . .
42	3	,, 2 in. ditto, moulded both sides, ditto .

26	3	,,	2¼ in. oak 6 panel bolection, moulded ditto, lower panels bead flush
35	9	,,	1¼ in. deal 2 panel bead flush, and square shutters, hung with brass pulleys, patent lines, and lead weights
15	2	,,	ditto, moulded and bead flush, folding ditto
13	0	,,	ditto, bead flush and square back-flaps
10	3	,,	ditto, proper boxings
105	4	,,	deal revolving shutter, with worm and wheel gearing
66	0	,,	1½ in. yellow deal treads, and 1 in. risers, glued and blocked to close-string, moulded nosing and two fir carriages
19	3	,,	ditto, ditto, winders
69	11	,,	1½ in. yellow deal treads, 1 in. risers, mitred to cut-string, glued and blocked, with moulded nosings, and 2 fir carriages
17	11	,,	ditto, winders
13	9	,,	ditto, rebated and beaded outer string, cut and mitred to risers
1	6	,,	ditto, writhe
11	11	,,	ditto, close-string
35	0	,,	ditto, wall ditto
19	0	,,	ditto ramp
21	11	,,	¾-in. deal, wrought 1 side and framed
2	3	,,	ditto, and beaded
8	0	,,	ditto, rebated and beaded
7	6	,,	ditto, both sides, and dovetailed
14	0	,,	ditto, tongued
31	8	,,	inch deal, wrought 1 side and tongued.
66	1	,,	ditto, and rebated
29	9	,,	ditto, square skirting
30	5	,,	ditto, torus ditto
7	11	,,	ditto, 1 side framed, moulded in 1 panel
21	9	,,	ditto, keyed frieze, joints feather-tongued, rebated for soffit
26	8	,,	ditto, wrought both sides
3	0	,,	ditto, framed and beaded
8	3	,,	1½ in. wrought 1 side, framed, moulded in 2 panels
9	7	,,	ditto, 1 panel
26	4	,,	ditto, both sides
42	3	,,	ditto, framed and beaded
7	6	,,	ditto, cut and diminished
19	0	,,	ditto, moulded and square framing
5	0	,,	ditto, ditto, circular on plan (½-in. rise to the foot)
22	9	,,	ditto, spandril
53	9	,,	ditto, moulded and rebated skirting, in two heights
12	10	,,	1½ in. deal, wrought 1 side, double rebated and beaded
21	11	,,	ditto, framed and moulded
18	2	,,	2 in. deal clamped dresser top
43	6	,,	cradling to entablature, ploughed and tongued blockings
24	0	,,	moulded cornice
7	0	Run,	½-in deal, wrought stop
7	8	,,	¾-in. ditto chamfered fillet, 2¼ in. wide
40	6	,,	ditto, skirting grounds, plugged
7	9	,,	ditto bead
43	0	,,	square angle-staff, plugged
9	6	,,	deal drawer runners
34	0	,,	groove
48	9	,,	ditto, and tongue
10	6	,,	1 in. nosing.
52	7	,,	ditto, skirting grounds, plugged
25	0	,,	ditto, picture grounds, ditto
4	6	,,	ditto, double beaded pinrail, 4½ in. wide
75	0	,,	ditto, architrave moulding, 2¼ in. ditto
60	6	,,	ditto, ditto, 3½ in. ditto
76	6	,,	1¼ in. ditto, ditto
6	6	,,	ditto, ditto, circular
20	0	,,	ditto, mitred border
9	6	,,	moulding, 4 inches girt
2	6	,,	ditto, ditto, circular
12	0	,,	2½ in. deal wrought and framed legs
15	6	,,	ditto, turned newells
13	0	,,	ditto, moulded handrail

We are compelled by want of space to terminate our ideal "Bill of Quantities" for joiner and ironmongery here at the conclusion of the articles which are measured by foot-run. On resuming the subject in our next lesson, we shall commence with such of the joiner's work as is taken by number.

TECHNICAL DRAWING.—LXXV.

DRAWING FOR BRICKLAYERS (*continued*).

THE example (Fig. 599) forming the subject of the present lesson is the ground-floor plan of a small villa built of malms, with stone dressings. The plan is drawn to the scale of ⅛-inch to the foot, the exterior walls being a brick and a half thick, whilst the interior ones are one brick thick.

On entering the house, we have first the hall, on the right-hand side of which is the dining-room, and on the left the drawing-room.

As the villa stands alone, or as it is termed "detached," these rooms which are at the corners have two windows each, by which means different views of the surrounding country are obtained, and the cheerful aspects are increased.

The front window in the drawing-room is a "bay" 7′ 6″ wide, and 3′ 3″ deep. This feature adds to the size of the room; makes a very pleasant recess, and is a great improvement to the elevation of the villa.

The side window may be made to open like a pair of folding-doors into a conservatory or garden; these are called "French casements."

On the same side of the hall, and immediately at the back of the drawing-room, is another smaller room, the library or study; this is also lighted by a window overlooking the garden, and thus the room is light, airy, and cheerful; but still it is from its situation removed from interruption. By placing a door where marked in the wall, access may be obtained from the drawing-room to the library, which being opened when occasion may require, will give increased accommodation.

Passing along the entrance-hall under the landing, we have a water-closet on the left, and a door leading to a little back lobby, on the other side of which is the back door leading to the kitchen garden or drying ground.

On the right-hand side of this lobby is the kitchen, beyond which is the scullery, and on the left side is the pantry and store-room.

It will be evident that when the door at A is closed, all communication between the kitchen and scullery, and the dining-room, library, and drawing-room is effectually cut off, thus preventing the annoyance, so often experienced in houses of this class, of the odour arising either from kitchen or scullery spreading into the other apartments. This door should be made self-closing by means of a spring, and could, of course, be hooked back when required.

By this disposition of the front and back doors a thorough current of fresh air passes from one side of the house to the other. They should therefore be opened together at certain periods every day, and if the windows of the rooms be opened at the same time, the whole mass of air in them will be purified. This does not apply to the ground floor only, but to the whole house.

Many persons are under the impression that a house is properly and efficiently cleansed by sweeping and dusting. There cannot be a greater mistake. Very much of the dust so disturbed rises and floats in the air, which is further vitiated by the breathing of the inhabitants, gas, etc. It is absolutely necessary not only that the floors and stairs, but the *whole atmosphere* of a house should be swept; and therefore, in the morning especially, the doors below should be opened, and the fresh air allowed to pass completely through the house, the bedroom doors and skylight having been previously opened. The impure air will thus be changed, and the comfort, cheerfulness, and health of all in the house will be improved accordingly.

The scullery or washhouse is placed adjoining to the kitchen, but may, of course, be separated from it by closing the door. The external door of the scullery opens directly on to the yard or drying-ground.

The pantry, which has already been mentioned, is for convenience placed opposite to the kitchen, so as to be as far as possible removed from the influence of the continuous fires. The floor is tiled, and slate and wooden shelves are affixed to the walls. Especial attention should be paid to the ventilation of the pantry. There should be an aperture at the bottom of the door covered with perforated zinc, and the upper panes of the windows should be replaced by pierced glass, or some other form of ventilation.

A door from the pantry leads to the store-room. The floor of

this room is boarded, and it is furnished with commodious cupboards. A small fireplace is also provided to prevent damp, and for the occasional airing of the room. A small aperture in the bottom of the door, covered with perforated zinc, will, together with the open chimney, keep the room ventilated, and more air may, of course, be obtained by opening the window. In the basement are coal, beer, and wine cellars, and other domestic offices, which would be shown in the basement plan.

This plan should be drawn on the lower part of the sheet of paper, so that the elevation may be projected from it. Great care must be taken in working accurately to the scale, and in preserving the rectangular forms of the rooms. This is best done by using the set-square against the T-square, as already explained.

Fig. 600 is the front elevation of the villa. The general widths of the various parts will be obtained by projection from the plan, whilst the heights and details are to be obtained from the examples. It is not usual in elevations to delineate the separate bricks, a few lines being merely drawn to indicate the character of the material of which the house is built. The same remark applies to the slates of the roof. All architectural drawings should be inked and coloured.

TO COLOUR ARCHITECTURAL DRAWINGS.

Assuming that the plan and elevation have been carefully inked, the next process is that of colouring them.

The plan of the walls, representing brickwork, is generally coloured with lake; but many draughtsmen prefer a full black, which really shows the exact forms to great advantage, especially in large drawings intended for exhibition.

For colouring elevations, crimson lake mixed with burnt sienna or Venetian red gives a nice tone of colour for *red* brickwork; very pale yellow ochre is generally used for malms; and the same, or pale sepia, for stonework used for the dressings. Granite is represented by pale Indian ink, and red sandstone by light red.

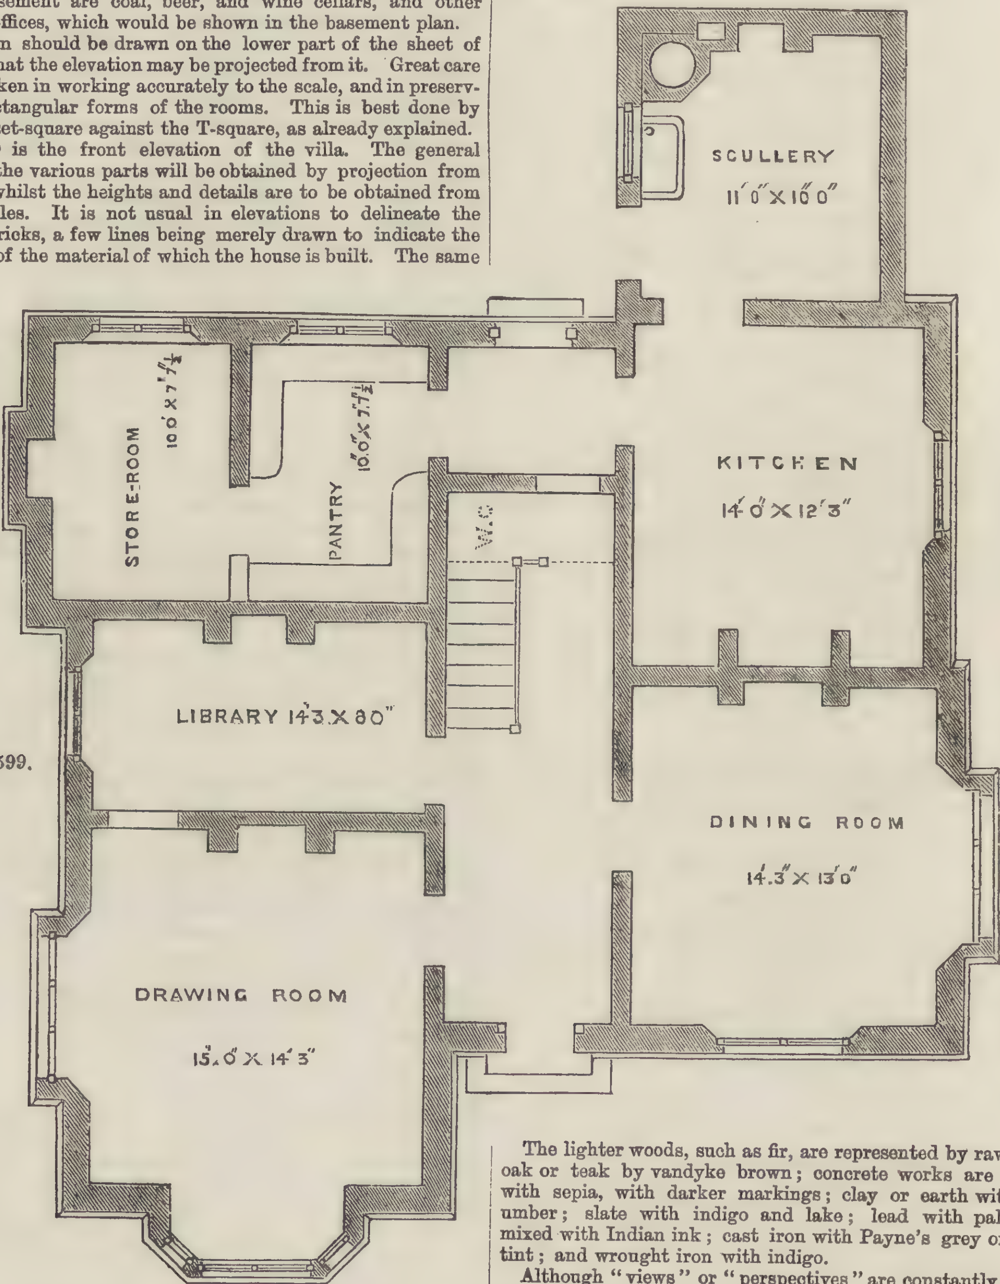

Fig. 599.

The lighter woods, such as fir, are represented by raw sienna; oak or teak by vandyke brown; concrete works are coloured with sepia, with darker markings; clay or earth with burnt umber; slate with indigo and lake; lead with pale indigo mixed with Indian ink; cast iron with Payne's grey or neutral tint; and wrought iron with indigo.

Although "views" or "perspectives" are constantly made by the architect, they are intended to show how the building will look when finished; but they are not in any way concerned in the construction. The drawings to which we have alluded are those required, and our instructions as to colouring will therefore in the present instance be limited to flat tinting, not by any means extending to "drawings in water-colours."

This must not be construed into any desire on our part to check the laudable ambition of the student; we merely wish to advise him to limit his efforts at first to that which is absolutely necessary; and this foundation once laid, a superstructure of the noblest character may with safety be raised on it.

We wish to impress on the student that no amount of shading or colouring, however well done, will improve a bad drawing; whilst a good outline will mostly represent the object without either one or the other; and therefore, although the learner is advised to spread flat tints over his earliest drawings so as to represent material only, by this means carrying on a course of improvement in both branches simultaneously, he is warned against spending time on making highly-finished picture views until he has mastered the principles of architectural construction, of architectural drawing and flat colouring, and until he shall have acquired such a knowledge of perspective as may ensure the correctness of the outline.

The colour for laying a flat tint must be very thin; it is very easy to spread another wash over it when dry, if not found dark enough, but if too dark it is not so easily lightened; in fact, this is seldom satisfactorily accomplished.

In mixing two colours, so as to produce a third, as in the case of lake and burnt sienna mentioned above, rub the colours in separate compartments of the slab, or at different parts of the palette, leaving a space between them, in which the colours are to be mixed with the brush. Never rub one cake in any other colour previously mixed; by this plan the end of the cake becomes stained, and consequently the purity of the colour afterwards rubbed from it will be impaired.

Use a large brush in preference to a small one wherever possible, especially in laying flat tints, which are liable to become streaky when coloured with a small brush.

The whole surface which is to receive a flat wash should be covered as rapidly as possible, but care must be taken that the brush does not pass over the outlines. Should this, however, occur, it is best to take up the colour covering the whole surface with blotting-paper, and allow the paper to dry; then repeat the outline, and colour as before, but with more care; the part at which the outline had been overstepped will then be visible, but of course not so dark as the rest. Now moisten this with a brush containing colour, and allow it to soak in for a moment, then take up the water from the surface with blotting-paper. Cover the part of the drawing which has been correctly coloured with a strip of paper, holding it tightly against the outline; rub the part coloured accidentally with a piece of clean india-rubber, and by this means it will in most cases be removed. If possible avoid scraping with a penknife or eraser, as the paper thus becomes roughened, and catches the dust more easily than if the above method has been pursued.

After the colour has been spread it should not be touched again whilst wet. If it should require any retouching, let this be done when it has dried; it will generally be made worse by any attempt to remedy it by stirring about in the wet colour, and, further, the surface of the paper will become roughened.

Fig. 600.

In order to obtain the necessary practice in laying flat washes, which is of great importance in architectural drawing, the student is advised to draw several squares, circles, rectangles, triangles, etc., of different sizes; to commence by colouring the smallest, and gradually proceeding to those of increased size. The brush should be held as upright as possible, so that the point and not the side may be used.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXXIV.—CHARLES SPALDING.

BY JAMES GRANT.

THIS ill-fated inventor of many improvements on the old diving-bell was born at Edinburgh, about the year 1735. He commenced life as a shop-lad; his parents were in humble circum-

stances; but being steady, thrifty, and industrious, he ultimately succeeded in establishing himself in an extensive business as a confectioner and sugar-refiner. All his leisure hours were turned to the study of mechanics, and among many other things to which he gave his attention was the diving-bell, which no man in Britain had ever attempted to use, since the days of Dr. Halley.

Spalding being a man of a brave and intrepid spirit, and inspired also by a keen curiosity to inspect the wonders of nature, made several attempts to descend into deep water with the bell, and ultimately succeeded, so that he could remain under the surface for a considerable time. This led him to consider attentively the general construction of the bell, and seek to render it more useful and safe.

The diving-bell is most conveniently made in the form of a truncated cone, the smaller end being closed and the larger opened. It is to be poised with lead, and so suspended, that it may sink full with air, and with its open face downward, and as nearly as may be in a situation perfectly parallel to the horizon, while the diver, sitting under it, sinks down with the included air to the depth required. If the cavity contained a ton of water, it would hold air sufficient for a man, for a full hour, at six fathoms deep; but the lower he went, the included air contracted, according to the pressure of the water, into a compass so small, as to become heated and unfit for respiration, so that there was a necessity for it being drawn, to recruit it, and then generally the diver was almost covered with water. To obviate these difficulties, Dr. Halley had contrived an apparatus which not only recruited the air from time to time, but also kept the water wholly out of the machine, which was so loaded with lead, that it would descend in a perpendicular direction, but no other. In the top was a window to admit light, and a cock to let out the hot air, while the fresh was supplied from two barrels that rose and fell like two buckets in a well; while by an additional contrivance, the diver could quit the bell and walk some distance, the air being constantly conveyed to him in a machine by small flexible pipes.

Such was the diving-bell as left by Dr. Halley, who died in 1741, and in it Spalding discovered several dangerous tendencies, the two chief being:—1st. The sinking or raising of the bell depended on the people who were at the surface of the water, as the bell when under it attained a very considerable weight, and thus to raise it required not only a great deal of labour, but there was a possibility of the suspension ropes breaking, and every person within it perishing. 2nd. As there are in many parts of the sea rocks, the form of which cannot be perceived from above, there was a chance that some of their ragged projections might arrest the edge of the bell in its descent, and thus overset it, before the divers could give any signal to those above, an event certain to be attended by the total destruction of all within it, as before trial it is impossible to know what the bottom of the sea may be like.

To obviate these defects and dangers was the first task of Spalding, and this object he attained in the following manner:—On iron hooks he suspended leaden weights to keep the mouth of the bell *always* parallel to the surface of the water, whether the machine taken is lighter or heavier than an equal bulk of water. By these weights alone, however, the bell would not sink, so he added another to be raised or lowered at pleasure, by a rope passing over a pulley and fastened to the sides. This he called "the balance weight," as it hung considerably below the mouth of the bell. It served also as an anchor, to keep the bell at any particular depth which the divers may deem necessary, or by pulling it quite up the descent may be continued to the bottom. By another ingenious contrivance, too long for description here, Spalding rendered it possible for the divers below to be independent of those above, and to raise the bell with all its weights to the surface, or to stop its descent at any depth they chose. For the wooden seats used by Dr. Halley, he substituted ropes, suspended by hooks, with two side windows of strong glass for the admission of light, and he maintained that one air-barrel, capable of containing thirty gallons, was sufficient for an ordinary machine. Steele, Rowe, and James have made considerable improvements since, even on Spalding's bell, but such was the nature of the machine in which he made several descents, and which finally, towards the close of the last century, attracted the attention of the government.

He became so proficient as a diver that he could remain in his bell for several hours at the depth of fourteen fathoms, and the *Edinburgh Advertiser*, for 1783, records that a lady and a gentleman named Watson went down with him in Leith Roads, "and remained at the bottom of the sea for half an hour."

A ship from London, bound for Leith, on board of which Spalding had much goods consigned to him, having been cast away, he made a proposal to the owners of the general cargo, "that if they would bear a share in the general expenses of his journey to where the wreck lay, he would make every effort in his power for the recovery of their joint property." On their declining, Spalding at his own risk visited the wreck, and though he recovered little or nothing of his own consignment, being chiefly sugar and other perishable commodities, he brought up much that belonged to others, which no law could wrest from him.

Few events at the time created a more profound sensation in Britain than the sinking of the *Royal George*, a line-of-battle-ship of 108 guns, which turned over when undergoing what the sailors term "a Parliament heel," in Portsmouth harbour, when the venerable Admiral Kempenfeldt (then in his seventieth year), and upwards of 400 officers, seamen, and marines, with nearly 200 women, perished, on the 29th of August, 1782. Immediately upon this, the Admiralty and Navy Boards sent to Edinburgh for Spalding, to have the wreck inspected, and, if possible, raised wholly or in part. He engaged to do this on condition "that he was to have one-third of all the property he could raise belonging to the *Royal George*."

To this the Lords of the Admiralty agreed, and he paid the wreck a series of visits in his diving-bell, and brought up seventeen brass guns, several of iron, and other stores to the value of £1,000, the whole being estimated at thrice that sum. For this, however, he only received £400, half of which went for his expenses. He reported "that the ship lay in very bad ground, surrounded by tides, and very deep."

The newspapers of the time record, that "Mr. Spalding being down, one very clear day alongside the *Royal George*, perceived every object on board as distinctly as above water, and beheld one of the most tremendous and shocking spectacles that the human mind can form. Great numbers of the dead bodies in various attitudes; some clinging to the carriages of the guns; others crushed with the guns above them; and when it is recollected what visages they must have in that state of putrefaction, no imagination can paint it without the utmost horror. But what sensations must he have felt when viewing it in reality! Through the cabin-windows he could see the body of the admiral floating about."

On the cold season setting in, he returned to Edinburgh in the October of 1782, pledging himself to resume operations when the weather permitted. In the meantime, he was sent for by the underwriters of the *Belgioso*, an Imperial East Indiaman, which had been wrecked some time before in Dublin Bay when outward bound from Liverpool. Every soul on board perished with her. Her cargo was valued at £150,000, of which £30,000 were in silver and lead, and their agreement was, "that he should have one-fourth of the silver and lead, and one-half the rest of the cargo; and though he should not recover an article, they were to defray his expenses from the day he left Edinburgh to the day he returned." As she lay in ten fathoms water, and six miles from the shore, not amid quicksands, with her masts visible at ebb, there was every prospect of his realising the liberal offers of the Liverpool underwriters prior to resuming his labours on the *Royal George*, the wreck of which he proposed to blow up, as has since been done, by gunpowder. At this time he was also in correspondence with Commodore Elliot, the Governor of Gibraltar, who wished him to raise 400 brass cannon, that were sunk in the Bay by the Spaniards when they abandoned the siege of that fortress on the famous 13th of September, 1782.

In May, 1783, he was at Dublin, and anchored his small brig in the Bay, with his diving-bell on board. On this occasion he was accompanied by a friend, Mr. Ebenezer Watson, also of Edinburgh, and together they paid four visits of inspection to the wreck of the great Indiaman, which lay near a place called the Kishes.

The fourth visit was paid by them on the 3rd of June, when the water was seven fathoms deep, and they were below it exactly an hour and a quarter. During the first hour the signals had

been properly attended to, and three supplies of fresh air were sent down; but it is supposed that unhappily, by some blunder of those above, the last barrel failed to reach them, and thus brought on almost instant suffocation. It must have been so immediate as to have prevented Spalding from adopting the mode of preservation invented by himself—viz., that of cutting away the weight that hung from the centre of the bell, by which means it must have instantly risen to the surface.

On drawing up the bell, Spalding and his young friend Watson were both found dead, the former resting on the breast of the latter, who was sitting erect in the slung seat. No medical man being at hand, when the brig ran into Dublin harbour all attempts at recovery were futile. At the inquest, the captain asserted that the signal ropes must have become entangled below water. By this catastrophe Spalding's widow and seven children were left in penury, and Watson's aged mother. The event made some sensation in Dublin, where Spalding and Watson were interred together in the churchyard of St. Mark. They were borne shoulder-high by the crew of his brig, and were preceded by the marine boys singing hymns. Many of the most influential citizens attended the funeral, and all the vessels in the harbour and bay had their flags half-hoisted as a tribute to Spalding's memory.

SHIP-BUILDING.—XVI.

BY W. H. WHITE,

Fellow of the Royal School of Naval Architecture, and Member of the Institution of Naval Architects.

THE DECKS OF SHIPS.

Decks were originally constructed in ships solely for purposes of convenience and accommodation; now they are recognised not only as valuable platforms, but also as important contributories to the structural strength. In some of the earlier papers attention was directed to this fact, and the usefulness of decks in assisting to prevent changes of form in either the longitudinal or the transverse direction was illustrated. Consequently it is unnecessary here to discuss the subject further; but taking for granted the importance attaching to the proper construction of decks, and their connection with the other parts of the structure, we will attempt to show how in practice these special requirements are met. As in other cases, our treatment must necessarily be brief, and only the principal features of the various arrangements can be described.

The surface of a deck is curved both longitudinally and transversely. The longitudinal curvature is termed "sheer," and the transverse curvature "round up." The latter is mainly given in order to facilitate the flow of water to the sides of the ship, where "scuppers" are formed to permit it to pass overboard. Sheer is given to the decks mainly for the sake of graceful appearance in the upper boundary lines of gunwales and topsides; the foremost and aftermost ends of the deck being usually higher than the amidship part. It is very commonly supposed that a loss of strength is caused by giving sheer to the decks instead of having them straight; but this is not true, provided the decks are so strongly connected with the sides of the ship, as to prevent any change in their relative positions; and there is no practical difficulty in securing the strength required for the purpose. Some ship-builders have even gone so far as to give the decks longitudinal curvature in the reverse sense from that usually given, thinking that the *arched* form thus obtained would be most valuable in resisting hogging strains; but in doing so they have overlooked the facts, that sagging as well as hogging strains have to be resisted, that change in the longitudinal form of the ship must affect the sides as well as the decks, and that the great aim of the builder should be to secure joint action and mutual support between the sides and decks.

Structurally considered, decks may be said to consist of the "flat" and the "framing." Under the former heading may be included the planking forming the platform upon which the various fittings are constructed, and the different weights directly rest, together with any iron plating that may be fitted beneath the planking. As framing may be reckoned those pieces which support the flat, just as the frames support the skin of a ship, these pieces are named beams, half-beams, carlings, etc., and closely associated with them are other pieces named "shelfs" and "waterways." The support of the decks does not wholly depend upon the strength of their framing, but is largely aided by pillars fitted between decks and in the hold. In building a ship the decks are first framed, and the flats are laid afterwards; so that the most natural course is to give precedence to the framing in the following remarks.

In nearly all ships the deck-framing is placed transversely. A few iron ships have been constructed by Mr. Taylorson with diagonal deck-framing, associated with other diagonal arrangements; and others built on Mr. Scott Russell's longitudinal system have had their decks supported by longitudinal girders; but these exceptional cases are so few as to merit no detailed description. The almost universal rule is to place the transverse deck-beams at moderate distances apart, and to make them stretch from side to side, strongly connecting their ends with the framing and skin of the ship. The spacing of the beams depends largely upon the positions of the hatchways and other openings in the decks, in wake of which the beams cannot, of course, be continuous from side to side; at such places short transverse pieces or half-beams are fitted instead. The outer ends of these half-beams are secured to the ship's side, and their inner ends rest upon longitudinal pieces of the deck-framing, termed "carlings," fitted between the beams. In some cases half-beams are fitted at other parts of decks, so that the spacing of the beams may be increased and the weight of the deck-framing reduced; but this practice is almost entirely confined to wood ships. These three classes of pieces—beams, half-beams, and carlings—form the deck-framing in most modern ships, whether wood, iron, or composite; and although in older wood vessels other modes of framing were employed, we cannot here attempt to describe them.

The beams of most wood ships consist of solid timbers of nearly uniform depth and of rectangular cross section (see 3, Fig. 5, Vol. III., p. 29). They commonly have to be made up in length by two or three pieces, which are joined by scarfs, either plain or hooked (see Fig. 8, Vol. III., p. 30). Their spacing, from centre to centre, varies from 3 to 4 or 4½ feet when there are no half-beams; and when half-beams are fitted in order to lighten the deck-framing without leaving the flat unsupported, the spacing is sometimes made as much as 5 or 6 feet. In determining the actual positions of the beams regard is had, as was said above, mainly to the positions of hatchways; but other considerations connected with deck fittings, special weights requiring support, possibility of fitting pillars, etc. etc., also have great influence. Half-beams and carlings are of similar sectional forms to the beams, but usually of less dimensions. Iron beams are sometimes used in wood ships, and in the next paper an example of such an arrangement will be given.

Wood beams were commonly used in the earlier iron ships, but they soon gave place to iron. The advantages of the flanged form possible with iron beams, as regards strength and lightness, have already been illustrated; and in 1 and 2, Fig. 5, two sectional forms for iron beams are shown. Section 1 has not been much used, and could not be rolled in one piece until quite recently; but we believe beams of considerable size on this pattern can now be rolled. The old plan of making it was to roll half the web and either the upper or lower flanges in one T-shaped piece, afterwards welding the two parts (at the bottom of the T) throughout the length of the beam. Section 2 is known as a "made" beam, and it has been largely employed. Besides these, many other sectional forms have been used, some of which will be illustrated hereafter. One of the simplest is the simple angle-iron form, but this is deficient in having only an upper and no lower flange. To supply this want a "reversed" angle-iron has sometimes been riveted to the simple angle-iron beam, and so a section like that of the frame of an iron ship (see Fig. 20, Vol. III., p. 150) has been obtained. Another plan has been to roll the angle-iron with a bulb at the lower part of the flange placed vertically; T-iron beams have also been used. Besides these we will only mention here the so-called "box-beams," sometimes used where great strength is required. They are of rectangular section, the sides, top, and bottom consisting of comparatively thin plates connected together by angle-irons fitted at the corners of the rectangular section. These beams are nothing less than small tubular girders, and they can be almost as readily made as the T-shaped beams similar to 2 in Fig. 5, Vol. III., page 29.

We have already remarked that in an iron beam there is no necessity for such elaborate connections of the pieces as there is in a wood beam. Usually the manufacturer sends the beams to

the iron ship-builder in such a state, that their ends have only to be cut off to the exact length, and the necessary holes drilled or punched, before the beams are put in place. In cases where made-beams are used the builder has to prepare them himself, but the operation is very simple. The plates forming the web may, in a large ship, be in two or three lengths, which are joined by welding; and a similar operation suffices to procure the necessary lengths of the angle-irons. Care is taken to make the welds of the plates and angle-irons forming a beam give shift to one another, in order that any specially weak section may be avoided; and in many cases, in disposing these butts, regard is had also to the positions of the similar butts on neighbouring beams. Much interest attaches to many of the operations connected with the manufacture of iron beams, but space forbids us to enlarge thereon further than in connection with some of the more common methods of forming the "knees."

Figs. 52 and 53 will aid our description of these operations, and also enable us to complete our remarks on the sectional forms of beams. In the former sketch the beam is made up of a bulb-plate with double angle-irons on the upper edge; this is a very common sectional form in iron and composite merchant ships, and is both cheap and efficient. The bulb-plate is rolled in one piece, and afterwards combined with the angle-irons. The section in Fig. 53 is generally known as the "Butterley beam," having been first made by the Butterley Iron Company. It was formerly always made in two pieces, which were afterwards welded together (by a patented process) along a line near the centre of the depth or the "neutral axis" of the beam. Now beams of considerable size and of similar sectional form can be rolled in one, and the expense and labour of welding saved; but the welding process is, we believe, still necessary with the largest beams, such as are used in our iron-clad ships. The advantages gained in having finished beams turned out from the rolls, instead of having to combine the separate parts, are too obvious to need discussion; and there is every probability that the iron manufacturers will be able eventually to meet the ship-builder's requirements in this respect.

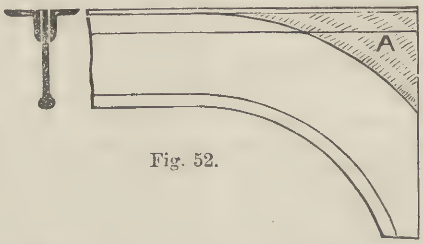

Fig. 52.

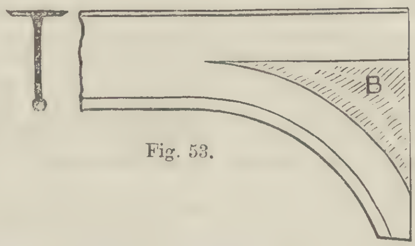

Fig. 53.

From these two sketches the outline of the form usually given to iron beam-knees will be seen, and hereafter the advantages gained thereby will be understood. The extreme depth of the knee is usually not less than $2\frac{1}{2}$ times the depth of the beam away from the knee. In Fig. 52 the desired form of knee is obtained by making the beam-end hot (before the angle-irons are riveted to the upper edge), and then bending the bulb-plate to the curve required for the under part of the knee; after which the piece of plate marked A, and dotted across, is welded on to form the upper corner. In Fig. 53 the plan followed is different. If the beam is formed of two pieces welded along the neutral axis, the welding is not performed for some two feet or so from the end; or if the beam is rolled in one piece the web is cut or split for an equal length, in order to separate the upper and lower parts. The beam-end is then heated, and the lower part turned down to the required curve to form the beam-knee; after which a plate marked B, and dotted across, is welded in to fill the space and complete the beam-arm. Sometimes the plate B does not entirely fill the space, but a triangular hole is left at the inner part. An example of this will be given hereafter. Care is, of course, required in welding plates (such as A and B) to the beam-web; and the operation takes some time, but when complete it makes very neat work.

I-shaped "made" beams usually have knees of similar shape to those we have just described, the web-plate being increased in depth for the purpose at the beam-end, and the angle-irons on the lower edge being bent to the curve of the lower edge of the knee. One of the best methods of forming such knees is to cut them out of a solid plate of sufficient breadth to allow two knees to be formed, and then by properly "lining" them out on the plate no great waste of material is involved. The knees, or "beam-arms" so formed, would extend in for 4 or 5 feet from the ship's side, and there be welded to the web-plate. It may occur to the reader that a plan similar to that in Fig. 52 might be applied here also, and this is the case when the beams are not of considerable depth; but as made-beams are mostly used where great strength is needed, there would be considerable difficulty in bending the deep web-plates to the curve required, and it is not usually attempted. Sometimes, to avoid the cost of cutting out the plate-knees, pieces of plate are either welded or riveted to the lower edge of the web-plate, in order to give the desired depth and form; and sometimes, instead of forming knees at all, the beams are continued of uniform depth quite out to the ship's side, and other means are adopted for securing their ends.

Half-beams in iron ships are usually of the same form and dimensions as beams, and have similar knees on their outer ends. The inner ends are simply secured to longitudinal carlings by short pieces of angle-iron, and the carlings themselves are similarly attached to the beams between which they are fitted. It is not usual to fit half-beams except in cases where some necessary arrangement of hatchways or deck-fittings prevents the beams from being made continuous from side to side. Almost without exception, the beams and half-beams are stationed at frames in iron ships, and their spacing consequently depends greatly upon the frame-space. In ordinary iron ships on most of the decks the beams occur at alternate frames, and are from $3\frac{1}{2}$ to 4 feet apart. In iron-clad ships the deck-beams are ordinarily spaced 4 feet apart; but in some cases where it has been desired to make the deck exceptionally strong, and very thick plating has been fitted, the beams have been only 2 feet apart. Such cases, however, must be regarded rather as having relation to necessities of defence, than of structural strength in the ordinary sense. The decks, in fact, are nothing less than targets strongly plated, and requiring to be strongly framed in order that the plating may be made as efficient as possible against the oblique or vertical impact of heavy projectiles.

Deck-beams are required to act not only as supports to the decks, but also as struts and ties keeping the two sides of the ship at a fixed distance apart, and to assist the framing in resisting any alteration in the form of transverse sections. The sectional forms of iron beams are practically regulated by the consideration of the strains brought upon them when acting simply as girders supporting the decks and the weights placed thereon. And when it is remembered that their strength as struts against compressive strains is very largely increased by their connection with the deck-flat, it will appear that this practical rule rests on a sound foundation. It is obviously fair to consider that with each beam we may associate, as a strong top flange, a portion of the deck-flat on each side of it extending to the middle of the beam-space. Supposing this to be true, and assuming the beam to be subjected to compressive strains tending to make it buckle, we see how great is the assistance it receives from the deck-flat to which it is fastened; and these are the strains to which a slight iron beam is most liable to yield when unstiffened. Direct tensile strains it can resist much better, and to enable its strength to be thoroughly developed it is only necessary to rivet it strongly to the frames. With wood beams there is no choice of any sectional form except the rectangular; and there is, of course, practically no danger of such beams failing under compressive strains, while the care exercised in scarfing the various pieces secures their efficient action as ties against tensile strains, provided their ends be securely fastened to the ship's sides.

Experience proves, however, that the greatest danger of change in transverse form arises from those strains which tend to produce alterations in the angle between the beam-end and the ship's side. The causes and mode of action of such strains have already been described; and in the next paper we shall try to illustrate the means employed to resist their action.

PATENTS AND PATENT LAW.—I.

By A Barrister.

UNPATENTED INVENTIONS.

In commencing the treatment of this interesting subject we must caution the reader that if he desires to make our information permanently useful he must carefully watch the proceedings of Parliament, as changes affecting the practice at least relating to patents are imminent. There is indeed a difference of opinion as to the advisability of preserving any monopoly, many persons whose judgment is entitled to weight being in favour of absolute free trade in ideas. At present the law rests upon a statute of James I., to which we shall presently allude—a statute which abolished monopolies generally, but expressly retained that which confers protection upon inventors whose discoveries relate to manufactures. That the law has remained for so long the same in principle is much in its favour; and it is indisputable that if our existing system be judiciously amended, the advantage to art and science will be as great as the original abuses of monopolies were enormous.

The most material question which we have to consider in the first place is the position of an individual who conceives a novelty in relation to matters covered by the term "manufactures," and who does not at once proceed to patent it. Has he any protection at all at common law, that is, as distinguished from statute law? M. Renouard, the author of an elaborate French work on patents, discusses the question whether an inventor has, by the principles of universal equity, an exclusive right to his invention; and an eminent American writer, Mr. Phillips, says that M. Renouard "very satisfactorily establishes the conclusion to which every mind is constrained to yield assent, that no such natural right exists." "Indeed," says the writer last cited, "there is no plausible ground whatever on which to rest such a right, since the fact of one person being the first inventor or discoverer affords no pretence for disfranchising others of the right, in their turn, of making use of the discovery." The only condition upon which an inventor can keep his invention to himself is that of secresy. It is the same with regard to literary productions as with mechanical inventions. The great American Chancellor, Kent, observes, "As long as these are kept within the possession of the author, he has the same right to the exclusive enjoyment of them as of any other species of personal property; for they have proprietary marks, and are distinguishable property. But when they are circulated abroad, and published with the author's consent, they become common property, and subject to the free use of the community." After many decisions of the courts, Lord Cottenham recognised as the established doctrine, that the property of an author or composer of any work, whether of literature, art, or science, in such work, unpublished and kept for his use and pleasure, cannot be disputed. And he added that if such right and property exist in the author of such works, it must so exist exclusively of all other persons. Upon this arises a very nice question as to what acts of an author or inventor will deprive him of his right—a question which has been frequently discussed on many different states of facts. And this is most important to inventors, inasmuch as by an indiscretion they may lose their right to a patent.

An instance of the danger of losing the benefit of his invention to which an inventor is liable is given in the work of Mr. Phillips already referred to. A person had invented an improvement upon spectacles, and as his patent was in a state of forwardness he had not been sufficiently cautious in keeping the invention to himself, so that another person in the same trade had acquired a knowledge of it, and hastily got a pair made upon the same construction, and exposed them in his window. Fortunately, however, the inventor happened to pass the shop, and seeing them, employed a friend to go and purchase them, in which he succeeded, and his patent passed the Great Seal the next day, before there was time to get any more made. It is difficult to see, however, that this patent could have been held good. There was knowledge of the secret, an actual making, and a public sale by a person who was not the patentee. All the world does not think alike on this subject of publication. France has adopted the English doctrine, but the United States law is satisfied if the invention was new at the time that it was made; and it is considered that the inventor is rather benefited by making known his invention as soon as he has reduced it to practice, because he supplies himself with proof of the date of the invention.

In the beginning of the present century a case was decided in the Court of Errors in France which well illustrates the rule which prevails in that country and in England. The inventors of a carding machine had disclosed their invention to the municipal administration of Orleans, who, at their request, had tested its utility by a public inspection and experiment, of which they had given a formal certificate to the inventors. The inventors, moreover, had voluntarily permitted a manufacturer to use their machine to card with. It was adjudged that in thus giving publicity to their invention they had voluntarily made it public property, and consequently, that the patent subsequently obtained by them, though in other respects legal, was invalid. The inventors protested that they did not intend to make their invention public, or to part with their rights, which we can well understand. But the only question in such a case must be, whether publicity has been given to the invention, from whatever cause; for it is the publicity which gives the public the right, and consequently deprives the inventors of their privilege.

It is desirable to fix with as much precision as possible the kind of proceeding on the part of an inventor which will prevent him from subsequently obtaining a patent. This was discussed in the great case of Betts' patent for metallic capsules, where it was said that a person named Dobbs had made the process public before the date of Betts' patent. Lord Chancellor Chelmsford considered carefully the "nature and extent of the information published to the world, which will be sufficient to disprove the novelty of a subsequent invention," that is to say, which (having regard to our present purpose) would disentitle an inventor to a patent at all. In one of the cases referred to, Lord Westbury answered the question thus: "There is not, I think, any other general answer that can be given to the question than this, that the information as to the alleged invention given by the prior publication must, for the purposes of practical utility, be equal to that given by the subsequent patent. If specific details are necessary for the practical working and real utility of the alleged invention, they must be found substantially in the prior publication." This was not entirely adopted by the Court of Queen's Bench dealing with the same patent; that court considering that whilst the earlier specification might insufficiently describe the process, so as to make the specification bad, it yet might disclose enough to show that what was claimed on the patentee's specification was not wholly new. And Lord Chelmsford expressed his entire concurrence with the view put forward by Mr. Justice Williams, "that the publication of a *notion* that a certain useful art may be discovered, without any information or means of discovery, cannot preclude a subsequent inventor of those means from taking out a patent for the entire art." A publication of a description of a machine in a book is enough to deprive the inventor of his property in it. "If," Lord Lyndhurst said in a case, "the machine is published in a book, distinctly and clearly described, corresponding with the description in the specification of the patent—though it has never been actually worked—is not that an answer to the patent?"

Then, in addition to publication, there is another process by which a new idea may be lost to its originator, and that is by public use. Mr. Justice Erle told a jury that manufacturing according to the subsequent patentee's invention, and sale "commercially" of the article so manufactured, would be a "public use." To support a public use a learned Vice-Chancellor required the evidence of "somebody who was an habitual purchaser." The same judge said "a manufacture of an unsaleable article will not be an anticipation of a patent which will produce a different, and a saleable, and a merchantable article." A doubt may well occur to the reader as to what is an unsaleable article. Lord Chelmsford supposes the words to mean a "worthless article;" "for," he said, "an article which is capable of some useful application may, from circumstances, be unsaleable at a particular time, and yet, if manufactured not for experiment, but in the way of trade, may prevent another patent having a claim to novelty." He further held that to establish a public use it is not even necessary that the patented article should have been previously manufactured for sale. As an example, a lock on a new principle was put on a gate adjoining a highway, and that was said to be a public use, so as to

defeat a subsequent patent. A late Baron of the Exchequer defined "public use" to mean "a use in public so as to come to the knowledge of others than the inventor, as contradistinguished from the use of it by himself in his chamber." Lord Abinger defined it thus: "the public use and exercise of an invention means a use of an invention *in* public, not *by* the public."

This reference to authoritative opinion on the subject we are dealing with makes it very clear, and it is only necessary to state what rules have been established as regards literary and artistic property, the law of copyright being distinctly on all-fours with the law of patents. These rules have been well summed up thus:—That the right of property of the author or composer of any works of literature, art, or science, in such works, so long as they remain unpublished, is so complete and absolute, that no one else, without his permission, may publish even a list or descriptive catalogue of them; that the circulation amongst a few private friends of impressions of etchings, not otherwise published, is not such a publication of them as disentitles the owner to the protection of this right, and that this right is but part of the general common law right of property. The question of publication is, of course, quite as important respecting this description of property as in the case of mechanical inventions; and in addition to the case of the etchings referred to above, we will give a few examples of what amounts to a publication so as to divest the author of his right of property. We may premise that the thing itself must be published, not something resembling it, such as an abridgment. A public performance of a play does not deprive the author of his common law right of property in it. By sending letters to another the right of publishing them is not lost; nor does the mere gift of copies of an author's works to a few friends amount to an abandonment of his copyright before publication. Unpublished lectures, delivered under certain conditions, musical and dramatic compositions, engravings, maps, and charts, are protected by statute.

We hope we have placed the position of an inventor at common law so clearly before the reader that any *résumé* may be unnecessary. But with reference to what we have to say further on, we will re-state the simple principle thus:—An inventor may retain the exclusive property in his invention without a patent, so long as he does not allow it to become publicly known by description in a publication or use in public. In the case of literary or artistic creations there may be a public use without amounting to a publication so as to deprive the author of his property in his work.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXXV.—HENRY CORT.

BY JAMES GRANT.

HENRY CORT, the founder of our iron aristocracy, was born at Lancaster in the year 1740. His father was by trade a builder and brickmaker. Of the early history of Henry Cort nothing is accurately known, but (according to a notice of him which appeared in the *Mechanics' Magazine*) he would seem to have raised himself by his own unaided efforts to a position of respectability. In his twenty-fifth year he was established as a navy agent in Surrey Street, Strand; and it was while managing business in that capacity that he seems first to have become aware of the inferiority of British iron, as compared with that which came from Russia and Sweden. The English nation could not carry on their manufactures without the foreign ore; hence their wrought iron was prohibited from all Government contracts, and their cast iron was too brittle for general use.

A supply of iron being required for the Royal Navy, first drew Henry Cort's attention to this state of matters in the iron trade, and he began a series of experiments with a view of improving the manufacture of the metal. What these experiments were, or how he achieved the results that he did, no one knows now. All that is known is that in the year 1775 he quitted his offices in Surrey Street, and took on lease certain premises at Fontley, near the seaport of Fareham, in Southampton, where he built a forge and iron-mill; and then he took into partnership a Mr. Samuel Jellicoe (son of the deputy-paymaster of seamens' wages), a measure that proved in the end a most unlucky one.

Henry Cort took up the art of manufacturing iron at the point where it had been left off by Dr. Roebuck in 1762, the Brothers Cranage in 1766, and others; and he succeeded so far with his new experiments at Fontley, that in 1783 and 1784 he published his patents. In his process he dispensed with a blast; but in that he had been anticipated by the Cranages, and in puddling by Peter Onions of the Merthyr Tydvil Works. Yet he introduced so many improvements of a new and original character, combined with the inventions of some of his predecessors, that in a few years he raised the iron manufacture to the highest state of prosperity—so true it was with Cort that "the man who will distance his competitors is he who masters his business, who preserves his integrity, who lives clearly and purely, who devotes his leisure to the acquisition of knowledge, who never gets in debt, who gains friends by deserving them, and who saves his money;" but, unfortunately for Cort, through his connection with Jellicoe he failed in the latter element of success.

So early as 1786 Lord Sheffield, of the Board of Trade, and a most distinguished writer on political economy, who died so lately as 1821, perceived the vast importance to the nation of Cort's improvements, and said in public:—

"If Mr. Cort's very ingenious and meritorious improvements in the art of making and working iron, the steam-engine of Boulton and Watt, and Lord Dundonald's discovery of making coke at half the present price, should *all succeed*, it is not asserting too much to say that the result will be more advantageous to Great Britain than the possession of the thirteen colonies of America, for it will give complete command of the iron-trade to this country, with all its vast advantages to navigation."

The peer he referred to as the discoverer of coke was the Scottish Earl of Dundonald, who, after serving in the cavalry, devoted a long life to scientific objects, chiefly with the view of benefiting the commercial and manufacturing interests of Scotland.

Cort states in his patents, that after great study and expense, "he had invented and brought to perfection a peculiar method and process of preparing, welding, and working various sorts of iron, and of reducing the same into uses by machinery: a furnace, and other apparatus adapted to the said process."

For anchors and similar iron-work, the fagots of piled iron were worked and welded into bars by rollers in lieu of forge-hammers; but it does not appear that there was any novelty in this use of rollers, as Cort refers to them in his specification as if already known. He had the merit of selecting and *combining* the best inventions of others, apparently, rather than of discovering much that was new.

An increased demand for iron was the result of all this, and hence the production of that manufacture, "which in the early part of the last century amounted to little more than 12,000 tons, about the middle of the century to 18,000, and at the time of Cort's patent to about 90,000 tons, was found in 1820 to have increased to 400,000 tons; and now the total quantity produced is upwards of *four millions* of tons of pig-iron yearly, or more than the entire production of all other European countries. There is little reason to doubt that this extraordinary development of the iron manufacture has been in a great measure due to Henry Cort; and it is said that at the present time (1863) there are not fewer than 8,200 of Cort's furnaces in operation in Great Britain alone."

Though the processes of Cort were discovered and adopted by others, the Lords of the Admiralty having, by persons appointed to test it, approved of his iron in particular, it was directed to be used alone in the navy for anchors and other iron-work, while numerous contracts for licences were entered into with Cort and his partner by the manufacturers of bar iron throughout the country. Cort now began to make arrangements for carrying on the manufacture of that metal on an enormous scale, and with that object obtained possession of a wharf at Gosport belonging to Adam Jellicoe, the father of his partner, when he succeeded in obtaining extensive Government orders for iron made after his patents, while licences were taken at royalties estimated to yield £27,500 to the owners of these patents.

Henry Cort seemed now on the high road to the realisation of

a princely fortune; "but there was a fatal canker at the root of this seeming prosperity, and in a few years the fabric which he had so laboriously raised crumbled into ruins; for, on the death of Adam Jellicoe, the father of Cort's partner, in August, 1789, defalcations were discovered in his public accounts to the extent of £39,676, and his books and papers were immediately taken possession of by the Government."

An examination proved that the debts due to Jellicoe senior amounted to £89,657, including the sum of £54,853 owing to him by the firm of Cort and Co., to which he had advanced money from time to time, to pursue experiments of an expensive character, securing himself, however, by a deed of agreement entitling him to one-half the stock and profits of all his contracts, and Cort subsequently assigned to him all his patent rights as collateral security. All this made the business connection a most unfortunate affair for him, as it was discovered that among the money advanced to the firm by Adam Jellicoe there was a sum of £27,500 entrusted to him for the pay of the officers and seamen of the Royal Navy! Embarrassments had fatally tempted him to make use of this money; and desperate attempts to set himself right only involved him more and more; the result preyed upon his health and shortened his life. On this discovery, the measures of the authorities were sharp and prompt.

"The body of Jellicoe was worth nothing to them, but they could secure the property in which he had fraudulently invested the public money entrusted to him. With this object the then Paymaster of the Navy proceeded to make an affidavit in the Exchequer that Henry Cort was indebted to His Majesty in the sum of £27,500 and upwards, in respect of moneys belonging to the public treasury, 'which Adam Jellicoe had at different times lent and advanced to the said Henry Cort, from whom the same now remains due and owing; and the deponent saith he verily believes that the said Henry Cort is much decayed in his credit and in very embarrassed circumstances; and therefore the deponent verily believes that the aforesaid debt so due and owing to His Majesty is in great danger of being lost if some more speedy means be not taken for the recovery than by the ordinary process of the Court.'"

The assignments which poor Cort had made of his patents were thus taken in security, while, most singular to say, Samuel Jellicoe, *the son of the defaulter*, was unjustly put in possession of the forges and mills at Fontley and Gosport, and continued to enjoy them, to the exclusion of Cort, for fourteen years.

It has been alleged that the simple process of demanding of the iron-masters who contracted with him their patent dues—amounting to £15,000 in 1789, to £15,000 in 1790, and to £25,000 in 1791—might have saved Cort from the irreparable ruin that fell upon him; but they were, however, prepared to dispute his rights at law, as they had been at variance with him.

"Mr. Cort has been most illiberally treated by the trade," wrote James Watt in 1784; "they are ignorant brutes; but he exposed himself to this, by showing them the process before it was perfect, and, seeing his ignorance of the common operations of making iron, laughed at and despised him; yet they will continue by some dirty evasion to use his process, or such parts as they like, without acknowledging him in it. *I shall be glad to be able to be of use to him.*"

It does not appear that more than £2,654 was raised from the ruin of Cort's estate towards the loss sustained by the public; and in 1805 the subject was again revived in a very unexpected manner, when the Whigs, in their attack upon the administration of Mr. Pitt, impeached Henry Dundas, Viscount Melville, for alleged malversation in his office as Treasurer of the Navy, though he held that office with success throughout the great naval war with France and Spain.

When Mr. Whitbread, the London brewer, spoke to the resolution for impeachment in the Commons, he averred that he strongly suspected "that Jellicoe was in the same partnership with Mark Sprott, Alexander Trotter, and Lord Melville, as he had been suffered to remain a public debtor for a whole year after he was known to be in arrear £24,000."

Bitter political enmity is said to have inspired Mr. Whitbread, whose speech was unwarrantable in tone, though serving its end, for Lord Melville was tried by his peers at Westminster Hall, and adjudged not guilty.

In the Report made by the Commissioners to the Houses of Parliament in 1805, the year of this remarkable impeachment, the value of Cort's patents was estimated then at only £100. Many of Jellicoe's debts were marked as bad; "and we apprehend," they added, "that the debt from Mr. Henry Cort, not so marked, of £54,000 and upwards, is of that description."

But all these parliamentary discussions availed Henry Cort nothing. With his wife and twelve young children he left his extensive works and handsome mansion, a bankrupt, ruined, heartbroken, and penniless. In vain did he appeal to Government for the restoration of his patents. However, Mr. Pitt granted him in 1794 a pension of £200 per annum; but, broken in health and spirits, he only enjoyed it six years, as he died in 1800, in the sixtieth year of his age.

"In the opinion of Mr. Fairbairn of Manchester," says the author of "Lives of the Engineers," "the inventions of Henry Cort have already added six hundred millions sterling to the wealth of the kingdom, while they have given employment to six hundred thousand working people, through three generations; and while the great iron-masters, by freely availing themselves of his inventions, have been adding estate to estate, the only estate secured by Henry Cort was the little domain of six feet by two, in which he lies interred in Hampstead churchyard!"

Such is the story of the man who founded the iron aristocracy of Great Britain. The small stone that marks his resting-place, with the date of his death, may still be seen. A few years ago it was quite illegible, but the kind hand of a relative has recently restored the inscription.

SHIP-BUILDING.—XVII.

BY W. H. WHITE,

Fellow of the Royal School of Naval Architecture, and Member of the Institution of Naval Architects.

DECKS OF SHIPS. (*continued*).

BEAM-END CONNECTIONS.

THIS branch of our subject is very important and extensive, so that no attempt will be made to exhaust it, but rather to illustrate arrangements which are, by common consent, pronounced good. Here, as elsewhere, we will take wood ships first, and afterwards pass to iron and composite ships.

Beam-end connections have long engaged the attention of wood shipbuilders, upon whose notice the matter has been forced by the weaknesses displayed by many vessels. In the old times, when the use of iron, except in the simplest forms, was unknown in ship-building, massive timber knees were used to connect the beams with the ship's sides. The beam-ends rested upon the edge of the internal planking, or "clamps," and were each secured by two knees—one (the "hanging knee") placed vertically, and bolted to the side of the beam and to the clamps; the other (the "lodging knee") placed horizontally, with one arm bolted to the beam and the other to the timbers. This clumsy arrangement has not yet fallen into entire disuse, but is adopted in some North American-built ships. In all probability the abundance and cheapness of timber there constitutes the chief reason for continuing to conform to the old-fashioned plan. In this country the departure from it was made long ago; and the plans which followed have in their turn been improved upon, giving place to others which are now in use. Our concern being chiefly with the latter, we will at once refer to an illustration, in Fig. 54, of the most improved beam-end connection, our sketch representing the practice of the Government service.

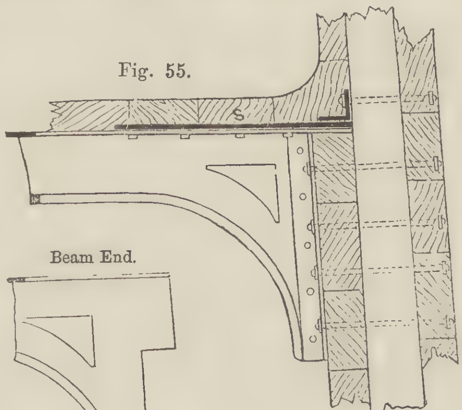
The beam-end is fitted closely against the timbers, great care being required in cutting the beam to the exact length required to ensure an accurate fit when the beam is set to the proper round-up. Underneath the beam-end comes the "shelf," *a*, a strong longitudinal timber, the lengths of which are joined by plain scarfs, well fitted and fastened. The shelf is usually fastened by a bolt in every timber, and also by circular dowels let half into the timbers and half into the shelf. It runs nearly the whole length of the ship from stem to stern, and constitutes a valuable longitudinal tie. Some shipbuilders have not entertained this opinion, and have not considered the shelf as more than a support for the beams; but in cases where this view has been acted upon, and the pieces of the shelf have been butted instead of being scarfed, exceptional weaknesses have been displayed. Sometimes the shelf is not worked directly against

the timbers, as in the sketch, but is wrought inside the upper strake of the clamps, which then extend up to the under side of the beams. Formerly this plan was commonly employed, and the shelf-pieces were of smaller dimensions. A dowel (*d*, in the sketch) is fitted in the bearing surfaces of the beam and shelf; with large beams two dowels are usually fitted.

The beam-knee in this case is an iron forging fitting under the beam, against the shelf, and over the clamps. Its fastenings consist of several bolts with clenched points passing through the clamps or shelf, the timbers, and the outside planking, and of other bolts passing through the beam and clenched upon its upper surface. These fastenings are obviously well distributed, and, by retaining the knee in place, do much to aid it in resisting any change of angle between the beam-end and the ship's side. As compared with the older plans, this form of beam-knee is most simple and efficient, and it has come very largely into use in merchant ships as well as in wood ships of the Royal Navy.

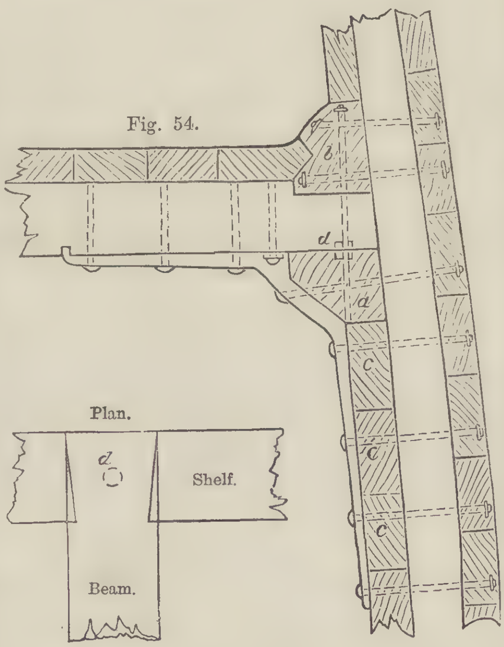
The third element in the beam-end connection is supplied by the thick "waterway," *b* in Fig. 54. This large timber is faced, or let-down, over the beam-end, but the latter is not cut away, except to the small extent required to form the dovetailed seating (shown in the plan) upon which the waterway fits. The fastenings of the waterway to the side generally consist of a through-bolt in each timber, the bolts over the beams being driven in the upper edge of the waterway, and those between the beams in the lower edge. The separate lengths forming the waterway are plain-butted, not scarfed; but the butts are often dowelled to a carling fitted for the purpose, and are thus sufficiently strapped to enable them to contribute somewhat to the longitudinal strength of the structure. The union of the waterway, beam, and shelf, is further strengthened by means of the vertical through-bolt, shown in the sketch. Adjacent to the thick waterway, and let into its front, is the "thin waterway," which forms the side boundary of the deck planking; and directly above the waterway, the internal planking known as the "spirketting" is fitted.

Fig. 55.



Beam End.

Fig. 54.



From this brief description, it will be obvious that the beam is so secured as to be capable of acting either as a strut or a tie between the two sides, and that considerable resistance is offered to change of the angle between the beam-end and the side. It is by no means unusual, however, when wood ships have been severely strained at sea, to find symptoms of slight changes having occurred in this angle, even when the arrangements of Fig. 55—which are probably not far from the best possible with wood beams—have been adopted. One other noteworthy fact is, that by means of the strongly-fastened shelf and waterway, the relative positions of the decks and sides are maintained when the vessel is subjected to longitudinal strains, and so the strength of the decks is developed, notwithstanding their sheer.

Next we will take an illustration of the mode of securing iron beams in wood ships. Fig. 55 will aid our description greatly. The beam there shown is of the Butterley pattern, and has the knee formed by welding in a piece—as described in the previous paper—only a space is left unfilled when the welding is performed. Allusion was made to this practice before, and the openings so formed in the beam-arms are often found useful for leading pipes or other longitudinal fittings along close to the side, where they are out of the way. The beam-end is formed (as shown) with a shoulder, so that it may rest upon the upper edge of the clamps and have its upper part fitted against the timbers. Short pieces of planking are then worked above the clamps, and between the beams, thus assisting in maintaining the beams in place. The main connection with the side is made by double angle-irons on the beam-knee, fastened by rivets to the beam, and by through-bolts to the ship's side. Upon the beam-end, close to the timbers, is fitted a "stringer-plate," s, riveted to the upper flanges of the beam, and secured by an angle-iron to the timbers. This stringer consequently adds much to the strength of the connection, and acts as a horizontal knee to each beam. The latter feature of its usefulness is by no means unimportant, although subordinate to its office as a longitudinal strengthening. For instance, if a ship be heeled over, and at the same time subjected to longitudinal bending strains, there would be a considerable tendency to rack or distort the deck, and to throw the beams out of their transverse position. Against these racking strains the stringer, considered as a horizontal knee, would be most efficient, and, from its great breadth, would probably aid the beams much more than the waterway fitted on wood beams, although the latter gives valuable assistance under similar circumstances. The remaining details in Fig. 55 are sufficiently explained by the sketch; and it will be obvious that the whole arrangement is both simple and efficient, especially in its resistance to any change of the angle between the beam-end and the ship's side. Here the knee is formed as part of the beam-arm, and so shaped and fitted as to render working much less likely than with iron-plate knees and wood-beams, like those of Fig. 54. It is not surprising, therefore, to find that the use of iron beams in wood ships is becoming common; and it will be shown hereafter that other considerable advantages are also gained by employing them.

Iron and composite ships usually have their beams stationed at and directly connected with the frames. One illustration will, therefore, serve for both these classes, and it will be found in Fig. 56. Here also a beam of the Butterley pattern is shown. On referring to the beam marked *aa* in the plan, it will be observed that the web of the beam is fitted directly against the side of the frame angle-iron; that one of the flanges is continued on with the web, and that the other flange is butted against the reversed angle-iron. Should there be no reversed angle-iron on the frame at which the beam is stationed, it is common to fit the beam-web on the "back" of the frame angle-iron, instead of in its "bosom," as in the sketch. If made-beams, or beams formed of a bulb-plate and double angle-irons are used, slight modifications of the arrangement illustrated might be necessary, but these are unimportant. In nearly all cases the main fastenings in the beam-arm are rivets through the frames, spaced either as shown, or else zig-zag fashion, if the frames be of greater depth. The connection with

the side is strengthened by means of a stringer-plate riveted to the upper flanges of the beams; nothing need now be said respecting it further than that it acts similarly to the stringer in Fig. 55; but in our next paper we shall again refer to the subject.

It would be difficult to imagine any simpler or more efficient beam-end connection than that usually adopted in iron ships. Working in any direction is rendered practically impossible, provided that the beams be made sufficiently strong, the fastenings properly arranged, and the pillars carefully fitted. Moreover, it must be remembered that the bulkheads fitted in iron ships afford the beam-arms valuable assistance in preventing changes in the transverse form.

Besides the common mode of securing beams shown in Fig. 56, there are many other plans used under special circumstances. For example, the hold-beams of merchant ships, which are spaced very much farther apart than the deck-beams, are sometimes fitted above a "shelf-plate" (*i.e.* a stringer is worked below instead of upon them), and knees are consequently given up. Brackets or gusset-plates are then usually fitted instead of knees, and indirectly connected with the beams. In other cases no knees are formed on the beam-ends, but triangular-shaped bracket-plates are used instead, being riveted directly to both frames and beams. This connection is almost limited to made beams of I or box section. Other exceptional cases are met with in which the beams are not stationed at frames, but are directly connected with the skin-plating; and this plan was not uncommon in the earlier iron vessels. When special strength is needed, as is the case where beams form the boundaries of the principal hatchways, and for a considerable length there is no complete transverse tie, it is often considered desirable to strengthen the beams themselves, and to add to their connection with the side by fitting deep bracket-plates extending the whole distance between decks. These deep brackets are sometimes termed "partial bulkheads." Besides the above-named, there are other special beam-end connections, which cannot be noticed here; and our remarks on this subject must be concluded by stating that only unusual and unavoidable requirements lead iron ship-builders to depart much from the excellent plan in common use, illustrated by Fig. 56.

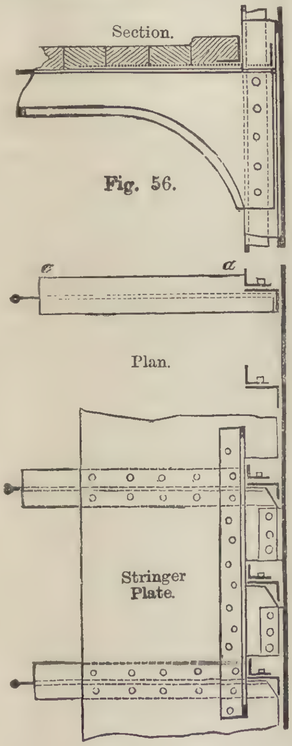


Fig. 56.

DECK-PILLARS.

Reference has been more than once made to the importance of efficient pillaring to the decks of ships; and a few words in the present paper will suffice to render this clear. Every one recognises the fact that pillars are needed as *struts* to support the decks, considered as platforms sustaining heavy weights; but many persons overlook the further very important consideration that under some circumstances the pillars must act as *ties* also, if they are to aid in preventing changes of transverse form. In order that these two requirements may be met, the pillars must be fastened at both their heads and their heels; but this is often left undone, and, as a consequence, the pillars can only act as struts, efficient against compressive strains.

Wood ships formerly had the pillars between decks, and the stanchions, or large pillars in the hold, were formed of wood; but now iron pillars, either solid or tubular in section, are largely employed. Iron and composite ships are always furnished with iron pillars. Tubular iron pillars are preferable to solid, especially for the larger sizes, because, with a given weight of material, they can be made much more efficient against failure by buckling under compressive strains, as well as against bending if struck horizontally. These hollow pillars can now be readily procured, and are largely used, especially in the Government service. The heads and heels are made solid, and forged similarly to those of ordinary solid or bar-iron pillars. With iron pillars it is possible to strongly bolt or rivet the heads to the beams, and the heels to the decks, or beams, or keelsons. Wood pillars cannot be so efficiently fastened; and, as usually fitted, they are not of service as ties against tensile strains. To secure equal strength they also require to be much larger than iron pillars, and this tells further against their use. They are now mainly used, if used at all, in the holds of wood ships.

In order to facilitate the work of pillaring it is customary to place the beams of successive decks directly over one another. The pillars are generally placed in rows, either at or on either side of the middle-line. The pillars, or stanchions in the hold, generally heel upon the keelson. At some parts of a ship it is difficult, if not impossible, to fit pillars to every beam. For instance, in the engine-room of a steam-ship, this is often the case; and it is then usual to fit longitudinal girders along under several beams, the ends of the girders resting upon pillars of exceptional strength. Where concentrated weights have to be supported, the pillars are, of course, both stronger and more numerous. All such arrangements rest very largely with the ship-builder, who can best determine as the work goes on where special strength should be given, and how it may be afforded.

SILK CULTURE.—VII.

By Alexander Wallace, M.D.

CULTURE AND MANAGEMENT OF BOMBYX PERNYI.

One more oak-feeding *Bombyx* requires particular mention, because it has of late years been the subject of experiment—viz., the oak-feeding silkworm of Manchouria and Northern China, *Bombyx Pernyi*. This name was given to it in honour of the French Archbishop Perny, by whose means this silkworm was first sent over to Europe. A few cocoons were at various times received in Paris, but though a few moths emerged, and eggs were obtained, the vitality of the parent insects was so depressed by the long journey that no healthy offspring was reared. A few cocoons, however, were forwarded to England by the late Mr. Meadows, H.B.M. acting consul at Newchwang, some of which were placed in my care. I therefore applied to the then Minister for Foreign Affairs, Lord Stanley (now Lord Derby), and he very kindly acceded to my request, and issued instructions to Mr. Meadows to forward to me for the next four years cocoons of this promising *Bombyx*, and also acorns of the oaks on which the worms were fed. Consignments of these cocoons in quantity have therefore enabled me to make a fair trial of its habits, to observe it closely, and to distribute the eggs of this species over Great Britain and Ireland, some parts of the Continent, America, Australia, and the Cape of Good Hope; and sufficient information is now obtained to enable us to judge of the value of the race for commercial purposes.

We will therefore first repeat here the information received from Mr. Meadows, and afterwards refer to our own observations.

In the commercial report for the year 1865, by Mr. Thomas Taylor Meadows, on the consular district of Newchwang, the most northerly of the ports of China opened to foreign trade by the Treaty of Tien-tsin, and situated in the Manchurian province of Tung-t'ien or Sheng-king, are contained some interesting details, derived from personal investigations, regarding "mountain silk," the product of the larvæ of a moth feeding on oak leaves.* "There are two crops of the mountain

* Mr. W. H. Lay, in his report on the trade of Chefoo for the year 1866, thus refers to what I suppose is the same production:—"Amongst the articles that can be exported from Chefoo there is brown silk, produced from the wild silkworms that swarm in the mountain forests; and the quantity of this article that could be brought into the market,

cocoon, a 'chun,' or spring crop, and a 'tsew,' or autumn crop. The latter is collected in the last half of September, and in October, and the cocoons are brought to market during this latter month. At this period the silk-growers pick out the best of the cocoons for the production in spring of the butterfly and worm for the spring crop. They are preserved in baskets, which are hung up in the Chinese dwelling-rooms. These almost always face the south, thus opposing a blank wall to the cold northerly winds prevalent in winter, and getting from the southerly windows the full advantage of the sun in that season, when, during nine days out of ten, there is a clear blue sky. Besides this the dwelling-rooms are partially heated by the warmth emanating from the surface of the "kang," or brick bench which occupies about one-third of the room, which serves as a sleeping-place at night, as seat, etc., during the day, and inside which is a winding flue with an aperture at one end in which a fire of millet stalks is occasionally lighted. In spite of all this, however, the temperature of a Chinese dwelling in the mountain-silk district is, during the greater part of the winter, considerably below the freezing-point. The worm, being indigenous, could doubtless stand the cold of the winter's night in its cocoon on the bushes on which the cocoon is formed; but apart from theft, destruction by wild animals, insects, etc., it is probable that in nights of unusual severity only the strongest and best enclosed might escape perishing from cold.

"The natural heat of spring suffices to bring the chrysalis out of the cocoon in the butterfly shape. The butterflies then couple, and in about four or five days after impregnation the female lays eggs. They are laid on native paper spread on mats, tables, etc. In about five or six days from each of these eggs is produced a small worm of about the size of a black ant, which is black in colour. This is about the time when the buds on the oak-bushes have begun to make their appearance: this must be in the last half of April. The young leaves are forced by twigs being cut off from the bushes and placed in water, in pools of the mountain streams, or in tubs in houses. From these the young tender leaves are taken, and are scattered over the paper as the worms appear from the eggs. The worms are thus nourished for some days, when they are transferred to the youngest, most tender-leaved oak-bushes on the hill-slopes. They are then about an inch in length, but are still black in colour. The transfer of the whole does not take place in one or two days. There is, during the whole existence of the animal in its worm stage, a difference of eight or ten days in the backwardness or forwardness of individuals.

"After some days the worm has its first sleep or torpor, at the close of which it changes its skin, and re-appears green in colour and larger in size. It has in all four of these sleeps or torpors, each of which lasts about two days. It changes its skin and becomes larger after each torpor, but retains, after the first, the same bright-green colour. For its next or fifth sleep it prepares by spinning itself into a cocoon, in which it assumes the chrysalis shape; then bursts out as a butterfly, and lays eggs, from which the small black worms are produced, when the processes just described are gone through again. These processes are, in the spring season, more rapidly performed than the similar processes in the autumn. The silk-growers told me that those of spring required about sixty days, those of autumn about one hundred. In each season, as fast as the worms consume the leaves on one bush they are removed by the attendant silk cultivators to another, the youngest bushes being used first.

"The worm is fed on three kinds of oak bushes called 'small tsing-kang-lew,' 'large tsing-kang-lew,' and 'hoo-pŏ-lŏ.' The only difference between the small and the large tsing-kang-lew seemed to me to be in the acorn cup, that of the former being smaller and also smoother outside than that of the latter. As for the hoo-pŏ-lŏ oak, its leaves are much larger and darker than those of the large or small tsing-kang-lew. Its acorns are also much larger, and, what at once marks the difference, the cup, instead of a hard exterior rendered more or less rough by small hard protuberances, is covered with longish feathery filaments, which give the cup the appearance of a small fur cap.

"The yield of the spring crop is said to be much less than that of the autumn crop—1,000 cocoons of the former giving no more than 500 of the latter; but the quality is said to be greatly superior, finer, whiter in itself, and more capable of taking dyes; but black, with various shades of reddish-brown or purple, seem to be the only dyes that either kind will take.

"The chrysalids which are not kept for breeding are used by the Chinese as an article of food.

"The mountain silk remains as yet the one article which this district is likely to furnish to England. My explorations of last summer convinced me that I did not, in my last report, over-estimate the extent of country in which it is produced, when I said 150 miles by 100. On the other hand, instead of saying that not one-fourth part of the hill-sides suitable for the oak-bushes is planted with them, I should now say that not one-tenth part is so planted. Viewing the nature of the article and the quantities that are now, and that could be furnished, the trade could be developed into one of appreciable importance even for our great manufacturing interests, unless exactions and jealousies of the local mandarins interposed to repress it."

The following remarks on the climate are also from Mr. Meadows's report:—

"The result of our five years' experience of the climate may be given here.

"The following is a table of the extreme temperature observed. It gives information much more required by the proposing resident or traveller in new countries than mean temperatures. It shows him what extremes of heat and cold he will have to encounter at times, and for which he must be prepared, or suffer severely in consequence. For mean temperatures people are rarely insufficiently prepared. The chief practical defect of the table is, accordingly, the absence of a column showing the heat of the sunshine in summer. The observations from which it is made were all taken from Fahrenheit's thermometers, suspended on the northern faces of house-walls, on which the sun never shines, therefore in the coldest and coolest places.

Month.	Coldest.		Warmest.	
	Morning at daybreak.	Afternoon at 2 to 4 p.m.	Morning at daybreak.	Afternoon at 2 to 4 p.m.
January	...	3°	39°	...
February	...	7	35	...
March	0°	14	43	44°
April	27	41	53	50
May	41	52	65	60
June	57	70	76	68
July	62	74	79	74
August	63	73	77	85
September	41	52	73	80
October	28	42	66	71
November	7	17	52	61
December	6	2	37	44

"The coolest months are December, January, and February. The greatest cold of a winter may occur in any of these months, but is most likely to occur in January and first half of February.

"The warmest months are June, July, and August. The greatest heat of a summer may occur in any of these months, but is most likely to occur in July and first half of August.

"The number of days in any one winter on which the thermometer stands at daybreak below zero does not exceed ten; and it rarely is below zero for more than two mornings in succession. In the coldest winter afternoon it always rises above zero.

"In a cool room with Venetian blinds the temperature does not rise above 80°, except for a few hours during some twenty-five to thirty-five afternoons in each summer, and these comparatively hot days do not occur together, but are distributed, with cool intervals, in groups of three to five, throughout June, July, and August. In these months the temperature always falls below 80° during the nights. In exceptionally hot summers, as in that of 1862, the thermometer may stand at daybreak at 75° to 79° for some twenty days; in cool summers it rarely stands above 70° at daybreak. As to the highest tem-

if prices suited, may be computed at not less than 12,000 bales a year. This silk is of different qualities, according to the process and care adopted in reeling it from the cocoons; and some of it is well adapted for manufacturers. The natives weave plain silk goods from it called 'pongees,' and about 100,000 pieces of these stuffs could be bought annually."

perature of the table, that of 85°, it has only once been attained in my library during five years; that was on 31st July, 1862."

All the preceding remarks refer to the climate of the port of Newchwang. The northern portions of the consular district of Newchwang are very much colder in winter, and have shorter and cooler summers.

The mean temperature of Pekin, as deduced by Kuppfer from thirteen years' observations, is—Spring 51° 8′, summer 68°, autumn 50° 4′, winter 29° 4′. A comparison of the temperatures of various European cities, as given in Mahlmann's elaborate tables, in the third volume of Humboldt's "Asie Centrale," will, I believe, prove my assertion.

It is therefore highly probable that on the hilly ranges where the *Bombyx Pernyi* breed the temperature will be found cooler even than that quoted by Mr. Meadows as peculiar to Newchwang.

The extreme hardiness of the race will first be noticed as contrasting greatly with the *Yama-Maï;* and all European experience bears me out in saying that this insect, in point of vitality and a hardy vigorous constitution, far exceeds the *Yama-Maï.* Indeed, the ease with which it has been transplanted, so to speak, into Europe, Africa, America, and Australia, and the difficulty which has attended the acclimatisation of the *Yama-Maï*, corroborates my statement that the *Bombyx Pernyi* is originally of a very vigorous and hardy constitution, and will thrive readily in other climates than its own. It will also be noticed that this insect is double brooded, and this, though an advantage perhaps in such climates as Australia and the Cape of Good Hope, which possess long summers and short winters, is a disadvantage in Great Britain, where our short and uncertain summer precludes the possibility of a second generation, except in very favourable seasons. This disadvantage also pertains to the *Bombyx Cynthia*, and, as in that insect, may be overcome by encouraging the adaptability of the race to the local peculiarity of the climate. Thus, by retarding the cocoons in the spring, and by adopting the same measures in the autumn, one generation can easily be obtained without much risk of a second. To this end the cocoons should be left in a cool cellar or out of doors in the shade, and in the autumn may even be preserved in sawdust in a hamper, and placed in a refrigerator, without detriment. This, therefore, is not the disadvantage practically which at first sight it appeared to be, and, as in the case of *Bombyx Cynthia*, an English acclimatised race of *Bombyx Pernyi* would gradually get accustomed to the climate and have normally but one generation. The climate of the country round Newchwang seems somewhat to resemble that of Northern Germany. The rainfall, as given by Mr. Meadows, is moderate, 22½ inches per annum being stated as an unusually high average; and a prevalence of strong winds is also noticed, which would materially lessen the temperature in the hilly regions where these worms are cultivated. It cannot, therefore, but be otherwise than that the temperature in these hills will have a lower average than that quoted by Mr. Meadows at Newchwang.

With regard to the oaks on which these larvæ feed, specimens of leaves and acorns have been sent to me and also to Kew Gardens, and from these materials the species of *Quercus* have been accurately determined. Two of these, called respectively, large and small "tsing-kang-lew," appear to be *Quercus Mongolica.* Another, called "hoo-pŏ-lŏ," is *Quercus obovata Buuge.* The leaves of this kind of oak are larger and darker in colour than those of *Quercus Mongolica;* there is also a marked difference in the acorns, which are also larger and darker in colour, and covered with long and tapering scales, thus giving to the cup the appearance of being covered with long brown fur, which also partly covers the acorn itself. A fourth species, called "tseen-tse-tszeo," is the *Quercus serrata* of Thunberg. The silkworms fed upon this oak produce the best silk. This tree, however, is not so common in the silk districts as either of the other species. The next best quality of silk is obtained from the leaves of the *Quercus Mongolica;* those obtained from *Quercus obovata* producing the most inferior description. In this country the larvæ seem to prefer the leaves of the ilex or evergreen oak, also of *Quercus cerris*, the Turkey oak, and the variety known as the Lucombe oak; but it has also been easily reared on our common oaks, *Quercus pedunculata* and *Quercus sessiliflora.*

The cocoon is large and heavy, weighing from 80 to 200 grains, of a greyish yellow-brown tint. The inside cavity is much larger than the chrysalis, hence there is a danger in transporting these cocoons for a long distance, for the pupæ inside may get bruised and injured by the shaking endured in the journey. It is attached by a pedicle to the branch, and is thus intended to remain suspended (all the winter if necessary) till the moth emerges. It is of a somewhat loose texture, and the apex is less closely spun than the cocoon of the *Yama-Maï*, hence arises some little difficulty in reeling. The moth is large, pretty, uniform in tint, of a greyish brown colour, more or less suffused with reddish brown; the males have magnificent large antennæ-organs which, when largely developed, are generally concomitant with large powerful wings and a restless habit, intended evidently for ranging over large areas in search of the female.

A clear ocellus in each of the four wings, which are falcate at the tip and very powerful, make it a typical example of its genus, *Antheræa.* The female is large, sluggish in flight, full of eggs: the wings are broader and less falcate than in the male.

The egg is light brown, very like that of *Yama-Maï* in size and appearance, except being somewhat less flat and of a lighter tint. From 300 to 400 may be laid by one female. The egg state lasts in warm weather about fourteen days; and the larvæ hatch out in early morning, vigorous black little wanderers, restless in their habits, and partial to a drink, and even to consume their empty egg-shells; impatient till they get on to the oak leaves, where they mostly prefer to sun themselves on the upper surface of the leaf; gregarious at first, totally unlike in habits and appearance those of the *Yama-Maï.*

After the first month a great change appears, for the larvæ lose their gregarious habits, have a green tint, and almost exactly resemble the larvæ of the *Yama-Maï* to the end of their career, except that their heads remain brown and are spotted with darker markings, whereas the heads of the *Yama-Maï* retain a green tint, while underneath the body of the *Pernyi* a red chocolate-coloured central line is manifest, which is absent in the *Yama-Maï.* The general ground-colour has a more yellow tint, and the spines are longer, and clubbed at the tip like the antennæ of a butterfly. This is wanting in the *Yama-Maï*, and is indeed quite unusual in lepidopterous larvæ. They eat more and grow faster also than the *Yama-Maï* larvæ, are less inclined to drink, and much less prone to disease. Indeed, they have been very successfully turned out in this country on the oak hedges, and allowed to take their chance year after year, and have spun their cocoons. Just before spinning the larva is a monster in size; and as he prefers to take his station at the tip end of a spray from which he has eaten all the leaves, he becomes an easy mark to birds. In one very important matter this species is inferior to the *Yama-Maï*—the cocoon is not so easily reeled. Indeed, though the Chinese are said to reel this cocoon—and, according to Mr. Lay's report, the pongees, an article of considerable supply and demand, are made and woven from the silk to the amount of 100,000 pieces annually—we are yet unable in Europe to reel it, and this is due to the apex of the cocoon being insufficiently closed by the spinning larva. When this difficulty is overcome—which it will be one day—then the cocoons of *Bombyx Pernyi* will rise considerably in value. It has also another disadvantage: the colour is a greyish yellow brown, and not so favourable as that of the *Yama-Maï;* it is also less easily dyed. For carding purposes it has been very favourably spoken of by a gentleman who kindly experimented for me with some of the cocoons, and it produced a strong but soft and pleasant-feeling thread.

If, therefore, it could be produced in quantity at little cost it would prove a valuable commodity, wherever naturalised and localised, so that, without much labour or oversight, the larvæ could be reared out of doors on the trees, without destruction from birds and other enemies, in large numbers. If, in fact, the cocoons could be gathered from oak bushes much as gooseberries are gathered from their bushes, then, no doubt, a good profit would accrue. But this state of things can scarcely be hoped for in England, but rather might be looked for in Australia, New Zealand, or the Cape, where it is reported to me that the ailanthus silkworm, *Bombyx Cynthia*, is similarly cultivated. And with regard to these countries, those possessing the drier climate seem most suitable for the *Pernyi*, while the *Yama-Maï* would do best in the moister regions. It must not be lost sight of that the pupæ are reported to be consumed as food by the Chinese.

About this *Bombyx*, therefore, there seems to be much

promise. It is evidently a hardy vigorous kind, easily reared; and if, by its means, oak leaves can be converted into silken produce for the use of mankind, its value in the scale of creation is by no means contemptible.

PRACTICAL APPLICATION OF THE FINE ARTS.—XIII.

By P. H. Delamotte, Professor of Drawing, King's College, London.

THE ART OF BOOKBINDING.

INTRODUCTION—FOLDING—ARRANGING AND COLLATING—BANDS AND SEWING—FORWARDING.

It will be requisite, in order to show how the general principles of Art are to be applied to the special art of bookbinding, to describe in detail the various processes (in some cases very peculiar) that belong to this branch of industry. This will be the more requisite, not only because the majority of people know scarcely anything about the details of this art—which is not to be picked up by looking either at the covers of well-bound books, or through the windows behind which bookbinders are at work—but also more particularly because there are but few accounts in cyclopædias of the individual steps, and these accounts are all more or less imperfect, and brief even to obscurity.

The art divides itself at once into two branches, though there is much which is common to both these classes. These two divisions are *cheap* binding and *good* binding—not that it is necessary that cheap binding should be bad, it only does not partake of the strength and excellence of the good; but it is necessary that good binding should not be cheap, inasmuch as expensive materials and skilled workmanship, extended over a considerable time, must be employed.

Folding.—As is known to most persons, the paper employed by printers is of a few sizes, differing somewhat, but not greatly, from one another: these are called foolscap, crown (octavos, quartos, and folios), super-royal (27 inches by 19), imperial (30 by 21), foolscap (18 by 14), demy (20 by 15), medium (22 by 17), royal (24 by 19), columbia (34 by 23), atlas (33 by 26), double elephant (40 by 26), antiquarian (52 by 31). These sheets are simply doubled in half for folio, into four for 4to (quarto), eight for 8vo (octavo), in twelve for 12mo (duodecimo), into sixteen for 16mo, eighteen for 18mo, and thirty-two for 32mo, 48mo, 64mo (see Thumb Bible), lower than which we do not know that paper is ever folded. The folding is done by women, who have an instrument called a folder, or a folding-stick, like a small paper-knife, made of ivory, boxwood, or some similar material. The edges are neatly brought together, then the folder brought sharply up to the inside of where the crease is to be, and lastly run along the outside of the crease. The neatness and accuracy of the folding adds considerably to the beauty of the book, since, when the edges are all even it is only necessary to cut off a very small portion to make them smooth, and thus we get what bibliopoles call "a tall copy." There is much difference amongst women as to the number that they can fold in a day. A quick hand will fold as many as 3,000 sheets a day, though some do only half that number.

Arranging and Collating.—As soon as the sheets are folded, they are arranged according to the letters, called *signatures* or *catch words*, at the bottom of the first page of each sheet. This work is also done by girls; and in some cases as many as 25,000 have been gathered by one girl in a day; but the girls' work is afterwards examined by a superintendent, who also cuts out any portions left blank by the printer in the first or last sheets. In the case of maps, diagrams, and illustrations, these have to be added afterwards, and this is done by the *Collator*, who cuts the engravings to a size which will bring them to the middle of the page when the rough edges of the book are cut off. Naturally this requires great care and some experience, so as not to cut too much, and so thrust the print too far into the book to be seen with advantage, nor to leave it out so far that the edge is left narrow.

Bands.—The book is now returned to the women's department—after being beaten, pressed, or rolled between cylinders—and it is sewn upon the bands. These bands differ in number, according to the size of the book and the character of the binding. Cheap school-books, for instance, sometimes have only two bands, but most books have four or five, whilst large, strongly-bound books require six. The bands are pieces of strongish string, or cord, which are fastened perpendicularly at fixed distances on a frame rising at the edge of a board, on which the sheets of the book are placed one by one. A sheet is placed on the board, with its folded back against the upright bands; it is then opened by the left hand of the operator, who with her right hand runs a needle, threaded with strong thread, through the sheet against the first band, to which the thread was originally attached. The needle is brought out beyond the second band, around which the thread is passed, and the needle again enters the middle of the sheet, and passes on to the next band. When the last band is reached, the next sheet is laid on, opened as before, and the threaded needle passed from band to band the reverse way. The ancient binders carried this sewing up to the headings of the pages, around which also they passed the thread; that process (called flexible, or monastic) is abandoned now, and the little piece of vellum, bound round with silk, at the top and bottom of the book is now added at a later period of the process. In the best binding the hole for the thread is made by the needle, and the band stands off from the back of the book, whereas in the cheaper and quicker work all the holes are made at once by a saw passed along the back, and in the groove thus made the band lies. The disadvantage of this step is, that the book will not lie so flatly open. When the whole of the sheets are sewed, the bands are cut off at some little distance from the book, and the ends thus left are afterwards unravelled, and spread out, so that they may catch as firmly as possible on the boards when glued for common binding. For good binding the slips are drawn through the board. When the book is sewn, but the leaves are still loose, the back is covered with glue, which penetrates some little way between the leaves, joins the various sheets together, and fixes the plates, etc., in their places. This glue must dry, and then the book goes to another department.

Fig. 1.—SEWING.

Forwarding.—The book now passes from the women to the forwarding room, where several processes occur. First it is pressed between two wooden boards, about three-eighths of an inch of the back projecting beyond the boards, one-eight to 8vo, and so on according to the thickness of the millboard. The workman

then, with a short-handled, heavy hammer, having one face large and flattened, and the other a blunt edge of nearly two inches wide, beats down the leaves, beginning with those nearest the boards, over the edge of them. This is first done with the edged face, but when the whole of the leaves have been beaten so as to incline to one side or the other, the whole is made into an even curve with the flat face. The process of beating the side leaves will have brought up the middle sheets, and will have caused a corresponding concavity in the front of the book. There is some little knack required in this process of beating down the back. A clever workman will, with a considerable number of blows adroitly given, beat the whole line of the back, so that when the book is opened wide the crease at the back will appear quite straight and even; but in a badly-bound book, done rapidly and carelessly, the crease will be irregular and uneven. To judge of whether a book is well bound or not, it is necessary to open it wide in several places; if it lies flat when opened, and the crease is one straight line, the work is good; but if the book closes itself, and has a number of irregular creases, it has been done quickly and unsatisfactorily. The wooden boards, too, by their pressure, will have left an indentation, into which the backing-boards, which are now always made of millboard, of greater or less thickness, can now be inserted. The monkish binders used to use wooden boards not unfrequently, but these are never employed now unless to humour the fancy of a customer. These boards have holes, through which the bands are inserted and glued. The leaves have now to be cut. The whole back is now rubbed hard with stiff paste on the glue, which has dried, and has been beaten round. This paste not only adds to the adhesiveness, but it also makes the glue less brittle and less liable to fall off. The cutting of the edges is done by pressing the book again between the two boards, one projecting beyond the edge of the book, the other being accurately placed on the line which it is desired to cut. A knife, which is fixed in a wooden machine to work evenly on the board, and is called a "plough," is passed backwards and forwards along this edge, until the whole book is cut through to the opposite board. This process is easy enough with the two ends, which are flat. With the face, the only requisite is to beat the back flat before the book is screwed up tight; it then makes the face flat after it has been cut straight; on the book being allowed to take its original curved shape, the front edges adopt the corresponding curve inwards. The edges of the leaves can now be coloured. Sometimes they are only sprinkled. This is done with a large hog's-hair brush, partly filled with colour, and jerked over them. The ancients used sometimes to blacken the edges with antimony in fine powder, rubbed on the damped edges, and burnished. Sometimes vermilion is rubbed on, with a little mucilage to make it stick. This too is burnished until it shines. Occasionally, in addition to these red edges, but more frequently without the red foundation, after having been simply rubbed with yellow-red ochre and size-water, the edges are gilt, which process is the same as ordinary gilding. Some white of egg thinned with water, or some similar mucilage, is applied to the edges of the leaves, and the requisite amount of gold leaf laid on. This gold is dried, and then burnished with a dog's tooth, agate, or bloodstone; and when the book is opened each leaf takes its own little modicum of gold. In some rare cases the edges are scraped before they are gilt. The most curious process is that of marbling, which is performed in the following manner:—A strong ley is made of linseed and fleeseed (gum tragacanth is the best); this should be of the consistency of cream, or thereabouts, and is spread over the surface of a wide but shallow trough. In the meantime colours are prepared by being ground very fine, with a small portion of ox-gall. These are thrown one after another on the surface of the ley, a little more ox-gall being added to each as it comes later in order. Those colours are left till the last, which appear most in spots on the top of the streaks of other colours. The ox-gall prevents the colours from mixing with one another, or with the somewhat oily mixture below; consequently each takes its own place in spots or streaks, as it may be thrown on the surface. We now have on the trough a surface of many colours, in those peculiar shapes we call marbling; all that remains is to dip the edges of the book, and the front, flattened as before, when it

Fig. 2.—FORWARDING.

Fig. 3.—FINISHING.

had to be cut, upon this coloured surface. The embossed surface takes up the colour to which it is applied, and only requires drying and burnishing. Considerable variety is caused in the character of the marbling by inserting a comb, and with it a slight amount of streaky small curve-like waves are produced; or by putting a stick in various places, and in each obtaining a little vortex around it; or by similar means: by tilting the trough a slight wave is produced, which will cause lines of greater or less intensity of colour. In this remarkable and amusing process there is plenty of room for ingenuity and taste, and an experienced workman may obtain considerable credit for his combinations of colour and form; whilst to the spectator beholding the process for the first time it is certainly a source of much amusement. When all the books have been marbled that are ready at the time, the remainder of the colour can be used up in staining paper for the insides of the covers, or for similar purposes.

The edges being coloured, the backs and boards are washed over with size, and are ready to be transferred to the men who put the actual cover on the book, be it leather, cloth, or paper.

As this introduces a new and a lengthy subject, we must reserve it for a future paper.

SANITARY ENGINEERING.—XXIV.

THE VENTILATION OF SEWERS.

Of all the questions involved in theories of sanitary engineering proper, this may perhaps be considered the *crux*, or crucial difficulty. The unwholesomeness of sewage arises from the deleterious gases evolved from fæcal or decomposing animal matter. Supposing, therefore, sewers to be thoroughly ventilated, these noxious elements are of course removed, and dispersed in the surrounding atmosphere, and the sanitary success accomplished. We are far, however, from having hitherto arrived at that desirable conclusion; and let us first remark that the circumstances to be dealt with are very different from those attending an ordinary limited area of house-drainage, which, by the judicious application of certain well-understood principles, may be made self-ventilating by the adoption of the methods indicated in our late paper upon the subject, or in some similar way; and we at once illustrate our meaning by referring to what is still the standing authority upon the question, the Report of W. Haywood, Esq., Engineer to the Commissioners of Sewers, published in 1858. At page 51, he says: "There are in the City of London 45½ miles of pipes large enough for men to enter, and 2½ miles of pipe sewers. To these sewers there are about—

2810 gullies of every description;
1065 air-shafts, with ventilators.

3875 openings to the sewers from the public ways."

And, by a further calculation, he arrives at the figures, that the total length of house-drains existing in the City must be about 168 miles. All these drains, of course, are more or less pervious to the external air, either from defects in the construction, bad jointing, imperfect trapping, or the absence of any trapping whatever—though this last defect is, no doubt, far less prevalent now than at the time when his report was made and published. Yet we may fairly take it that the extent of the drainage system, and most of its general conditions, are much in the same state now as they were then, though, doubtless, there have been many modern improvements introduced in matters of detail. Our object is not, however, to report upon the present condition of drainage in the City: we simply quote the figures as supplying some sort of basis upon which an idea may be formed as to the difficulty of the general problem—the ventilation of sewers. Various schemes have been propounded at different times, many of them fully considered in the Report above quoted; and we may venture to say that the conclusion to which most authorities upon the subject have arrived is, that the ventilation of any existing system of sewage must be a carefully considered question of detail. We instance the City first, as there—probably from the large proportion of population to area, the confined width of many of the streets, and various other local causes—the difficulties that have to be met are at least as great, if not greater, than are to be met with elsewhere; and yet we may state, without contradiction, that the hygienic statistics of the City contrast well with many other portions of the metropolis, and are in satisfactory advance of some of our larger provincial centres. Ventilation by means of an air-gully in the centre of the street, at certain intervals guided by circumstances, aided occasionally in very narrow throughfares by ventilating pipes conducting the sewer emanations to the level of the chimney-tops of the adjoining houses; a careful attention to flushing and cleansing the drains as requisite, and an abundant supply of water, may be mentioned as the most efficient means, either in London or elsewhere, of providing for the easy and innocuous escape of sewer gases.

The currents of air that travel through the sewers are subject to the most uncertain laws. This fact, however, seems to be established, that in any district in which there is considerable variation of level, the usual course of matters is this: the ventilating gullies in the upper portion of the district act as up-cast, and in the lower portion as down-cast shafts. But we may broach the theory here, that the more a district is subdivided, and the more ample provision is made for the self-acting ventilation of each particular section, the more perfect the result is likely to be. Experiments were made in Paris, and also in Antwerp, many years ago, with a view of ventilating a large area of sewage by a lofty chimney, the ventilating power being either a furnace or a fan driven by mechanical means; but in each case the result was only partial; as we may well imagine that the influx of fresh air necessarily created by the powerful draught from the numerous openings and gullies neutralises its effect beyond a comparatively small radius of the centre of its sphere of action. We may ask our readers—especially those with some technical and mechanical knowledge—to refer to the figures quoted above as relating to the City of London, and judge for themselves whether any system of artificial ventilation from a central point does not strike them from the first as chimerical, if not on the score of feasibility, at all events on the score of expense. Many such ideas have been started, and some of them are fully dealt with in the Report we have quoted above, and from which we again append the result of some valuable observations as to the comparative temperature of sewers as compared with the upper external air at various seasons of the year. We find at page 84:—"Inspection of the tables will show that between 9 a.m. and 6 p.m. of some days of the summer months, when the external temperature at the period of reading ranged from 55° to 72°, the mean being 65°, the mean temperature of the sewer was 62°, or 3° below that of the open air;" and the Report goes on to show that when such a state of things existed no ventilation could be depended upon for an up-cast draught, and therefore the effluvium from the sewers become unpleasantly evident. Also, further:—"The mean temperature of June, July, and August, registered at Greenwich for a period of fourteen years, was about 61°; the mean temperature of the sewers during those months may be taken as about the same. Thus, during three of the most important months of the year, when the nuisance from sewers is the greatest, these shafts would be useless."

The average difference at night between the minimum open air temperature and that of the sewers may be from 12° to 15°, and therefore we may fairly assume that any system of ventilation, as adapted to sewage, is more efficient at night, although, as we have shown in previous papers, the actual quantity of sewage passing is very considerably less in the night than during the day. "A difference of 6° may be said to exist throughout the year."

It must also be borne in mind, in dealing with all questions of the ventilation of sewers, whether in London or elsewhere, on an extensive scale, that we have not a new, recently erected, well-considered, and complete scheme of construction to deal with, but in many instances, we might almost say, a thing of shreds and patches, the date of many improvements being each marked by the class of work done at that particular period. Many of the sewers now actually in use in the neighbourhood of London were constructed more than fifty years ago, and have all the defects in section and construction of old-fashioned work of that date. So much for actual structural difficulty as to any combined system. With regard to the control of matters in detail, we again quote:—

"I do not anticipate that the three-quarters of a million of inlets to the metropolitan sewers can be by any amount of inspection kept in such a perfect condition that imperfect traps in houses, inoperative gully-valves, the opening of side entrances, the reparation of drains, will not cause a vast amount

of leakage which will present one of the principal if not the main difficulty to be overcome." Now in this element of what is called leakage lies, to our mind, one of the greatest elements of actual assistance to the ventilation of sewers, as considered in detail; for be it remembered, that as the foul air escapes it must be replaced by fresh in some way or other; and this object once attained to a sufficient extent, the only other object is so to arrange matters that the foul air may be allowed its vent at points where it is least perceptible to the public—or we should rather say, least deleterious—and we most emphatically protest against any attempt at hermetically sealing any very large section of drainage of any description whatever, where natural ventilation only is employed; as, if this is done, should a defect exist anywhere within the limits of a private house, most disastrous results may be expected to arise.

The foregoing remarks may be taken as applying to any extensive system of sewers, either in the metropolis or in the great provincial centres. In country towns, where there is abundance of air-space, the same difficulties do not exist in the same degree; but at the same time, bearing in mind the risk arising from the fact of any system of drainage communicating with houses in which stoneware drains are used, the necessary precautions for the escape of the gases should never be neglected, and there are some peculiar conditions under which express attention to this point is very desirable—*e.g.*, in all cases which are subject to tidal influence. Many of our sea-port towns which drain into the sea, discharge only at the time of low water. As the tide rises the sewage in the drains finds its level, and perhaps for several hours out of the twenty-four the lower section of the pipes does not discharge, but becomes for the short period in question a mere receptacle for sewage. In these cases a special provision for ventilation by means of shafts or otherwise is very desirable.

The circumstances under which different systems of drainage have to be constructed vary so entirely that it is impossible to lay down any fixed method for general adoption. Our object has been to point out the nature of the danger, and to indicate the general principles to be adopted f sanitary protection. Closely allied to the question of the ven ion of sewers is that of the disinfection of sewage gases. W have already alluded to the subject, and given some general data in relation to house-drainage only. In our next paper we shall take up the subject of disinfection of sewage, solid and liquid, upon an extensive scale, giving an account of some of the largest operations now carried on for the purpose in the metropolis and elsewhere throughout the country.

MUSEUMS: THEIR CONSTRUCTION, ARRANGEMENT, AND MANAGEMENT.

BY SAMUEL HIGHLEY, F.G.S.

XI.—NATIONAL MUSEUMS (*continued*).

Style of Architecture.—Not being conversant with architectural construction, I have only indicated the requirements of curators in the preceding description of what modern naturalists conceive a national museum of natural history should comprise, without attempting to indicate in any way how such a skeleton should be clothed with the garments of art. The Pointed Gothic style of architecture is much in vogue at the present day, as it is said to be "an elastic style," readily adaptable to any requirements; but it seems to me that the so-called "Palladian Style" (illustrated at page 9, Vol. IV. of THE POPULAR EDUCATOR) is well adapted to the plan of building previously described, as it is two-storied, with unencumbered windows, admits of a cupola, bold portico, statues of celebrated naturalists, preferably on the pedestals of the balustrades than among the chimney-pots, or, as at the University of London, in niches, that would help to break the lower line of wall below the windows, as these, by requirements of wall-cases, can only commence nine feet from the lower floor. In short, it is simple and inexpensive, yet withal bears a classic aspect.

As to internal decorations, a hint might be taken from the Oxford Museum, especially if the Gothic style be adopted—viz., to utilise all shafts, pillars, etc., for the illustration of petrology, by making them of various kinds of granite, serpentines, marbles, limestones, sandstones, slates, conglomerates, etc., of the different geological formations, and crowning them with capitals and corbels, carved with natural objects, representing chiefly groups of typical plants, sometimes with animal forms geographically and naturally associated with them, as *Bromus* (wheat, barley, oats, Indian corn, and sugar-cane) with sparrows; rice, and canary-grass with buntings, canaries, and quails, similar to a typical illustration of *Gramineæ* that ornaments the capital and corbels which surmount a shaft of Limerick mountain limestone at the Oxford Museum. If the University of Oxford can afford thus to deck its sanctuary of science, surely the British nation can follow its example. Dr. Acland's "Remarks on the Oxford Museum" are well worth consulting by all persons interested in the decorative details of museum architecture.

Details of Gallery Construction.—On referring to the "Estimate of Space for New Museum," Vol. III., p. 320, it will be noted that the length of certain galleries would have to be increased by the re-distribution of other departments, according to the requirements of modern naturalists. Thus, mammalia requires a length of 850 feet; to this Professor Owen adds 550 for mammalian osteology; and the memorialists of 1858 would make a considerable further addition by blending the fossil with recent mammalia, together with dissected and embryological preparations, models, etc. In other groups mimetic illustrations must be added. As it would be impracticable to have galleries of, say over 1,500 feet in length, of one class, the required length must be gained by the system of reduplication of wall-cases, pre-

Fig. 7.

viously described, and now shown in Figs. 8 and 9, whereby in a straight length of 35 feet a frontage of even 115 feet could be attained *on each side* of a gallery, by throwing out the projecting cases 20 feet, or a total frontage of 230 feet, with space for table-cases in each recess. In the latter case each bay would constitute a separate room, with a gangway 10 feet wide. For cleanliness, the space above the cases might be covered with Minton's plain or ornamental tiles, and white ones where reflected light was needed.

Details of Studies and Keepers' Rooms.—The arrangement of the private rooms is shown in Fig. 7, in a section taken at right angles to Fig. 8. They are arranged on two floors, the lower one being the study, reached from the public gallery, and devoted to the same class of objects; the upper floor being the work-rooms of the keepers, assistant-keepers, and other officials—the communication between the two floors being by a spiral staircase. The studies are filled with tables, T, of various widths—two, three, and six feet—facing lofty windows, L, looking out upon the interior open court. These tables should be supported on blocks fitted with store drawers, with interspaces for chairs, to keep each student's space distinctly separate; the tables next the window being devoted to microscopic or other minute examinations, those farthest away for the larger objects. Each end of the studies would be fitted with book-cases for the special class-libraries, placed on each side of the intercommunicating doors. Every study should be supplied with dissecting and compound microscopes with powers and appliances suited to the special class of study, as, for instance, goniometers, polariscopes, etc., in the mineralogical studies.

The official apartment above would be fitted round with presses,

A to F, for drawers, trays, book-boxes, etc., according to the nature of the objects to be stored, and from this room access would be obtained to the store-cases, K, ranged behind the wall-space above the wall-cases, W, of the public gallery. In fact, the principle of arrangement of studies and keepers' rooms would be to *make provision* for every available space being utilised for storeage according to the progressive annual increase of the collections. By this arrangement the work of the keeper and his officials need not be interrupted by the advent of students or naturalists with whom the staff might be personally acquainted, except to meet their special requirements for information, as subordinate attendants could supply the wants of those visiting the studies.

Details of Library.—In all the plans hitherto proposed provision has been made for a central library from which books could be taken to the studies, so that the difficulties experienced at the British Museum might be surmounted in regard to the complaint that "the books cannot be brought to the specimens nor the specimens to the books;" but I believe it would be found far more convenient and practical, as involving a great saving of time, if the books, memoirs, and papers* on descriptive, analytical, and systematic natural history, were distributed among the studies according to the subjects to which they specially pertained, so that each study should contain its own special bibliography—an opinion in which I am confirmed by Professor Agassiz, who has recently re-arranged his museum library on this system. Each study should be supplied with geological and physical maps showing the distribution of the class of objects it contains. Works on general natural history might be consulted in a small library attached to the private rooms of the heads of departments placed in the supplementary buildings, B (Fig. 4).

Professor Owen considers, that as ninety-nine out of a hundred who would consult the "Banksian Library" would be naturalists, it ought to be removed from the British Museum Library, and go with the natural history collections to the new Museum, especially as Dryander's very perfect printed catalogues of that library are in the possession of most naturalists. If this were done, the cost of a duplicate natural history library of modern books, etc., for the new Museum has been estimated to cost £10,000.

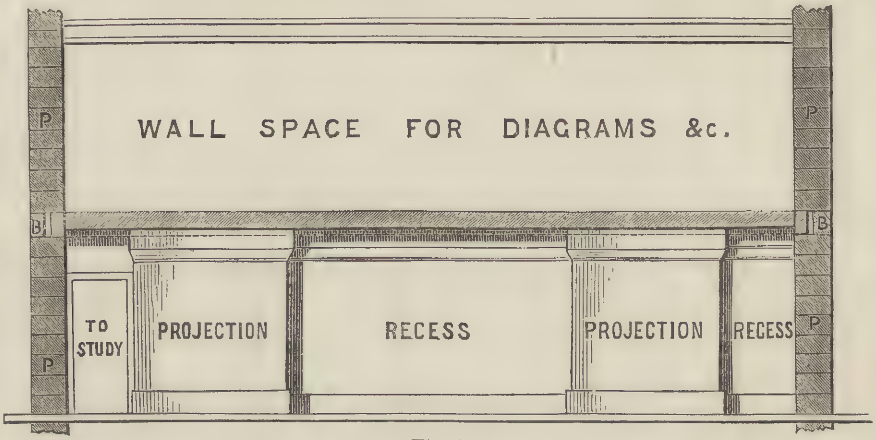

Fig. 8.

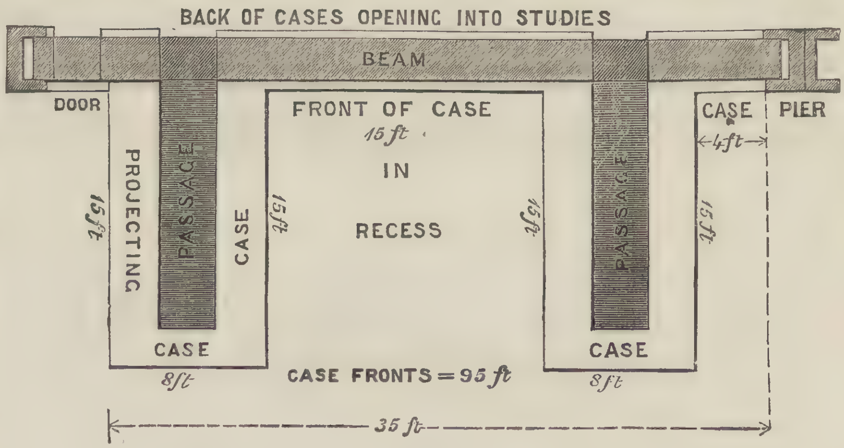

Fig. 9.

General Details of Arrangement.—"Wall-cases" with hermetically sealed glass fronts and back entrances to allow of specimens being removed into the studies, have, from their close association with the subject of construction, been previously described; but it is right to notice the objections that have been raised to this kind of case by Dr. Wallace, with which many other naturalists agree:—

1. They admit of any object being seen by the smallest number of persons at once, so that any one person studying an object almost necessarily monopolises it, and prevents others from approaching it, an inconvenience that reaches its maximum in the recessed cases exhibited in Dr. Sclater's plan.

2. Objects in wall-cases can be seen only on *one* side, which, as *all* sides of natural objects require to be seen, would necessitate many specimens to do the duty of one.

3. The observer on the one side from which alone he can see an object will generally stand in his own light, and will often have distinct vision further impaired by reflection from the glass.

4. When small objects occur alternately with large ones, a great waste of space occurs, and the attention is distracted from the less conspicuous object.

Objection 3 might be obviated by placing two wall-cases to the right and left of a window, and at right angles to it. The wall space then given up to window space might be made up for by placing a narrow floor-case between the two wall-cases. Thus arranged, two wall-cases would stand back to back between each window-pier, on the reduplicated system.

It only remains to note that internal metal fittings must be provided, to allow of the shelves being set at suitable heights, angles, etc., that bars pierced with holes for the reception of small socket-pieces and their clamp-screws, may in many instances be screwed near the fronts of the cases for the reception of small trays adjustable both for distance and angle, and swivel rods for suspending specimens in suitable positions. When the general run of objects in a class is small, "dwarf wall-cases," similar to that shown in Fig. 10, may be advantageously placed around the galleries. The tops of such cases are only as high as the level of the eye when an adult stands erect. The upper part is fitted with shelves six or eight inches wide, adjustable to any angle; the lower part is wider

* Two sets of all the scientific periodicals, reports, etc., would provide for each scientific paper being separated and bound up in separate form, or, if short, with other papers of an allied character on the same class, and deposited in its appropriate class library.

by eighteen inches, forming a shelf that can be looked down on; beneath this it is filled with drawers: the whole of this arrangement can be fitted into the partition that separates gallery from study, so that shelves and drawers are alike accessible from the studies only.

"Floor-cases" (Fig. 13), are very convenient for the display of the vertebrate classes. Such cases should be ten feet long by seven feet high, the width varying according to absolute requirement, if arranged in a manner similar to that recommended for table-cases presently decribed, as in Fig. 14.

To meet special requirements these may be made shorter, so that two cases may be grouped in the same space as a 10-foot case. This allows of scarce specimens—such as the gorilla group in the British Museum—being viewed on all sides; for the same reason one specimen may be made to do the service of two, when both its sides should be examined. Again, in some instances the length may exceed the standard length of ten feet in making provision for the walruses, cetacea, or the height, as for the giraffes. In the new Museum the floor-space of each class gallery must be occupied by specimens belonging to that class, not as at present, corals with mammals, oysters with "oyster catchers" of the avian class, etc., to the utter disregard of that method of silent instruction which may be conveyed through the eye by the proper association of allied species. Such floor-cases must replace the present table-cases, to give cover to new specimens that must replace the mangy cows, and the hippopotamus. These cases must be fitted up with shelves, blocks, suspending rods, etc., according to requirement, to meet the proper height or angle for the most efficient display of objects.

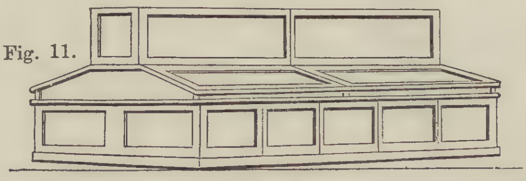

Fig. 11.

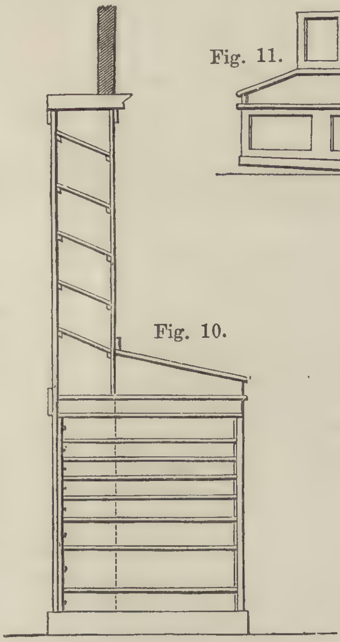

Fig. 10.

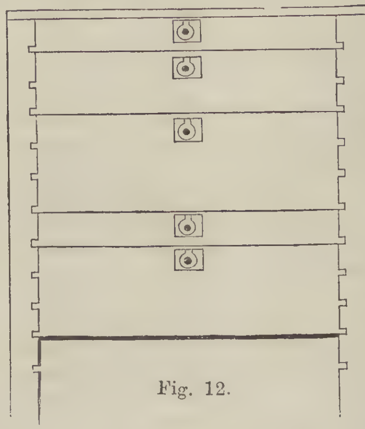

Fig. 12.

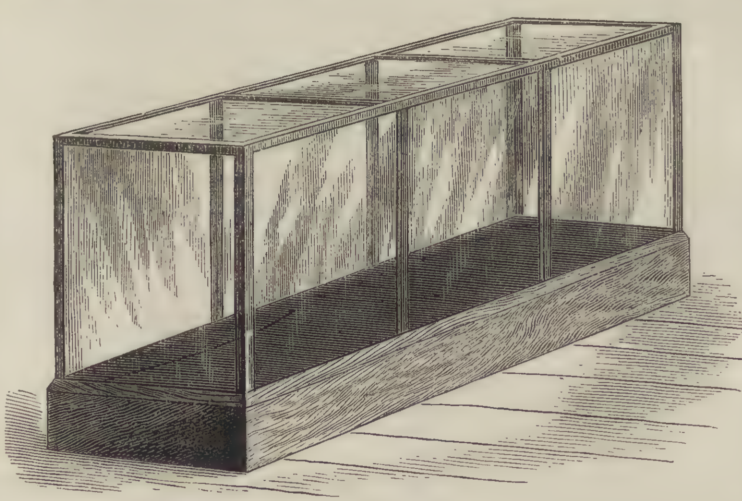

Fig. 13.

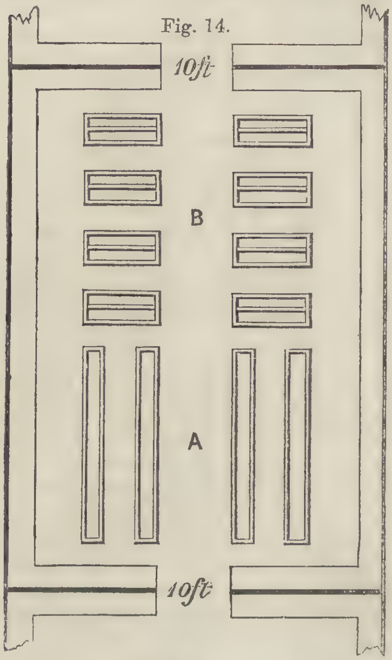
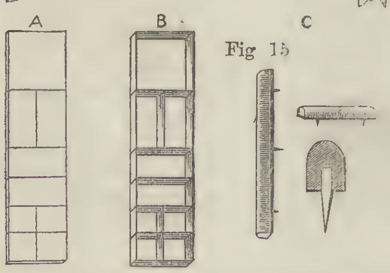
"Table-cases" are extremely convenient for the examination of small objects requiring a top light, such as most of the invertebrates, minerals, sections of woods, etc. A good model is shown in Fig. 11, which is 10 feet long by 5 feet 5 inches wide, by 5 feet 10 inches high, filled beneath with drawers.* The upper part may in some instances be replaced with shallow trays, or altogether dispensed with. The best plan for excluding dust from cases that must of necessity be opened at times in a public gallery, and the flap-lids or doors of which are usually permeable, is to line the flat surfaces on which the doors or flaps shut with felt, as this entangles the dust driven inwards by any draught, and if this be combined with a valley-and-ridge fitting the case may be regarded as hermetically sealed. The most convenient way of fitting the drawer space beneath for systematic natural history purposes is to groove the sides at exact intervals of an inch, for the reception of fillets placed on the sides of the drawers, trays, etc., as shown in Fig. 12. The drawers, etc., must be made an inch or the multiple of an inch in depth, so that according to the depth of the largest specimen in any series of objects, a drawer of suitable depth may be selected, to allow such object falling into its exact systematic position, instead of being placed in a supplemental drawer for large objects, as would have to be the case if the drawers were made in the usual way all of one size, or of gradually increasing depths from top to bottom of a tier, which is palpably an unpractical arrangement, as the curator or collector, in classifying his objects, is forced to group large and small specimens in the same drawer, or one drawer may contain shallow specimens, and the next large ones, and if all the drawers were made equal to the depth of the largest object in any given series there would be a palpable loss of cabinet space. By my method, shown in Fig. 12, it will be seen that the curator can "cut his coat according to his cloth," and select drawers according to the exact depth the largest specimens in a group necessitate: thus the first drawer may be one inch deep, the next two inches, the next three inches. Again, having arranged a series of objects, if it becomes necessary to intercalate a fresh group, it is not necessary to re-arrange the entire series of specimens, but simply to remove the drawers below the point where the new group is to be inserted, and to replace the drawers in advanced order. This method applies to drawers, trays, etc., in cabinets, store-cases, table-blocks, and, it will be seen, involves a vast saving of valuable space. I need hardly say it requires good cabinet-work, and strict attention to standard gauges, when in a large series of drawers one may be taken from one part of a room and placed in another block without the drawers sticking, and a certainty that the fronts of the drawers will fit close under each other so as to exclude dust. Agassiz, in a recent Report, calls attention to the loss his museum has recently sustained through the access of moth, etc., to a great

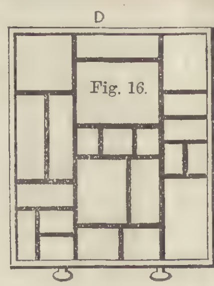
* This is the form adopted at the Liverpool Free Public Museum.

extent due to bad cabinet work; and he says, "It is true, and worth repeating, that the more expensive way of putting up specimens, viz., in good and costly cases or boxes, is in the end the cheapest mode, saving time as well as specimens." If a cabinet of drawers is properly made each drawer should glide in and out without jarring, sticking, etc., even if moved to and fro by one handle only. Great injury may be done to a collection of insects, delicate shells, etc., through bad cabinet-work, as well as by those persons—the terror of curators and collectors—who never learn that a naturalist's drawers should be handled as tenderly as a baby. A whole drawer-full of mounted shells may, by bad handling, be dismounted from their tablet at one shock. Each drawer should be covered with a sheet of glass that drops upon a rebate.





The method of arranging "table-cases" in a gallery is a matter that requires consideration. If placed with their fronts facing a gangway, as shown in A (Fig. 13), it will be seen that those stopping to examine specimens impede the general traffic, and involves mutual discomfort to those stopping and those moving onwards; but if placed with their fronts across the room, with intervals of three to four feet between each case, as shown at B, such arrangement tends to draw off the traffic from the main gangway, and distributes the examining visitors over a gallery out of the way of the passing throng. Table-cases and drawers are usually devoted to objects that require mounting on slabs or in trays. Slabs are made of well-seasoned pine a quarter of an inch thick, and covered on both sides with tinted paper. Extinct species should be mounted on slabs covered with paper tinted to correspond with a geological scale of colours, such as the key to the Geological Survey Maps, or, better still, one formed of the various tinted covering papers cut to represent the relative thickness of strata and arranged in proper sequence, the names, thicknesses, etc., being printed in. Such a geological scale should be hung in every gallery as a key to the tinted papers on which recent and extinct species are fixed. The geographical regions may be indicated by coloured lines placed round the slab, in the same manner as adopted at the International Exhibition, previously described and represented at p. 212, Vol. III., keys for which should also be hung in each gallery. These slabs must be unwarpable. They are cut up in subdivisions of a full-sized gauged tablet, to allow of specimens being grouped, as shown at A (Fig. 15), to economise space and produce an orderly aspect. Trays are made of card or thin wood, and, like the slabs, are made so as to be exact subdivisions of a standard size, as shown by B (Fig. 15). For many years past I have employed a method that allows greater freedom in spacing out specimens than the tray system admits of, for it frequently happens that a specimen is just too large for a tray, so the next size must be taken, with consequent loss of space. My method consists of the employment of long ebonised fillets, fitted with three or more needle points, and short pieces of various lengths fitted with two needle points, shown at C (Fig. 15), so that if a drawer is to be arranged say for minerals, the bottom is first covered with a thick layer of fine cotton wool or velvet, the long slips are then hammered in at equal distances apart, and as each specimen is placed in position, a cross piece is pressed into the drawer bottom, so that each specimen receives the exact amount of space required for its proper display. This system will be understood by the aid of D (Fig. 16), which represents a drawer thus divided.



SEATS OF INDUSTRY.—XXXI.

BRISTOL (*continued*).

BY WILLIAM WATT WEBSTER.

EXTENSIVE improvements were effected in the harbour of Bristol in the first decade of the nineteenth century, by cutting a new channel for the river Avon—the old channel being converted into a graving-dock nearly three miles long, forming several graving-docks—and by enlarging the quay, which has now a length of 2,000 yards, extending along the banks of the Avon and the Frome. These works also included the construction of two capacious basins, the Cumberland and the Bathurst. The floating-dock covers an area of eighty-two acres, and the entire works cost £600,000. After a considerable decrease had taken place in the trade of the port, in consequence of the high rate of the port dues as compared with those of Liverpool, London, and other places, an Act of Parliament was procured in 1848 for transferring the management of the harbour from a company to the corporation, and the change was followed by a reduction of the rates which, combined with the provision of better accommodation, has caused a steady increase in the traffic.

The principal foreign imports of Bristol are sugar, molasses, rum, tea, and cocoa, the next most important being tobacco, timber, wine, brandy, tallow, fruit, wool, hemp, dye-stuffs, oils, saltpetre, and hides. The exports consist chiefly of the various articles manufactured in the city, with salt, iron, coal, and culm, in part the produce of the district. In 1863 the customs duties amounted to £1,150,599, and the total shipping that entered the port consisted of 6,495 vessels, of an aggregate burden of 494,511 tons, of which 1,780 were steamers representing 307,254 tons burden. There belonged to the port in the same year 380 sailing vessels and 41 steamers. Steam communication was established between Bristol and Ireland as early as 1826, and this was the first port in the kingdom that established a regular communication by steam with the United States, the first voyage having been performed by the *Great Western* steam-ship in 1838. This vessel was built at Bristol at a cost of £60,000, and the *Great Britain* and the ill-fated *Demerara* were also "cradled" there, the former costing £120,000. About 400 carpenters are at present employed in the ship-building yards of Bristol. The city has canal communication with the Severn and the Thames, and thence with all England. It is a terminus of the Great Western, of the Bristol and Gloucester, and of the Bristol and Exeter Railways, the former of which was constructed between 1834 and 1838, according to the plans of Isambard Kingdom Brunel, and was the first broad-gauge line in Great Britain. Numerous branch lines connect Bristol with all the principal towns in the west. The most important manufactures of the city are refined sugars, brass and copper wares, soap, glass bottles, crown and flint glass, chain cables, anchors, steam-engines and machinery, tobacco, earthenware, floor-cloth, brass wire pins, patent shot, sheet-lead, zinc, saltpetre, tin pipes, hats, drugs, colours, dyes, starch, bricks, British spirits, malt liquors, and soda. About 1,700 persons are employed at the Great Western cotton works, established in 1840, and the manufacture of woollens, worsted, paper, silk, linen, etc., occupies a large number of persons. Many of the iron foundries in the neighbourhood are on an extensive scale, and they

are increasing both in number and in size. Coal is found in abundance in the neighbourhood of Bristol, and large supplies are obtained from collieries in Gloucestershire.

During the latter half of the last century the population of Bristol would seem to have declined considerably, as the city, including the parish of Bedminster, only contained 66,922 inhabitants in 1801; in 1811 its population numbered 76,952; and in 1821, 95,758. Bristol proper had a population of 65,781 in 1851, but its suburban districts contained 116,094 inhabitants, giving a total population of 181,875. Within the municipal boundaries in that year there were 137,328 inhabitants. The parliamentary borough, which is conterminous with the municipal, extends over 4,674 acres, and in 1861 it comprised 23,590 houses inhabited by a population of 154,093, which, according to the census of 1871, have respectively increased to 27,547 houses and 182,527 inhabitants. Bristol has regularly returned two representatives to Parliament since the electoral franchise was first conferred on the city by Edward I., and the municipal government is vested in a mayor, sixteen aldermen, forty-eight town councillors, a Lord Lieutenant and Lord High Steward. The city is situated on the banks of the rivers Avon and Frome, about eight miles from the point where those rivers debouch into the Bristol Channel, and is on the borders of Gloucestershire and Somersetshire. It extends over seven hills and their intermediate valleys, and is surrounded by a beautiful and fertile district. A few ancient houses, constructed of wood and plaster, with the upper storeys projecting over narrow streets, are still to be found in the older quarters of the town near the river-side, but the greater part of the city consists of spacious streets and squares lined with well-built and substantial houses. Bristol is exceedingly rich in ecclesiastical antiquities. The remains of Roman encampments are to be seen at Clifton and Leigh, and traces of Druidical edifices have been discovered at Stoke and Stanton Drew. The interior of the venerable Cathedral in College Green has lately been restored, and its carvings and fittings renovated. Where the bishop's throne now stands, Bishop Butler, the author of the "Analogy," lies buried. Among the ancient monuments in Bristol Cathedral, the most interesting are those of Robert Fitzhardinge, and certain abbots, bishops, and crusaders; and among the modern, are Bacon's monument to Mrs. Draper (Sterne's "Eliza"), one to Lady Hesketh, the friend of Cowper, a monument to Southey by Bailey, and a fine figure of Charity by Chantrey. The elaborate Gothic gateway at the western end is considered the finest in England. St. Mary Redcliff, on the summit of a hill of the same name, is one of the best specimens of Gothic architecture in the kingdom. It contains several interesting brasses and monuments to Canynge and Admiral Penn, the father of the founder of Pennsylvania, and others, and its muniment room has been made famous in connection with the forgeries of Chatterton, "the marvellous boy" having alleged that he found the Rowley Poems and papers there. The altar-piece of this church was painted by Hogarth. There are forty-four places of worship in connection with the Church of England in Bristol, but the Dissenters are both numerous and influential: the Wesleyan communities have twenty-five chapels, the Independents about twenty, and other sects about thirty-five. Among the celebrated natives of Bristol are numbered William of Worcester the topographer, William Canynge, Sebastian Cabot, Edward Colston, Sir Wm. Draper, Thomas Chatterton, Robert Southey, Sir Thomas Lawrence the painter, Edward Hodges Bailey the sculptor; and the celebrities connected with the city include Samuel Taylor Coleridge, Robert Hall, and Sydney Smith, who was a Canon of Bristol Cathedral.

TECHNICAL DRAWING.—LXXVI.

DRAWING FOR CABINET-MAKERS.

LINEAR DRAWING.

In order that the student may be able to represent or design furniture or any other objects, he must carefully study the numerous and ever-varying combinations of lines, the geometrical methods of constructing rapidly and correctly the various forms required, and the system by which one view is projected from another, or from given dimensions.

These are some of the branches comprehended under the term "Linear Drawing;" and the object of the present course of lessons is to show their immediate application to the work of the cabinet-maker, whose peculiar work is the construction of furniture, etc.

The construction of the geometrical figures is fully demonstrated in "Practical Geometry applied to Linear Drawing," page 63, Vol. I. of The Technical Educator, and hence only such will be added as may be required for the immediate

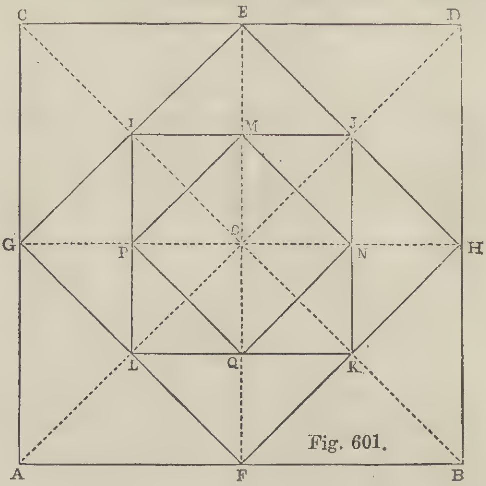


Fig. 601.

subject of any particular lesson. The student is therefore urged to work attentively through the lessons referred to, forming as they do the stepping-stones to all special branches of geometrical drawing.

The general principles of construction in wood, the methods of lengthening timber and joining boards, etc., have been given with numerous illustrations in "Drawing for Carpenters and Joiners;" and therefore these are not here repeated, in order

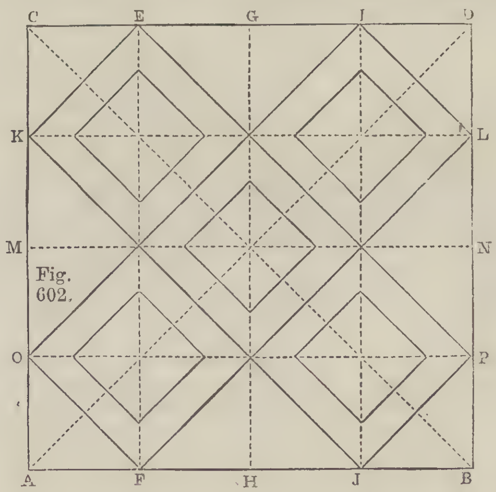

Fig. 602.

that special attention may be given to the Perspective of Furniture and Freehand Drawing, adapted to the present branch of industry.

The subject of this lesson is given with the view of affording the student practice in accurate combination of straight lines; and the forms are such as will at once show any imperfections, thus enabling the student to test his work as he goes on. These forms are in appearance very simple, but they are important, since, in the refinement required in the delineation of furniture, a single line out of place, be it ever so little, is liable to injure the entire drawing. The truth of this will be often exemplified as our lessons progress.

Fig. 601.—Construct the square A B D C. Draw diagonals A D and B C. Draw the lines E F and G H through the inter-

section (o) of the diagonals. Join F G, G E, E H, H F, thus constructing a square within A B C D.

The diagonals pass through the sides of this inner square in I J K L. Join these points, and another square parallel to the original one will be formed.

The lines E F, G H, cut through the sides of this square in M N Q P, and these points being joined, a fourth square will be formed, the sides of which will be parallel to F G E H.

The cabinet-maker, who is constantly called upon to cut numerous pieces of veneer into accurate forms, will find useful practice in this figure by drawing it on thick paper or card-board, and cutting it according to the lines. If correctly worked, the triangles G C E, E D H, H B F, and G A F should be equal to each other, and also to the four triangles G O E, E O H, H O F, and F O G. Consequently, these four triangles when placed together should form a square equal to F G E H.

Similarly, the triangles L G I, I E J, J H K, and K F L, are together equal to the square I J K L, and this same system will apply to the inner square.

Fig. 602.—This is another study of the same character as the last.

Draw the outer square A B D C, and divide it into sixteen equal squares by the lines E F, G H, I J, K L, M N, O P.

Join E P, K J, K E, and P J. Then the rectangle K E P J will consist of three equal squares placed upon and parallel to the diagonal B C. Again, join I O, F L, O F, and I L, and a similar rectangle parallel to the diagonal A D will be formed.

The inserted figure will then consist of four equal squares surrounding a fifth. The squares within these are drawn parallel to the others.

Fig. 603.—We now proceed to the delineation of a simple article of school furniture—viz., a master's pedestal table, with cupboard and drawers; and take the elevation facing the room first, being the simpler. The scale is ¾ inch to the foot.

Draw the ground-line, and the rostrum or platform on which the table stands. This platform is 9 inches high, and extends 1 foot on each side of the plinth of the table.

The body of the table is 4′ 6″ across, the plinth projecting ¾ inch all round, and the total height is 2′ 6″, out of which the thickness of the top occupies 1 inch, projecting 1½ inch on each side.

The front here presented is formed of three panels, the framing of which is 4 inches wide.

Proceed now to draw the plinth, commencing with the perpendiculars *a b*, and the horizontal *c d*. Next draw the perpendiculars *e f* at ¾ inch on each side within *a c* and *b d*, and then complete the general outline by drawing the top.

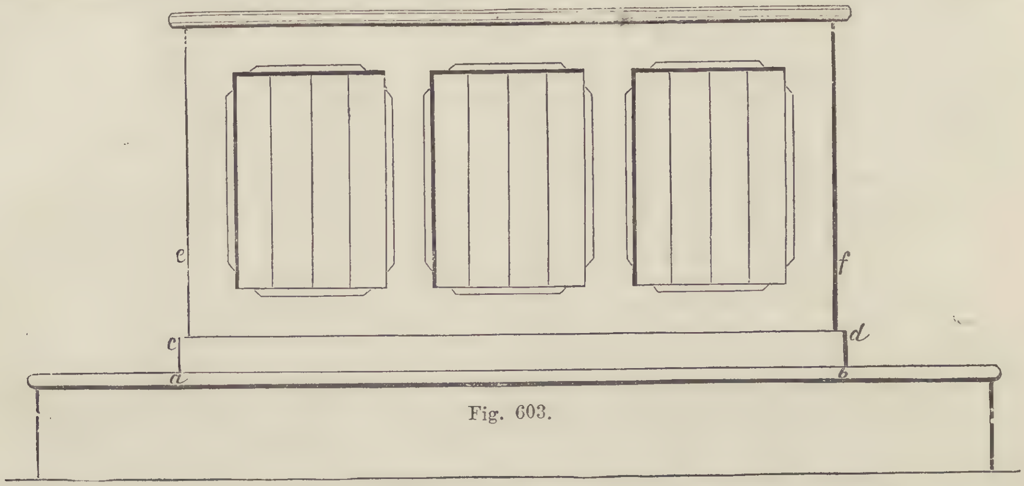

Fig. 603.

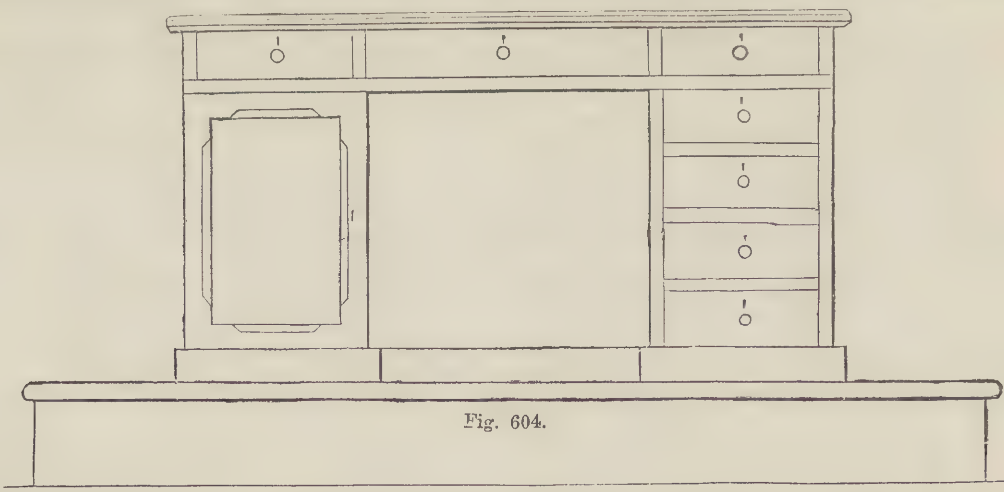

Fig. 604.

Draw the rectangles for the panels, the framing being 4 inches wide, chamfered at the edges up to 2 inches from the angles. This has the effect of lightening the appearance. The panels are made up of separate boards, the edges of which also are chamfered at their juncture, but too slightly to be shown in this illustration.

Fig. 604 is the true front of the same table, showing the pedestals, which are 1′ 3″ wide; the one contains a closet, and the other four drawers. The top of the table also contains three drawers, and is with the plate 6 inches deep. The general measurements are of course the same as in the other elevation, and the method of drawing this subject is precisely similar.

MINING AND QUARRYING.—XXVII.

BY GEORGE GLADSTONE, F.C.S.

LEAD (*continued*).

SHEET LEAD—PIPING—ADHESION OF LEAD AND TIN—ALLOYS—SHOT-MAKING—MASSICOT AND LITHARGE—PROPERTIES OF LITHARGE—REDUCTION OF LITHARGE—PEROXIDE OF LEAD.

THE large sheets of lead which are in such extensive use by plumbers for roofing and the making of water-tanks, are made in the following manner :—The pig lead is melted and cast in a rectangular mould, so as to form a large block of that shape, after which it is rolled out to the desired thickness. The first thing necessary for this purpose is a melting pot, large enough to contain eight or nine tons of lead at a time. The pot, A, Fig. 1, is made of iron, and hemispherical in form, having a pipe, B, issuing from the lower part of it, by which the molten metal is drawn off. Below the melting pot is a fire-grate, C; and before the lead is thrown in, the iron pot is heated up to redness; the charge is then introduced, and an iron hood, D, Fig. 2, which is suspended over the pot, and can be raised or lowered at pleasure, is let down upon it. The hood serves the double purpose of preventing the heat from being dissipated, and also the escape into the workshop of the hot gases from the melting lead, which would be injurious to the health of the workmen: these are carried off through a telescope pipe, E, Fig. 2, in the top, which is connected with the flue. The heat from the red-hot iron of the pot will be sufficient to melt the lead without keeping up the fire below, and it is not desirable to heat it beyond this point, or greater loss of metal will occur. When the lead is all melted it is skimmed, and then drawn off into the mould by the removal of an iron plug, F, in the pipe. The mould is entirely made of iron, the four sides being strongly bolted together and to the bottom plate, G. It is usually 6 or 7 feet across from side to side, and 8 or 9 inches deep. The bottom plate of the mould should be slightly concave in the centre, which will compensate the slight sinking of the surface in the middle of the casting during the process of cooling. Some care is necessary in letting the lead flow into the mould, as it comes out with great force, and is liable even, unless checked, to carry away the sides. Immediately the mould is filled, a wooden bar of the exact width of the mould is drawn over the surface of the liquid metal to remove all impurities, and this is repeated as often as may be necessary to keep the surface quite bright during the cooling. As soon as the lead has solidified the sides of the mould are removed, and the great block of lead is lifted off and deposited upon the rolling apparatus. This consists of a pair of very heavy iron rolls about 9 feet long, and nearly 2 feet in diameter, between which it is passed forwards and backwards a great number of times until it is gradually reduced to the required thickness; for this purpose the rolls are from time to time brought nearer and nearer together by means of adjusting screws. A series of wooden rollers on each side, which move freely, support the sheet of lead in a horizontal position while passing to and fro. The lead is generally slightly warm when the rolling commences, but that is not necessary to the success of the operation, and it is practically rolled cold.

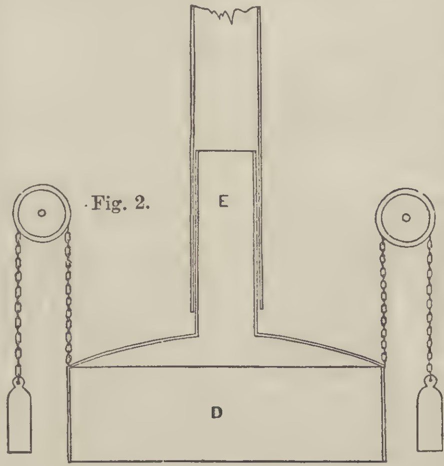

Fig. 2.

In addition to its domestic uses, which are sufficiently familiar, a considerable quantity of sheet lead, and that of the finest quality, is used in the construction of sulphuric acid chambers, as it is one of the few articles not affected by the oil of vitriol. Some idea of the quantity required for this purpose will be gathered from the article on sulphuric acid, in the series on "Chemistry applied to the Arts."

In lead pipes the soft desilverised lead is considered best, as it resists a greater pressure from within than the inferior qualities will; but many plumbers have a fancy for piping made of a harder metal, as the latter will better retain its circular form, and is therefore more easily manipulated. Antimony is even added purposely sometimes, for the sake of satisfying those who wish a hard pipe, though in other respects it is certainly not improved thereby. The lead is forced by great pressure through perforated dies corresponding to the respective sections of piping that may be desired, in the same way that the circular clay drainage pipes are made; by this means perfect uniformity will be secured throughout its whole length, and no seams will be required.

This operation is suggestive of one peculiar property of lead not hitherto mentioned, viz., that if the surfaces are thoroughly clean and bright, two pieces of lead can be perfectly united by mere pressure. In the same way, precipitated lead in the state of a fine powder may be compressed into a solid mass.

Tin-foil can be made to adhere to sheet lead in the same effectual manner by passing the two metals under heavy rollers; and this fact has been taken advantage of in the manufacture of the so-called patent metallic capsules, which are now very commonly used for protecting the corks of bottles.

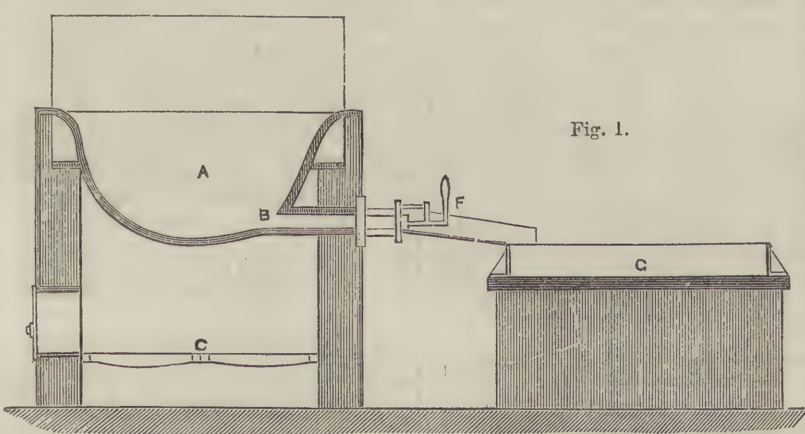

Fig. 1.

Lead forms some alloys with other metals which are of value in the arts. Those with tin, forming solder of different kinds, have already been described; others will be treated subsequently under the headings of the respective metals with which the lead combines; but there is one compound of which lead is the chief ingredient, which forms an article of very much greater commercial importance than most persons would readily imagine. We refer to what is commonly known as shot metal.

Pure lead will not answer the purpose of the maker of small shot. In order to enable it to take a strictly spherical form, it has to be combined with a certain quantity of arsenic. The arsenide of lead, though harder than the pure metal when cold, is very liquid when melted, so as greatly to resemble mercury, the readiness of which to separate into small round globules is so well known. If the lead is of soft quality, about 0·3 per cent. of arsenic will suffice; but for a hard lead about 1 per cent. will be necessary. To ascertain when the lead has taken up the precise quantity required to make a good alloy requires

some little experience on the part of the manufacturer. The lead, to the quantity of two or three tons, is melted in a pot, and then the surface of the metal is strewn with a little powdered charcoal, immediately after which the arsenic, either in the form of arsenious acid or orpiment (the sulphide), is added, and briskly stirred in with the metal. The pot is then covered up, and after two or three hours the arsenic is reduced to the metallic state, and has entered into combination with the lead. During this process a good deal of the arsenic is unavoidably lost, so that even when dealing with good lead it is usual to add about 1 per cent. On uncovering the pot the surface of the metal will be found covered with a coating of oxide, which contains a considerable proportion of arsenic. To ascertain whether a suitable alloy has been formed, a little of the metal is taken out and allowed to fall through a perforated plate into water. The form presented by the grains will indicate whether there is a sufficiency or otherwise of arsenic, the composition which contains a right proportion of this substance yielding particles of a strictly spherical shape.

A satisfactory test having been attained, the metal is run into small ingots ready to be converted into shot. These ingots, for future use, are raised to the top of the shot tower, which should be upwards of 150 feet in height, and here they are remelted when required. The perforated frames, or cullenders, through which the molten metal has to pass, are kept hot by being surrounded with a charcoal fire, and the surface of the frames is dressed with a little oxide, which has the effect of allowing the metal to pass freely through the perforations without adhering to the edges. The apertures vary in size from 1-50th to 1-360th of an inch for the sizes known as numbers 0 to 9; but these will not be found to correspond with the size of the shot produced, which is always considerably larger than the perforation through which the metal has passed, as it widens out into the spherical form in falling. The smaller sizes are allowed to fall about 100 feet, but the larger about 150. At some of the shot towers on the Continent provision is made for a much greater fall than even this. At the bottom of the tower is a well filled with water to the depth of 5 or 6 feet, which receives the shot.

The desired quantity having thus been made, the shot is put upon a stove to dry. A perforated cylinder is then filled with the shot, and made to revolve. The first series of holes in the cylinder correspond to the smallest shot, and underneath this part is a box to receive the grains as they pass through. The larger sizes follow in succession, with their corresponding receptacles, so that by the revolution of the cylinder the whole mass of shot is separated into the various sizes required in the trade. The bright surface is afterwards given to the shot by their being agitated for some time in a vessel containing a small quantity of blacklead. The defective grains have yet to be separated, which is done by allowing all the shot to roll down a table which is very slightly inclined. Those which are truly spherical will run with a straight course to the receptacle at the lower end, but the defective ones will gradually find their way to the sides, where they are collected and put apart for remelting.

There are several salts of lead which are of importance in the arts. The oxide (protoxide, PbO) has already been referred to as one of the compounds produced in the course of smelting; but it will be more especially so when we come to speak of the separation of silver from lead, which will be described under the head of the more valuable metal. This compound is known both by the name of massicot and litharge, according to its colour, the former being more decidedly yellow than the latter. The chemical constitution appears to be the same in both cases, and the reddish tinge which litharge possesses is probably due to some difference in the molecular arrangement of the particles. It is a better article for ordinary purposes, as it is more stable than massicot, and resists better the action of the atmosphere. It is used as a pigment, and by the manufacturers of glass and earthenware. To the metallurgist it possesses properties of considerable value, as it forms fusible compounds with some of the metallic oxides which are infusible by themselves, and thus enables them to be readily separated from others. Those of copper and antimony are rendered fusible by a very small addition of litharge; those of tin, zinc, iron, titanium, manganese, and arsenic require a somewhat larger proportion. Sulphur is converted into sulphurous acid on heating it with an excess of litharge.

Notwithstanding the various useful purposes to which this oxide may be put, the quantity which is necessarily produced in the final processes for the separation of lead from silver, by cupellation, is so much in excess of what is required in trade, that the litharge has again to be reduced to the metallic state.

In many parts of the Continent this is done in blast furnaces; but in England preference is given to a large reverberatory furnace of ordinary construction, having a tap-hole at the lower end or side of the sole, with a pipe communicating with the receiving pot outside. The tap-hole should be protected by a dam of clay, over which the lead, when it has accumulated sufficiently, will run, the dam being only removed to draw off the remainder of the lead at the end of the operation, when the whole of the metal in the charge has been reduced. The work commences by raising the furnace to a red heat, and then throwing in a quantity of small coal of a quality which will leave but little ash. This must be spread evenly over the sole of the furnace to the depth of two or three inches. When the coal has thoroughly united, the litharge, mixed with some more small coal, is thrown in until the furnace is as full as convenient. The oxygen contained in the litharge combines with the carbon of the coal, and is evolved as carbonic acid, leaving the lead free, which is soon found to be flowing towards the bottom of the hearth. In a hour or two so much lead will have accumulated, that it will begin to flow over the dam into the receiving pot. For the next six hours fresh supplies of litharge and small coal are thrown in to keep the furnace full, and as the lead continues to flow into the pot, it is lifted out with ladles and poured into the pig moulds to cool. When the lead ceases to flow from the furnace, the dam is broken down, a greater heat is got up, and the residue well rabbled in order to separate the lead that will be mechanically mixed with the cinder, which should consist of little else than the ash from the coal. If the litharge, however, is impure, and contains the oxides of some of the other metals not uncommon in lead, some quantity of slag will be left at the close of the operation.

The peroxide of lead, PbO_2, acts the part of an acid in combining with the alkalies, calcium, barium, and other bases; but its principal use is in the manufacture of lucifer matches, in which considerable quantities are now employed. It may be conveniently made by boiling the acetate of lead in an excess of hypochlorite of lime solution, until the odour of acetic acid takes the place of that of the chlorine, when the whole of the lead in the acetate will be converted into the peroxide. The product has then only to be thoroughly washed. It can also be made by gently heating litharge with a mixture of the chlorate and nitrate of potash, care being taken to keep the temperature low, or minium, instead of the peroxide, will be the result.

NOTABLE INVENTIONS AND INVENTORS.

XXXII.—SIR SAMUEL MORLAND.

BY JOHN TIMBS.

Sir Samuel Morland, although born just upon two centuries and a half since, must not be left among forgotten inventors. He is entitled to special regard, for the glimpses which his mechanical inventions afford us of the science of the period, apart from his personal history, which is interesting. He was the son of the Rev. Thomas Morland, of Subhamstead-Bannister, near Reading, in Berkshire, and was born about the year 1625. He was educated at Winchester and Cambridge. He remained at the university for ten years, but never took a degree. Soon after leaving college, we find him sent on the famous embassy to the Queen of Sweden, in company with Whitelocke and a retinue of other gentlemen. Whitelocke, in his Journal, calls him "a very civil man, and an excellent scholar." On his return, Morland became assistant to Thurloe, the secretary to Oliver Cromwell. He is said to have been privy to the plot usually known as Sir Richard Willis's Plot. In his chambers at Lincoln's Inn, Thurloe is reported to have discussed with Cromwell Willis's plot for seizing Charles II., early in 1659. In the same room sat Thurloe's assistant, young Morland, at his desk, apparently asleep, and whom Cromwell would have dispatched with his sword, had not Thurloe assured him that Morland had sat up two nights, and was certainly fast asleep.

He, however, divulged the plot to the king, and thus saved Charles's life. Birch relates the story in his Life of Thurloe; but it is not considered supported by proper evidence. Echard, in his History of England, produces a letter from Morland to Willis, dated March 10th, 1660, in which he expressly denies the above statement; but Morland's own testimony, in his Autobiography, is to the contrary; if he did write it at all, it was probably intended merely as a means of protection from the wrath of Sir Richard Willis.

Morland had already shown his genius for mechanical science. On the restoration of Charles he was made Master of Mechanics to His Majesty, who soon afterwards made him a gentleman of His Majesty's privy chamber.

It is now time to speak of his writings and mechanical inventions. From some correspondence between Morland and Dr. John Bell, it appears that Sir Samuel, as early as 1666, had intended to publish a work on the Quadrature of Curvilinear Spaces, and had actually proceeded to print a portion of it, when, by the advice of the latter, he was persuaded to lay it aside altogether. Morland not only yielded implicitly, but, in a letter written shortly afterwards, he furnishes arguments against some propositions of his own treatise. "I should desire," says he to Bell, "to bee altogether mute, and to submitt to your judgement in all things." Bell, in another place, informs us that two sheets of the work were actually printed.

It was about this time that Morland invented his arithmetical machine, which he mentions in a letter dated May 13th, 1666. He did not, however, publish an account of it before the year 1673, when, "by the importunity of his very good friends," it was made public. The little work in which it is described is illustrated with twelve plates, in which the different parts of the machine are exhibited. Its operations are conducted by means of dial-plates and small indices, movable with a steel pin. By these means the four fundamental rules of arithmetic are very readily worked, and to use the author's words, "without charging the memory, disturbing the mind, or exposing the operations to any uncertainty." His "Perpetual Almanack" is given at the end, which was often printed separately. One copy of Morland's little book, long in the possession of Professor Davies of Woolwich, contains a very beautiful portrait of the author, but with this exception, we have never seen an exemplar so distinguished.

The invention of the speaking trumpet in its present form is attributed to Morland, though it is warmly contested for Athanasius Kircher. The ancient contrivances of this kind resembled hearing rather than speaking trumpets. Some have considered the great horn described in an old manuscript in the Vatican Library, as having been used by Alexander the Great to assemble his army, to be the oldest speaking-trumpet on record; but the description does not state that Alexander *spoke* through the horn. Morland published the account of his useful instrument at London, in 1671, under the title of "A Description of the Tuba Stentorophonica, an instrument of excellent use, as well by sea as by land." In this rare tract, consisting of eight pages, he gives an account of the various experiments that he made before his instrument had attained a certain degree of perfection. The first trumpet that he constructed, "although," says Sir Samuel, "the invention had been long before digested in my thoughts," was made in glass in the year 1670, being about 2 feet 2 inches in length, the diameter of the greater end 11 inches, and that of the other end $2\frac{1}{2}$ inches. "With this," he says, "I was heard speaking at a considerable distance by several persons, and found that it did very considerably multiply the voice." The next he made was of brass, about $4\frac{1}{2}$ feet long, 12 inches in diameter at the large end, and only 2 inches at the small end, to which was affixed a mouthpiece, "made somewhat after the manner of bellows," to move with the mouth, and thereby prevent the escape of the breath. This was tried in St. James's Park, and rendered the voice audible at a distance of nearly half a mile. The third instrument was of copper, recurved in the form of a common trumpet; its total length was 16 feet 8 inches, the large end 19 inches and the small end 2 inches in diameter; with this the voice was heard about a mile and a half. After giving a description of some experiments with other trumpets, he enters into a philosophical description of the nature of sound, and the best form of speaking trumpet, which he leaves doubtful, and concludes with "an account of the manifold uses" of his instrument, which are very excusably exaggerated. He appears to have overrated the power of his trumpet, for, in his "Urim of Conscience," he says that he has no doubt but that it might be improved so as to carry the voice for the distance of ten miles. Yet Dr. Young records that at Gibraltar the human voice has been heard at a distance of ten miles. With the largest of Morland's trumpets, tried at Deal Castle, the voice was conducted a distance of between two and three miles over the sea. An advertisement prefixed to a French translation of Morland's treatise, published in London in 1671, states that Morland's tubes were sold by Moses Pitt, a bookseller in St. Paul's Churchyard, at the price of £2 5s. There is one of Morland's original trumpets, about six feet long, now preserved in Trinity College Library, Cambridge. It is in bad condition, and no one knew what it was till our time, when it was identified by a member of the college.

The invention excited such general interest at the time, as to make Butler say in "Hudibras:"—

> "I heard a formidable voice,
> Loud as the stentophonic noise."

The invention of the fire-engine has been claimed for Morland; but he was rather an improver than the inventor of that machine, which originated with Ctesibius, a distinguished Greek mechanician, who lived in the reign of Ptolemy Philadelphus. Hero, a pupil of Ctesibius, describes a sort of forcing pump with two cylinders, employed for extinguishing fires. Apollodorus, architect to the Emperor Trajan, has left a description of a machine consisting of leathern bottles, with pipes attached to them; when the bottle was squeezed, a jet of water flowed through the pipe, and was thus used to extinguish fires. Beckmann found, in the accounts of many of the German towns, entries for the cost of such machines: thus, in the accounts for the building of Augsburg for 1518, fire-engines are mentioned under the name of "instruments of fire," or "water-syringes." As early as 1590, Cyprian Lucar described a rude fire-engine, or squirt, which acted precisely on the principle of that instrument; Evelyn also mentions a fire-engine invented by Greatorex in 1656, which was ten years before he saw the "quench-fires" of Morland. In the vestry of the church of St. Dionis Backchurch, Fenchurch Street, London, are preserved four large syringes, which were formerly used for the extinction of fires; they are about 2 feet 2 inches long, and were attached by straps to the bodies of the firemen. At the present day a species of squirt is used among Oriental nations to extinguish fires. An old engraving purports that John Lofting, a merchant of London, was the inventor and patentee of the fire-engine; in one corner is represented the Monument, and in another the Royal Exchange; the engines are represented at work.

The principal objects of Morland's study were, however, water-engines, pumps, etc., which he carried to a high degree of perfection; his pumps brought water from Blackmore Park, near Winkfield, to the top of Windsor Castle. In 1675 he obtained a patent "for certain pumps and water-engines by him invented." In 1697, two years after his death, a tract by Sir Samuel was published at the expense of his son. It is entitled "Hydrostatics, or Instructions concerning Waterworks," and contains an account of his various methods of raising water, besides tables of square and cube roots. From the close of Joseph Morland's preface it appears that many of his father's works were left unpublished. There is also a treatise by Sir Samuel, in the Harleian collection of MSS., which is entitled "Élévation des Eaux, par toute sorte de Machines, reduite à la mesure, au poids, et à la balance. Présentée à sa Majesté très Chrétienne, 1683." At page 25 commences a very short tract on the steam-engine, entitled "The Principles of the New Force of Fire, invented by Chev. Morland in 1682, and presented to His most Christian Majesty, 1683," and these principles are explained as follows:—

"Water being converted into vapour by the force of fire, these vapours shortly require a larger space (about 2,000 times) than the water before occupied, and rather than be constantly confined, would split a cannon; but being duly regulated according to the rules of statics, and by science reduced to measure, weight, and balance, then they bear their load peacefully (like good horses), and thus become of great use to mankind, particularly for raising water, according to the following table, which shows the number of pounds that may be raised 1,800

times per hour to a height of 6 inches, by cylinders half filled with water, as well as the different diameters and depths of the said cylinders." Then follows his table of the depths of different sized cylinders. This evidently indicates a perfect knowledge of the subject; and, to his great credit also, let it not be forgotten that he has correctly stated the increase of volume which water occupies in a state of vapour, which must have been the result of experiment. His researches, however, seem to have had little influence on the progress of the practical application of steam (*Penny Cyclopædia*). It should be added that Morland does not indicate the form of the machine by which he proposed to render the force of steam a useful mover. It is, however, remarkable that at this early period, before experiments had been made on the expansion which water undergoes in evaporation, Morland should have given so near an approximation to the actual amount of that expansion. It can scarcely be supposed that such an estimate could be obtained by him otherwise than by experiments.

Among Morland's written works, according to Beughem, in his "Bibliographica Britannica," are "Articles and Rules for the better government of His Majesty's Forces by Land and Sea, during this present War." His "Doctrine of Interest, both Simple and Compound," published in 1679, has the tables very accurately calculated; but his "New Rule for the Equation of Payments" is erroneous. Another tract by Morland, consisting of four leaves, and entitled "The Count of Pagau's Method of Delineating all manner of Fortifications (Regular and Irregular) from the exterior Poligone, reduced to English Measure," etc., was published in 1672. The "Urim of Conscience," already mentioned, was written during Morland's blindness, and is a very singular piece of composition; it contains reflections on the fallen state and insignificance of man, and the uncertainty of life. Morland is said to have written a treatise on the barometer, which was answered by Lord North in another tract on the same subject. He is also said to have invented the capstan to heave up anchors; but he must be considered rather as an improver than the inventor of that machine. The same remark will apply to various other performances which have been elsewhere attributed to him.

Of more popular interest are the minor inventions of Morland, of which his abodes bore traces almost unto our time. Lysons, upon the authority of an enrolment in the Duchy of Cornwall Office, states that Sir Samuel Morland, in 1675, "obtained a lease of Vauxhall House, made it his residence, and considerably improved the premises." Aubrey tells us that some years before, Morland had built "a fine room at Vauxhall, anno 1667, the inside all of looking-glass, and fountains very pleasant to behold, which is much visited by strangers; it stands in the middle of the garden." And Mr. Bray, the historian of Surrey, was informed by one of the proprietors of Vauxhall Gardens, in 1813, of a circumstance which shows that the dwelling-house then connected with the garden once belonged to Sir Samuel Morland. From the back kitchen of the house a lead pump was removed, about 1794, bearing the mark—S.M. 1694. The room mentioned by Aubrey as having been erected by Morland, is believed to have stood where the orchestra was afterwards built; and grave old Mr. Bray hints at the probability of a room having been erected by Sir Samuel for the reception of Charles II., when he visited this place with his ladies. In the above house and grounds Morland formed a large collection of mechanical contrivances. He received his baronetcy in 1660, and subsequently had a pension of £400 settled upon him; but embarrassments in his affairs, owing to an imprudent marriage, obliged him to dispose of the house at Vauxhall. He afterwards removed to a house at Hammersmith, near the water-side, where he died December 30th of the following year (1695). Poverty and loss of sight compelled him to rely almost solely on the charity of Archbishop Tenison. In a letter dated March 5th, 1694, he returns him thanks for his kindness, "which was far greater," says Sir Samuel, "than such a poor wretch as I could ever hope for." This letter, written when he was blind, is a very curious relic, and is now preserved in the library at Lambeth Palace. John Evelyn, in his Diary, describes Morland when suffering under this accumulated load of misfortunes:—"25th October, 1695.—The Archbishop [Tenison] and myself went to Hammersmith, to visit Sir Samuel Morland, who was entirely blind, a very mortifying sight. He showed us his invention of writing, which was very ingenious, also his wooden calendar, which instructed him all by feeling, and other pretty and useful inventions of mills, pumps, etc.; and the pump he had erected that serves to water his garden, and to passengers, with an inscription, and brings from the filthy part of the Thames near it a most perfect and pure water. He had newly buried £200 worth of music-books, being, as he said, love-songs and vanity. He plays himself psalms and religious hymns on the theorbo." The inscription to which Evelyn refers is on a stone tablet fixed in the wall, and is as follows:—"Sir Samuel Morland's Well, the use of which he freely gives to all persons; hoping that none who shall come after him will adventure to incur God's displeasure by denying a cup of cold water (provided at another's cost, and not their own) to either neighbour, stranger, passenger, or poor thirsty beggar. July 8, 1695."

Morland constructed for himself a coach, with a movable kitchen in it, so fitted with clockwork machinery that he could broil steaks, roast a joint of meat, and make soup as he travelled along the road. The side-table in his dining-room was furnished with a large fountain of water; and every part of his house bore evidence of his ingenuity.

CAPITAL AND LABOUR.—III.

By J. E. Thorold Rogers, M.A., Tooke Professor of Economic Science.

THE WAGES OF LABOUR.

We have seen from the statements made in the preceding chapters that the true profits of capital are only wages under another name, and that these wages are due to the employer, because he superintends and directs other labour which is inferior or subordinate to his own. It is plain also that any contest between capitalist and labourer which has for its object—as either of the parties provokes or continues the contest—the advantage of one side at the expense of the other, is really a struggle between two classes of labourers, and that such a struggle could not occur except it were in the distribution of a stock or quantity, the several claimants of which base their demands on strictly analogous work. The amount of rent paid by an occupier of land, the rate of interest paid by a borrower, are not and cannot be objects of dispute, for they are settled upon considerations which are purely scientific, and therefore spontaneous in their origin, and precise in their quantity. A strike or a lock-out, in order to lower or heighten rent, to depress or exalt the rate of interest, would be a plain absurdity, to which no rational person would have recourse.

The wages of labour depend, exactly as every other article in value depends, on three causes. One of these is the demand for labour—*i.e.*, not labour in general, but the particular kind of labour. For since man must work in order to subsist, there always must be a demand, and a very energetic demand, for labour in general, or in the abstract. The second cause is the cost which has been incurred in order to produce the labourer—*i.e.*, to make him fit to carry on his work. The third is the probable duration of those powers, to the possession of which the labourer owes his power of producing something useful, and therefore of procuring employment. The labourer whose possession of such powers is temporary will as a rule obtain, relatively speaking, high wages during the time that his power lasts. For instance, I presume that the period in which a professional cricketer keeps his best strength, activity, and speed, is brief. The best-paid juvenile labour is that of a chorister in a cathedral. But the chorister's voice is sure to give way very soon after he has attained the best use of it. Those adults who are engaged in any dangerous or deadly trades, as, for instance, dry grinders, are paid at much higher rates than could be obtained for the skill which they possess, because those who are engaged in such a calling are notoriously short-lived. In short, the human body is a machine, which certainly wears out at some time or another, and may be deprived of those qualities which make it valuable at a very early date. The certain cessation and the possible arrest of those powers are risks of a less or more urgent kind, and must be provided against in just the same way that other risks are, by an extra payment.

At any given time, there may be too much of any given kind of labour in the market seeking for employment. In some callings this excess is chronic. Such is the case with needlewomen, with barristers, and perhaps with clergymen, the causes

of this excess being different. There are few employments open to women, and consequently those which can be followed are constantly overcrowded. The professions of the bar and the church are held in great esteem, and possess great occasional prizes. The first of these facts is practically an equivalent of wages; the second, owing to the natural disposition of mankind towards enterprise, and the general tendency of most persons to overvalue their abilities and their prospects, makes the callings attractive. And here it may be observed that self-esteem, which is odious in the individual, is, as a motive influencing men in the mass, one of the principal causes of social progress.

Sometimes again the cause is transitional. By this I mean that circumstances have arisen which render some kinds of labour unprofitable, and therefore depress the wages of those who ply the industry. At the present time such a state of things undoubtedly characterises the labour of the tailor and the shoemaker. Of late years work which used to be performed by hand is done by machinery. Now it is perfectly true that the substitution of mechanical labour for manual work is a gain to society; the substitution would never have occurred otherwise. A man who makes any process easier—and the motive which leads to the adoption of machinery is the design to make work easier—intends to sell the product of such work more cheaply, because in this way only can he get any advantage of increased sale in the general market. Generally, too, as the mass of society is benefited by the improvement, so the workman is not much harmed, since labour is in demand for the manufacture of the machines, and most industries are not of so rigid and special a kind as to disable the workman from seeking some similar employment. But there are cases where machinery annihilates an industry, or depresses it so seriously as to cause considerable distress to the workman. Such, as I have observed, is the case with the tailor and shoemaker. Similarly, I imagine, the art of photography has put an end to the calling, as a rule, of the miniature painter, and has induced similar effects on that of the engraver.

Lastly, the excess may be temporary. To this excess all callings whatsoever are liable, though in variable degree. In the winter months, the artisans employed in the building trades are ordinarily in excess. When the price of wool or cotton rises so high as to check the use of cloth manufactured from these materials, operatives in these callings are in excess. It is, however, superfluous to illustrate this kind of fact, for anybody who has had any experience whatever of social life could supply himself with instances.

We have thus been able to account for two of the causes which determine the rate of wages. These are the demand for the labour which the workman brings into the market, and the duration of those powers on which the value of labour depends. The remaining cause, the cost of producing the labourer, to which may be added the cost of maintaining the labourer, is, when the two other causes are accounted for, permanent, and governed by an invariable law. The law is, *If two persons of equal, or nearly equal natural capacity, are able to supply some labour which is in demand, the wages which each person will receive will be determined by the cost incurred in supplying the labourer, together with the charge which is necessary in order to enable the labourer to carry on his avocation.* To this law there is no exception.

My reader will see why I have used the expression, "of equal, or nearly equal capacity." There is, I am aware, an opinion that, in many callings at least, the capacities of men are equal, and that real differences in effectiveness are due to the fact that the ablest person has had the best education. If this be true, the case is covered by my definition, for greater cost has been incurred in preparing the individual for his calling. But if, as is certainly the case in some callings, and probably is in all, there are great differences of natural capacity or quickness, it is necessary to take account of such capacity, just as one does of the fertility which attaches to a particular field, or more notably still to some site for business premises. In some callings, natural capacity or genius is undeniably the primary cause of success, or, in economical language, of value. For example, the most mysterious of all natural gifts, that of the construction of music, has been developed at so early an age, and in so marked a manner, that no education can explain the phenomenon. It would be absurd to assign the genius of Mozart to training; and, in a kindred art, that of Shakespeare to careful instruction.

In order to enable us to deal with the effect of cost in producing the labourer on the rate of wages earned by the labourer, it will be convenient to explain the other element in the definition or law given above. Wages must include the cost of maintenance. No one could reckon the profit earned by a machine, unless he first deducted the cost of supplying the machine with the force necessary for its motion. So with the wages of labour. Now this cost varies with the labour. Take, for example, a physician in practice, a clerk in a counting-house, and an artisan. The first of these will be put to considerable cost in providing his home and his equipage, and in his manner of life. The second will need to have his home and his dress of such a kind as will probably be a considerable charge on his earnings. The last may be clad in very cheap garments, and does not need, as far as his habitation is concerned, any but the commonest and cheapest kind of lodging.

We now come to the most important constituent in determining the cost of labour, or the rate of wages, phrases which we will temporarily take to be synonymous. I say temporarily, for it is clear that low wages may mean dear labour, and high wages may mean cheap labour. If we merely gave the cost of their keep as the wages of a troop of unskilled and listless savages, as the condition of their performing the manual labour of a farm, we should find that our bargain would be a bad one. Contrariwise, if we were able to pick out the best farm workmen and artisans we might, even though we gave them wages which were considerably in excess of the average rate, we should find that the increased charge would be more than counterbalanced by an increased gain.

For the purpose of argument, however, we must assume that the labour is average in point of effectiveness, and that therefore the wages paid correspond to the cost incurred in producing that on which the labourer is engaged. We have taken into consideration what the charge is which must be incurred by the labourer himself, in order that he may be able to work at all; in other words, we have accounted for the cost of his maintenance. Besides this, we have assumed that the supply of labour is not in excess of the demands of the public; or, to vary the phrase, we are considering that labour only, the quantity of which is ordinarily equal to the use which the general wants of society can find for the service which is tendered. The remainder of the workman's wages is exactly proportioned to the cost or difficulty which has been incurred in order to provide him at all. If this cost has been high, the wages paid will be high; if, on the contrary, it is low, the wages will be low. It makes no difference how the cost has been diminished, whether it be brought about by the fact that the workman has been brought up and trained at the public expense, or has been cheaply taught by his relatives and friends. Similarly it makes no difference whether the workman has been made scarce or costly because it is hard to train him, or because some artificial expedients have been adopted in order to make his service expensive. The illustration of these several means by which labour may be made cheap or expensive will form the subject of this paper, and will amply prove my contention.

Some workmen are brought up and trained at the public expense, both for the highest and for the commonest callings. Thus, out of a feeling of religion or humanity, the practice of modern society will not allow any destitute person to starve; and least of all, those who are destitute without any fault of their own—such as children who have lost their parents, or have parents who are unwilling or unable to support them. Such children are maintained and educated by public charity, the funds necessary for the process being compulsorily levied on the occupiers of property. Now these children, if they are brought up, as they must be brought up, to compete for employment against others, reduce the average wages of all against whom they compete, by the cost of their bringing up. Similarly, the principle operates in the case of those who are bred up to professions, or assisted in entering such professions, by the funds which are derived from educational endowments. Long ago, Adam Smith pointed out that the scanty incomes obtained by clergymen in his time were, in part at least, to be ascribed to the fact that in a great measure the cost of their maintenance and education was defrayed from the endowments of the two great English universities. Again, there

is hardly a country in the world where the remuneration of the teacher is, on the whole—particularly in those branches of learning which require long and careful preparation—lower than it is in England. The reason referred to already is the explanation of this fact. The endowments in aid of the work done by the teacher are very great in this country, amounting, in the aggregate to several millions of annual income, and devoted partly to preparing the teacher for his calling, partly to assisting him with an income after he has entered on his calling. It is probable that half the students in Oxford and Cambridge are assisted largely in the cost of their education, and everybody knows how numerous, and in some cases how wealthy, endowed grammar-schools are. These permanent contributions to the education and incomes of teachers lower the sums which are paid to those who do not share in them.

Again, if the skill needed for any calling is cheaply imparted, the labour, however skilful it may be, is always scantily remunerated. A good agricultural labourer knows more than any other workman does. His knowledge is the growth of ages of accumulated skill. It is astonishing to think how many difficult operations he is competent to perform. None but they who have tried it can conceive how difficult it is to drive a long straight furrow, of uniform depth, with a plough. It is really a high art, and needs long and careful teaching. But this is only one among many kinds of skill which a good farm hand possesses. Still he is the worst-paid labourer in the country, and it is a wonder how he can live. The rule, however, which has been given above will explain the reason. He costs very little to bring up. From his earliest years he is set to farm work, and so earns his poor living. As soon as he has strength to do so, he follows his father to the plough, and gets instructed in his calling. His eye and hand are continually being educated in the numerous operations which he will be called on to perform, and which he will perform well. If, on the other hand, he was debarred from earning his living till he reached, or nearly reached, the maturity of his powers, his wages would be far higher than they are under his present circumstances.

I will now deal with such instances as exhibit the contrary phenomena. There are some callings in which the opportunity for earning a living is only accorded after a protracted delay. Such a calling, for example, is that of a barrister. The mere education of a barrister is not very expensive. At any rate, it is far less costly than that of many other callings. But the chance of success is doubtful; and, except in very rare cases, the fact of success is very slowly realised. Many men do not obtain a moderate income in this profession till they have reached middle life. As a consequence their training is peculiarly costly, for, in accordance with the rule given above, the successful advocate is remunerated not only for his own outlay, but for the outlay of those who are unsuccessful. The same facts are found in those occupations where great personal reputation is needed in order to command remuneration. Such a reputation is naturally of slow growth, and is accorded only after great scrutiny on the part of those who repose trust in the individual. It is no easy matter for a man to acquire fame as a physician, or as an attorney.

The same circumstances surround those callings in which the cost of producing the labourer are artificially enhanced, and the same consequences ensue. It was with a design to obtain larger wages for equal amounts of skill and labour that the custom of requiring an apprenticeship was first established, and has since been maintained. It is to prevent the flooding of a calling with a host of competing labourers, and thereby the lowering of wages in that calling, that combinations of artisans have carefully regulated the conditions under which persons can be admitted into this or that kind of so-called skilled labour. No business is easier to learn than that of a bricklayer. It is not supposed that there is any great labour required in order to fit a man to become a compositor. Were these callings thrown open to any one who might choose to qualify himself in any irregular manner, there is little doubt that many could do so, and that by these means the rate of wages in these and many analogous callings would be greatly lowered.

Wages, then, may be lowered either because the workman is assisted in obtaining the skill necessary for carrying on his calling, or because he learns the business in which he is engaged with little cost, and at an early period. On the other hand, they may be heightened because the period at which the workman earns his living is usually late in his life, and because his training is therefore costly; or the workman may, by some expedient, be debarred from learning his craft easily, or taking to it in early youth. In all these cases the rule laid down above is illustrated—that the rate of wages conforms to the cost of producing the labourer.

SEATS OF INDUSTRY.—XXXII.

LEITH.

BY WILLIAM WATT WEBSTER.

LEITH is the principal port on the eastern coast of Scotland, and until quite recently it was the sole harbour of Edinburgh, the capital of the northern division of the kingdom, of which it may be said to be a commercial and manufacturing suburb. The greater part of Leith is built on the level ground on both sides of a small river called the Water of Leith, near its confluence with the Frith of Forth, and is about two miles distant from Edinburgh, but an unbroken line of houses now connects Leith with the Scottish metropolis. This proximity to Edinburgh has powerfully influenced the fortunes of Leith. It is a striking instance of a port that has had, and still has, to contend against natural disadvantages of a formidable description; but which, nevertheless, has contrived to maintain, to a great extent, the commercial pre-eminence it early acquired among the sea-coast towns of Scotland.

In the twelfth century Leith was already a town of some note. The earliest reference to it that has been discovered occurs in the charter of Holyrood Abbey, which was founded by David I. in 1128. It is there termed *Inverleith*, and, so far as is known, this is the original name of the town. In 1313 the shipping in the port of Leith was burned by the English, and in 1329 the magistrates of Edinburgh obtained a charter from King Robert Bruce, granting them the harbour and mills of Leith. Subsequently the authorities of the capital purchased all the other rights and privileges of the town from Logan of Restalrig, and its municipal government and harbour administration remained in their hands until the passing of the Scottish Burgh Reform Act in 1833, which conferred on Leith the right of electing its own magistrates and councillors, and of managing its own municipal affairs. It was visited again by an English fleet in 1410, and its shipping destroyed. Before the close of the fifteenth century, we find the magistrates of Edinburgh abusing the extraordinary powers placed in their hands by Robert I., for in 1485 they passed an Act ordaining that no merchant of Edinburgh should presume to enter into partnership with an inhabitant of Leith under the penalty of forty shillings Scots, and the loss of the freedom of the city. The subjection of Leith to Edinburgh naturally excited bad feeling between the inhabitants of the two towns, and the jealousy survived for some time after Leith acquired its independence. A bridge was built over the river in 1493 by Robert Bellenden, Abbot of Holyrood House, which was used till 1788, when the first drawbridge was erected. In 1544 Leith was almost entirely destroyed, and its whole shipping was carried off by an English fleet under the command of the Earl of Hertford; and five years later a body of French troops sent to assist Mary of Guise, the Queen Regent, in the attempt she made to suppress the Reformation in Scotland, took possession of the town. Leith was besieged and captured in 1560, by the combined forces of Queen Elizabeth and the Lords of the Congregation, the leaders of the Scottish Protestants. The Solemn League and Covenant was subscribed by many of the inhabitants in 1643; and in 1649 the town suffered from a plague, which proved fatal to 2,000 out of the 4,000 inhabitants it then contained. After the defeat of the Scottish army by Cromwell at Dunbar, in 1650, Leith was occupied by an English force, under the command of Major-General Lambert, while the Protector took possession of Edinburgh; and shortly afterwards General Monk took charge of Leith. This last-mentioned officer induced several English families to settle in the town, and to their influence a large portion of the commercial enterprise subsequently manifested by its inhabitants is ascribed. During Cromwell's occupation of Leith, the inhabitants petitioned him to relieve them from "the sad and most grievous oppressions" they lay under from the magistrates of Edinburgh, but without effect. Cromwell repaired the fortifications of the town, and erected a citadel with five bastions at North

Leith, for the purpose of defending the harbour. A large portion of these works were demolished at the Restoration. Races were introduced at Leith in the reign of Charles II. The citadel was held for a short time by the Pretender in 1715. In 1779 the American privateer officer, Paul Jones, appeared in the Forth with three armed ships, and created a great panic by threatening to destroy all the vessels in the Frith and harbour; and about 1783 a battery of nine guns was erected to the west of the site of the citadel, for the protection of the port. This battery was afterwards enlarged into a fort and garrisoned by the Royal Artillery, Leith being the head-quarters in Scotland of that branch of the military service. At one period Leith was walled in on the land side.

Within the last one hundred and fifty years very large sums of money, partly supplied by the Government, have been spent on the improvement of the port. In 1720 a dock was formed on the east side of the river, and in 1777 a small quay, called the Custom-house Quay, was built. In the year 1800 a magnificent suite of wet-docks was planned, and by 1817 two were completed, each measuring 750 feet in length by 300 feet in width, and having a united area of about 10 acres. In 1831 an addition of 500 yards was made to the Old or East Pier, which, however, still gave but 17 feet of water over the bar at its mouth at high spring tides, so that no vessel above 400 tons could enter the harbour without lightening. Between 1848 and 1855, more gigantic works were constructed, including the formation of the Victoria Dock, which is equal in size to any of the others; the erection of the New or Western Pier and low-water landing slip; and the extension of the Eastern Pier 1,000 feet seawards. Vessels of 2,000 tons burden can be accommodated in the Victoria Dock. By the extension of the piers, which approach each other at their extremities, leaving an entrance of 250 feet, ships are enabled to get into smooth water in easterly gales sooner than formerly. The harbour stretches out upwards of a mile into the Firth of Forth, and has a depth of from 20 to 25 feet at high water. A line of railway has been laid on the Western Pier, so that vessels may use it either in discharging the whole of their cargoes, or in lightening in order that they may proceed up to the inner port. These piers are unsurpassed, and in addition to other useful purposes, they furnish the citizens with a healthful and pleasant promenade. Lighthouses are erected on both piers. The aggregate length of the quays is 8,400 feet, and they, together with the docks, are lined with extensive warehouses, furnished with powerful cranes and other machinery for loading and discharging, and have a line of railway connecting them with the Leith terminus of the Edinburgh, Perth, and Dundee line, and also with the North British Railway. There are six graving docks at Leith, one of which is 400 feet long by 80 feet broad at the coping, and 24 feet deep on the sill at spring tides. But, notwithstanding all that has been done, Leith is not by any means a thoroughly efficient port. Commenting on the enormous outlay that has been made on the harbour of Leith, and the results that have been obtained by it, Mr. J. R. M'Culloch says:—"The object in carrying out the piers was to form a harbour which at their extremity should have water sufficient to enable vessels to come to the landing stage at all times of the tide. But this object has not been fully attained; and though it had, we should have been inclined to regard the outlay upon it as little better than thrown away. The truth is, the docks and the new harbour at Leith are entirely misplaced. Instead of being where they are, the docks should have been constructed at Trinity or Granton, about three-fourths of a mile or one mile from Leith, being, however, nearer to it than the extremity of the new pier." A harbour has been formed at Granton by the Duke of Buccleuch, consisting of a pier built on the most approved principle, in the shape of the letter T, having harbours and landing stages on both sides, and projecting into the sea about 1,700 feet, and the duke has also constructed a breakwater. Previous to 1866, Granton was a creek of the port of Leith, but in that year it was made an independent port.

The manufactures of Leith are numerous and considerable, but it is to its commerce that the town chiefly owes its importance. In 1692 the shipping belonging to the port consisted of 29 ships, with an aggregate burden of 1,702 tons. In 1850 the shipping registered at Leith numbered 210 of which 187 were sailing vessels aggregating 19,490 tons burden, and 23 were steamers aggregating 3,790 tons; while in the same year 2,349 sailing vessels, representing 164,000 tons burden, and 807 steamers representing 191,060 tons entered the port, and 1,203 sailing vessels, with a total burden of 98,872 tons, and 800 steamers, with a total burden of 190,687 tons, cleared the port. In 1855 the number of vessels belonging to the port amounted to 168 sailing ships of an aggregate of 19,067 tons, besides 25 steamers of an aggregate of 6,326 tons. The total value of the exports in 1859 amounted to £872,673, and the Customs revenue of the port in the same year amounted to £572,872. In 1862, 4,761 vessels, with a total burden of 930,670 tons, entered and cleared the port. Among the principal imports of 1862 were 481,530 qrs. wheat, 213,538 qrs. barley; 47,075 qrs. oats; 51,547 qrs. beans and pease; 11,746 qrs. Indian corn; 86,192 sacks and barrels of flour; 58,352 loads of timber; 14,604 tons of guano; and wine and tobacco also figured largely in the returns. The registered shipping in 1864 consisted of 136 sailing vessels of a total burden of 23,614 tons, and 63 steamers of 13,984 tons burden. The Customs duties on goods imported into Leith in 1867 amounted to £607,264, and there belonged to the port in that year 84 sailing vessels of 50 tons and upwards, and 58 of less than 50 tons, the aggregate burden of the former being 22,479 tons, and of the latter 1,798 tons, and 52 large and 21 small steamers having a joint burden of 20,859 tons. The proportion of steam vessels to sailing ships, it will be observed, steadily and rapidly increases. Leith has an extensive foreign and colonial trade with Russia, Holland, Denmark, Sweden, Germany, the Levant, the East and West Indies, America, China, and Australia; but it is with the northern countries of Europe, and especially with the towns on the shores of the Baltic, that most business is done. It has frequent steam communications with St. Petersburg, Copenhagen, Rotterdam, Hamburg, Dantzig, etc. The home trade of Leith is also very large, and steamers ply constantly between it and London, Liverpool, Hull, Newcastle, Greenock, Glasgow, Aberdeen, Wick, Lerwick, and other British ports. The chief exports of the town are iron, hardware, machinery, coal, cottons, linen, silks, woollens, and haberdashery. Its principal manufactures consist of ropes, canvas, soap, candles, colours, paints, leather, bottles, and glass, the latter industry having been, it is believed, introduced into Leith by English settlers in the time of Cromwell. It also possesses several large ship-building yards, a sugar-refinery, meat-preserving and fish-curing establishments, several breweries, a distillery, extensive saw mills, cooperages, and iron foundries, and a number of very extensive flour mills.

Previous to the passing of the Reform Bill in 1832, Leith had no representative in Parliament, but since that time it has sent one member to the House of Commons. The local government is vested in a Provost, who bears the ancient title of "Admiral of Leith," four baillies, a treasurer, and councillors. The courts held by the magistrates are designated the Admiral and Bailie Courts. In 1851 the district of Leith, embracing Leith, Musselburgh, and Portobello, contained a population numbering 30,919, which in 1861 had increased to 45,417, and is still growing. On the whole, Leith has a mean and dirty appearance, and in the older quarters of the town the streets are narrow and inconvenient, and the houses closely built and dilapidated; but many of the more modern streets, especially in the neighbourhood of the "Links," an open down on the south-east, are wide thoroughfares, lined with handsome houses. The part of Leith which stands on the north-west side of the river is known as North Leith, and that on the opposite side as South Leith. It is in the former that the principal places of business, warehouses, and even residences of the merchants are situated. Among the public buildings the most noteworthy are the Town Hall and Court House, built in 1828, where the Borough and Sheriff Courts are held; the Custom House, a Grecian structure with pediment and columns; and the Trinity House, built in 1817, in place of the edifice erected in 1555, which is adorned with a large and important picture by David Scott. The Female Asylum for Incurables, which was given to the town by Sir John Gladstone, the Premier's father and a native of Leith, deserves mention. This noted Liverpool merchant also built a church called St. Thomas, in his native town, which he handed over to the General Assembly of the Established Kirk of Scotland. The Rev. John Home, the author of "Douglas," and the solitary dramatic writer of any note that Scotland has produced, and Hugh Arnot, the historian of Edinburgh, were natives of Leith.

TECHNICAL DRAWING.—LXXVII.

DRAWING FOR CABINET MAKERS (*continued*).

THE first subject of this lesson (Fig. 605) is a portion of a piece of furniture called a *Secretaire*, adapted either for a library, parlour, or bedroom. It consists of two heights; the upper one being fitted with shelves to contain a small selection of books, whilst the lower case contains drawers. The upper portion of this lower case is not, however, a drawer as appears externally, but is provided with a hinged flap, which folds down on its lower edge so as to form a writing-board; and behind this is the nest of pigeon-holes shown in the present example.

In this nest the pigeon-holes are ranged above the drawers, the space in the centre being closed by a small door, opened and shut by a secret contrivance; and behind this are other pigeon-holes and drawers for cash or private papers.

The door is hung on pivots placed horizontally at about $\frac{3}{8}$ inch from the top, and is so arranged that on being pressed inward at the top it yields backward and tilts out below, affording a hold by which it is raised parallel to the cross-cheeks, and thrust into them.

In commencing to copy this example, draw the perpendiculars *a* and *b*, and the horizontals *c e* and *d f*, thus constructing the rectangle *c d e f*, which is the boundary of the nest of pigeon-holes. Next draw the pilasters and cornice of the whole case, and the horizontal line *g h*. The rectangle *d f g h* is the edge of the writing-flap, which is here represented as turned down at right angles to the front of the secretaire, in order fully to expose the pigeon-holes. Draw the inner line of the nest, representing the thickness of the wood, and then the horizontal line *i j* dividing the pigeon-holes from the drawers. The rectangle *c e f d* is now divided horizontally into two others. In the lower portion set off on each side the upright cheeks of the middle compartment *k l*, rule the horizontal lines, and divide the left and right spaces into drawers.

Now carefully divide the upper compartment into twelve equal parts, and on each side of the points of division set off half the thickness of the wood forming the sides of the pigeon-holes; across these draw the springing-line for the arches, and on this set off the centres from which these are to be struck. The rest of the subject will now be easily followed from the example.

The next subject (Fig. 606) is the front elevation of a dwarf mahogany book-case, drawn to the scale of 1 inch to the foot.*

In commencing to copy this object, having drawn the ground-line and the external perpendiculars for the sides of the case, draw the two horizontal lines representing the thickness of the top. Next draw the bottom line, and then the inner edges of the pilasters. This may be followed by the narrow fillet, which is the bottom of the transverse member, representing an architrave supporting the top, but in reality forming a portion of the main framing of the case, as will be seen by the section, Fig. 607.

The shelves are now to be drawn; but on this head no instructions will be required. The feet are to be commenced by a central perpendicular, crossed by a horizontal dividing the two portions. On this line are situated the centres from which, with radius extending to A, the upper curves are struck; the centres for the lower curves are on the ground-line, at the distance marked B.

Fig. 607 is the section on A B. From this it will be seen that the top does not depend only on the general carcase of the case, for, as is seen in the elevation, the whole front is open, whilst the section shows that the back affords but little support, since it consists merely of a framed panel, screwed into the sides, the cross-pieces, and the bottom. The main support of the top is obtained from two stout pieces of timber, the section of which is shown at *c* and *d*. These are at their ends dovetailed into the tops of the sides; the one is screwed to the front ledge, whilst the framing of the back is screwed (as already described) to the other. The object of this additional strength in the top of the case is to provide for heavy objects, such as air-pumps, microscopes, and other philosophical instruments, being placed upon it.

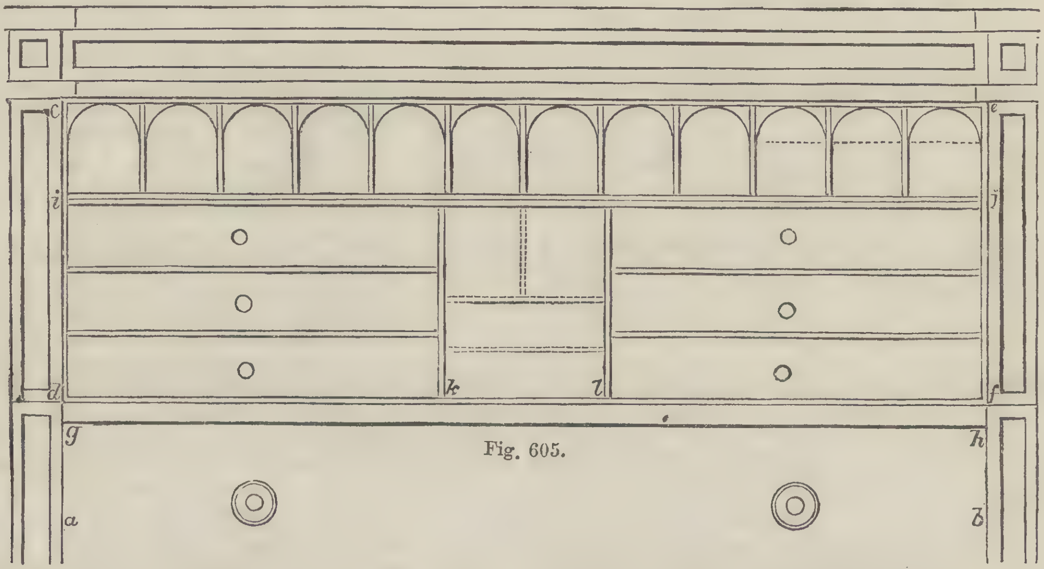

Fig. 605.

The inside of the book-case is provided with movable shelves resting on racks. These consist of a pair of toothed slips, *e f*, (about) $1\frac{1}{4}$ inch broad by $\frac{3}{8}$ inch thick, exactly similar to, and equidistant from, each other, glued along the insides of the walls of the case. Cross-ledges, *g g*, of the same thickness, and bearing the shelves, *h h*, are fitted between the slips, so as to rest on the teeth of the slips, with which, when pressed in, they become flush, and the heights of the shelves may be changed as required by moving the cross-ledges.

In simple book-shelves this is sometimes accomplished by cutting saw-like grooves in the sides, and bevelling the ends of the shelves, which thus slide in and out. This could not be applied in the present case, since the front of the pilasters projects beyond the mere thickness of the sides; they are therefore put in obliquely, and then dropped down on to the ledges, a small piece being taken out of each corner to allow space for the slips.

Another method is by wooden pins placed in holes, ranged in pairs at different heights in the sides. This is not generally satisfactory, since the pins have a tendency to fall out, causing the trouble of removing the books in order to replace them.

The method of drawing the section is precisely similar to that

* For the method of constructing a plain scale the student is referred to the TECHNICAL EDUCATOR, Vol. I., page 38.

pursued in regard to the elevation, and therefore it is not deemed necessary to give any further directions. It will be observed that the top projects more at the back than in the front. This is to allow for the skirting near the floor, so that the top may be brought close up to the wall.

Fig. 608 is the front elevation of a small mahogany writing-table with drawers and desk-top. Fig. 609 is the end elevation, showing the method by which the top is raised or lowered. The upper surface of the body of the table, and the under surface of the top, are each sunk about $\frac{3}{8}$ inch to allow of the support lying flat between them when the top is flat. This support works on toothed slips or racks, so that the slant of the top may be adjusted as necessary, at will.

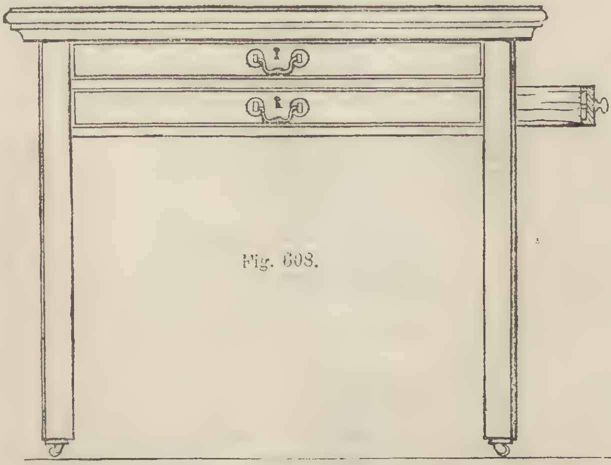

Fig. 608.

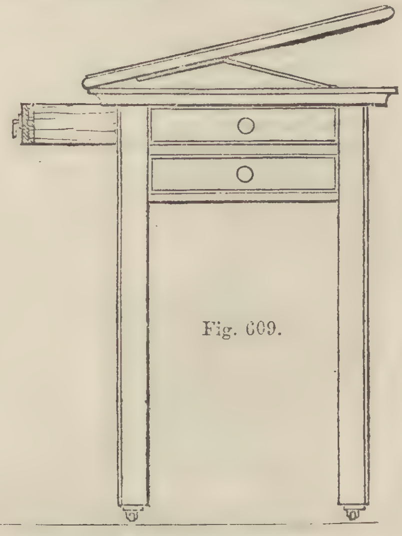

Fig. 609.

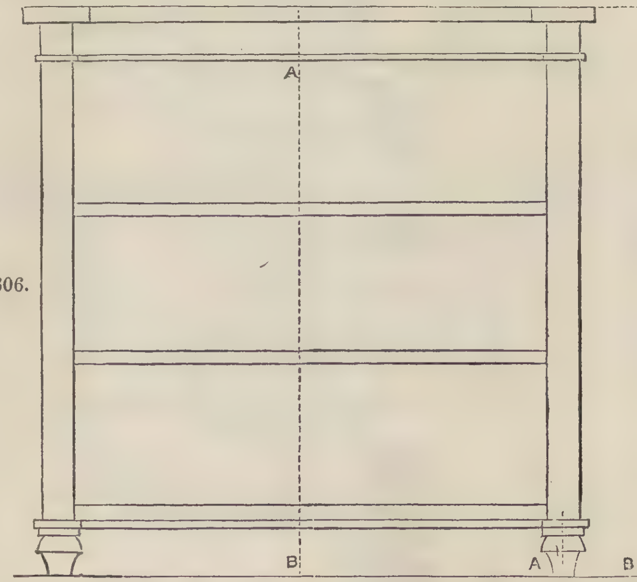
the perpendiculars for the legs; and it may here be mentioned that it will save time and add to the accuracy if both the views be proceeded with simultaneously, as the heights can thus be ruled with the same horizontal lines.

At a little distance, therefore, from the front, draw the perpendiculars for the legs of the end elevation. Having done this, next draw the horizontals for the framing, the top, and drawers, and unite those of the top by curves for the mouldings. Of course, in the end elevation the top is not formed by horizontal lines, and in copying the example the angle should be measured by the method shown in "Linear Drawing," so that the inclination in the copy may correspond with that of the original. The handles, castors, etc., do not call for any special instructions. The handles in the drawer and false drawer in the front of the writing-table are made of brass, and turn on pins passing through sockets in the circular plates, from each of which a screw projects, which is passed through the woodwork of the drawer, and fastened within by a nut. Handles of this kind are useful, as they admit of an easy application of the key. When solid knobs are used instead of a swing-handle, as in the side drawer which has no hole, and which therefore requires only one knob, two should be used, one on either side of the lock in the centre.

Fig. 606.



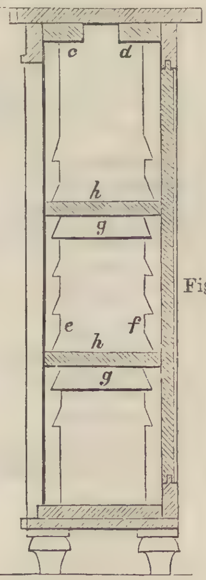


Fig. 607.

The top drawer in the front, and the lower drawer in each end, are made to open, the others being necessarily sham drawers; for it will be clear that the space which would be required for a bottom drawer in the front is occupied by the drawers in the end, and the space which would be wanted for the top drawers in the ends is taken up by the top drawer in the front. This is plainly visible in the two figures.

The outer edges of the legs are rounded off and beaded. In commencing these subjects draw the ground-line, and another above it, at a height equal to that of the castors. Next draw

BUILDERS' QUANTITIES AND MEASUREMENTS.—XIX.

BY E. WYNDHAM TARN, M.A.

BILL OF QUANTITIES (*continued*).

JOINER AND IRONMONGER.

		Numbers in deal—
		63 housings of flyers to string . . . .
		6 ditto winders, ditto . . . . .
		15 ditto balusters to handrail . . . .
		4 ditto steps into newell . . . .
		30 ditto dovetailed for balusters . . . .
		6 rounded corners to shelf . . . .
		2 ditto 2 in. dresser . . . . .
		2 Ogee cut ends to stiles of sash . . .
		2 tongued angles to string . . . .
		10 ditto mitred angles to 15 in. skirting. .
		8 ditto mitres to 9 in. ditto . . . .
		3 dovetail blockings . . . . .
		2 pendants to newell . . . . .
		15 $1\frac{1}{4}$-in. square balusters . . . .
		30 $1\frac{1}{2}$-in. turned ditto . . . . .
		15 returned moulded nosings to treads . .
		15 cut brackets to string of stairs . . .
		1 curtail scroll end to step . . . .
		2 elbow caps. 2 soffits to boxings . .
FT.		Mahogany French polished—
2	2	Supl., $\frac{3}{4}$-in. wrought both sides . . .
11	5	„ 1 in. ditto seat and riser . . .
6	2	„ ditto beaded flap and frame . . .
34	6	„ ditto moulded and square framing
25	6	„ $1\frac{1}{4}$ in. ditto counter top, glued and blocked . . . . . .
24	6	„ 2 in. ditto astragal and hollow folding sash door, diminished stiles, lower panels moulded and bead flush . .
66	6	„ $2\frac{1}{4}$ in. lamb's-tongue shop sash . .
17	6	„ ditto, ditto, circular . . . .
3	6	Run, moulded nosing . . . . .
7	0	„ $\frac{1}{2}$ in. skirting, 4 in. wide . . .
15	0	„ 3 in. moulded handrail. . . .
3	0	„ ditto, writhe . . . . .
18	0	„ beaded door frame, 3″ × 3″ . . .
3	0	„ wrought and chamfered fillet . .
6	0	„ mortise clamp . . . . .
6	0	„ heading joint . . . . .
		Numbers in mahogany—
		1 dished hole in seat of water-closet . .
		1 beaded hand-hole, ditto . . . .
		2 rounded corners to skirting . . .
		1 fitting and hanging flap to counter . .
		4 mitres . . . .
		1 $\frac{3}{4}$-in. quadrant shelf, 9″ × 9″, on fillets .
		1 handrail scroll . . . . . .
		30 housings in handrail. . . . .
		Ironmongery and fixing—
		3 pair $1\frac{1}{2}$-in. wrought iron butts and back-flap hinges . . . .
		2 „ 2-in. ditto. . . . . .
		3 „ $2\frac{1}{2}$-in. ditto . . . . .
		1 „ 3-in. ditto . . . . .
		1 „ $3\frac{1}{2}$-in. ditto . . . . .
		1 „ $1\frac{1}{2}$-in. brass butts and gilt head screws
		3 „ 2-in. ditto . . . . .
		1 „ 4-in. ditto . . . . .
		1 „ 5-in. ditto. . . . . .
		2 cupboard locks. . . . . .
		1 iron-rimmed lock, and brass furniture .
		2 6-in. mortice locks, and china ditto . .
		1 10-in. drawback lock. . . . .
		1 patent latch . . . . . .
		2 brass escutcheons . . . . .
		3 brass sash fastenings . . . .
		2 ditto casement ditto . . . .
		1 wrought-iron shutter-bar, 3 feet long, and plates . . . . . .
		1 brass rack chain fastening . . .
		3 „ knob turnbuckle . . . .
		1 „ thumbscrew and plates . . .
		2 „ hook and eye . . . . .
		2 „ 10-in. barrel bolt . . . .
		3 handrail screws . . . . .
		2 screw bolts to newell . . . .
		1 screw nut and joint to newell cap . .
		1 cast-iron newell . . . . .
		2 ditto shelf brackets . . . . .
		6 japanned cloak pins . . . . . .
		2 pair china finger plates . . . . .
		4 ebony drawer knobs . . . . . .
		3 brass sunk flush rings . . . . .
		3 dozen brass hooks . . . . . .
		2 pair swing centres . . . . . .
		4 brass handles . . . .
		Carried to summary . . £

PLASTERER.

YDS.	FT.	
		Portland cement, with three parts sand—
53	6	Supl., render plain work on brick and jointed
27	4	„ ditto pilasters . . . . . .
37	11	„ ditto moulding . . . . . .
205	6	„ ditto hearths and floors . . .
38	3	„ dubbing out for extra thickness . .
FT.	IN.	
44	0	Run, arris edge . . . .
66	0	„ $4\frac{1}{2}$-in. reveals . . . . . .
70	0	„ 3-in. moulding . . . . . .
25	6	„ chamfered edge . . . . . .
52	0	„ 7-in. skirting . . . . . .
		Numbers in Portland cement—
		4 mitres to 15-in. moulding . . . .
		8 ditto 3-in. ditto . . . . . .
		10 brackets, 12″ × 6″ . . . . . .
YDS.		
44	0	Supl., render and rough cast . . . .
SQRS.		
$3\frac{3}{4}$		„ pugging $1\frac{1}{2}$-in. thick . . . .
YDS.	FT.	Parian cement—
57	0	Supl., trowelled for painting . . . .
0	21	„ pilasters . . . .
0	6	„ moulding . . . .
0	42	Run, quirk . . . .
0	45	„ skirting, 9-in. high with 3-in. moulding.
		Number—
		6 mitres to ditto . . . . . .
		Plaster—
57	0	Supl., render and set . . . . . .
57	0	„ ditto float and set . . . . .
$27\frac{3}{4}$	0	„ lath, plaster, and set . . . . .
$49\frac{3}{4}$	0	„ ditto float and set . . . . .
$77\frac{1}{2}$	0	„ stop, claircolle, and whiten . . . .
0	81	„ ditto, and distemper, two tints to cornice
0	162	„ cornice . . . .
0	87	Run, quirk . . . .
0	54	„ enrichment 6 in. wide . . . . .
		Numbers—
		12 mitres to 18-in. cornice . . . .
		2 36-in. centre flowers . . . . .
		Carried to summary . . £

SMITH AND BELL-HANGER.

CWT.	LB.	
		Cast iron—
36	109	Columns and girders . . . . . .
FT.		
3	9	Supl., casement and frame . . . . .
YDS.		
$8\frac{1}{2}$		Run of Ogee gutter, with clips and brackets .
$9\frac{1}{2}$		„ half round eaves, ditto . . . . .
16		„ 3-in. rain-water pipe, jointed with red lead
FT.	IN.	
10	6	„ balcony, 21 in. high, with wrought-iron top-rail and standards . . .
25	0	„ coping on 9-in. wall . . . . .
		Numbers—
		2 heads and shoes to 3-in. rain-water pipe .
		2 nozzles. 2 angles to Ogee gutter . .
		2 coal plates and hooks. 4 air-bricks . .
LB.		Wrought iron—
144		Chimney bars . . . .
217		Guard bars . . . .
$137\frac{1}{2}$		Shelf . . . .
$93\frac{3}{4}$		Rail . . . .
433		Bars . . . .
15		Lead for running . . . .
FT.		
15	0	Supl., $\frac{1}{2}$-in. wrought-iron door and frame, with hinges, lock, and brass knob . .
10	0	„ $\frac{1}{8}$-in. sheet-iron linings to panels, and drilling holes therein . . . .
		Numbers—
		40 points to 1-in. bars . . . . . .

	40 holes in ½-in. rail
	1 frame and door to copper
	30 ½-in. bolts, 15 in. long, with heads, nuts, and screws
	2 ditto, 12 in. long, ditto
	2 1-in. ditto, 12 feet long, ditto
	1 4 ft. 6 in. kitchener
	1 copper, weight 14 lb
	2 36-in. register stoves, steel front
	4 30-in. ditto, Berlin black

BELL-HANGER.

Number—	
	10 bells hung complete, with cranks, tubing, springs, back-carriage, pendulums, etc.
	4 ornamental lever pulls
	1 brass knob pull and plate
	1 ditto slide ditto
	Carried to summary . . £

PLUMBER.

CWT.	LB.	
45	0	Milled lead, and laying on roofs
2	1	Ditto, ditto, gutter
5	70	Ditto, ditto, hips
1	101	Ditto, ditto, step flashing
2	89	Ditto, ditto, cistern
17	6	Run, soldered angle to cistern
15	0	„ close nailing, with copper nails
12	0	„ ¾-in. strong pipe and joints
45	0	„ 1-in. ditto
35	0	„ 1¼-in. ditto
16	0	„ 1½-in. ditto
32	0	„ 5-in. soil ditto
		Numbers—
		2 solder joints to ¾-in. pipe
		2 ditto, 1-in. ditto
		2 ditto, 1¼-in. ditto
		2 ditto, 1½-in. ditto
		2 1¼-in. brass washer and waste
		1 1¼-in. trumpet standing waste-pipe, 27 in. long
		1 service-box soldered to cistern
		1 brass grating ditto
		1 ¾-in. ball-cock and copper ball
		1 ditto bib-cock
		1 1-in. stop-cock
		1 D-trap
		1 syphon-trap in 1½-in. pipe
		1 water-closet apparatus, with blue and white basin, brass handle, etc.
		1 2½-in. force-pump
		1 bend to 5-in. soil pipe
		Carried to summary . . £

ZINC-WORKER.

FT.		
120	0	Supl., 25 oz. zinc, laid on flats
24	0	Run, 4-in. eaves gutter and fixing
30	0	„ 2½-in. rain-water pipe, and ditto
		Numbers—
		2 octagon heads to rain-water pipe
		2 shoes ditto
		2 nozzles. 4 stopped ends to 4-in. gutter
		Carried to summary . . £

GAS-FITTER.

FT.	IN.	
55	0	Run, 1-in. wrought iron welded tubing
30	0	„ ½-in. tin ditto
		Numbers—
		5 short pieces of 1-in. iron tubing
		3 bends ditto
		2 tees ditto
		1 cross ditto
		1 connecting piece, ditto
		1 1-in. stop-cock
		8 ½-in. union joints
		4 12-in. plain brackets
		2 24-in. double ditto
		1 pendant with hydraulic joint
		1 5-light chandelier, ditto
		Carried to summary . . £

GLAZIER.

FT.	IN.	
62	3	Supl., glazing with seconds crown, in squares, 14″ × 10″
36	0	„ ditto, with best crown, in squares 18″ × 12″
19	6	„ ditto, with best 26 oz. British sheet, in squares 39″ × 18″
19	6	„ polishing to ditto
73	6	„ glazing, with ½-in. best British plate, in squares 7 ft. by 3 ft. 6 in.
10	0	„ ditto, with ¼-in. ditto, in squares 48″ × 15″
13	6	„ ditto, rough plate
24	6	„ bending plate glass
96	0	„ glazing in lead quarries with tinted cathedral, copper ties soldered on, and cementing to stonework
6	0	„ hacking out old glass
		Numbers—
		8 dozen squares cleaned
		4 glass tiles, 20″ × 10″
		Carried to summary . . £

PAINTER AND DECORATOR.

YDS.		
8⅓		Supl., knotting, stopping, priming, and 3 oils
31		„ ditto, 4 oils
4		„ ditto, to skylight, ditto
96		„ 4 oils, and flat ash green to plaster
10½		„ grained and twice varnished
FT.	IN.	
16	0	Run, knotting, priming, and 2 oils, shelf edge
34	0	„ ditto, 3 oils, cutting to treads of stairs
30	0	„ ditto, ditto, strings, ditto
240	0	„ ditto, 4 oils skirting
40	0	„ ditto, ditto, staff bead
96	0	„ grained and twice varnished, skirting
		Numbers—
		3 shutter bars, 3 oils
		4 sash frames, both sides, 6 ft. by 4 ft., 4 oils
		2 ditto, ditto, 8 ft. by 5 ft. 6 in. ditto
		8 doz. small squares, ditto
		2 ditto large ditto, ditto
		2 small casements, ditto
		4 stone chimney-pieces, 5 oils
YDS.		
4⅓		Supl., staining deal, sizing, and twice varnishing
40		„ distemper, two tints
IN.		
102		Run, 4-in. letters, gold and shaded
FT.	IN.	
48	0	„ 1-in. moulding gilt
		Carried to summary . . £

PAPER-HANGER.

YDS.	
47	Supl., canvas lining
36	Run, border
FT.	
130	„ 1-in. gold moulding, fixed with needle points
	Numbers—
	8 pieces of paper, value 1d. per yard, hung, including preparing and sizing walls
	11 ditto, 2d. ditto
	13 ditto, 6d. ditto
	15 ditto, marbled, 3d. per yard, hung in blocks, lined, sized, and varnished
	39 ditto, hanging lining paper, preparing and sizing walls
	Carried to summary . . £

SHIP-BUILDING.—XVIII.

BY W. H. WHITE,
Fellow of the Royal School of Naval Architecture, and Member of the Institution of Naval Architects.

DECKS OF SHIPS (*concluded*).

THE framing of decks occupies a position, in relation to what we have termed the "deck-flat," similar to that occupied by the frames of ordinary ships in relation to the skin planking or plating. Consequently the transverse beams do not aid the flat in resisting longitudinal bending strains, although they are most important aids to the maintenance of transverse form. There have, however, only been very few cases in which transverse deck framing has been given up in favour of other arrangements. Having to act independently, it becomes most important that the deck-flats should be made strong, in order that they may lend efficient help to the skin and the longitudinal pieces of the framing, in their resistance to longitudinal bending strains. This fact has long been recognised by writers on the theory of ship-building, but it has only within the last few years had any considerable influence on practice; and probably its general recognition at the present time is as much due to the necessity for much greater strength in the long ships now built as it is to any other cause. Wood ships were expected to display some amount of weakness in the upper works after having served for a moderate time, even when the best possible arrangements of the deck-flats had been made; and in the earlier iron ships the decks were little, if anything, stronger than those of wood ships, advantage not being taken of the superior qualities of the new material. This neglect led in some cases to serious, if not fatal, accidents. Such accidents, and evidences of weakness in numerous other cases, have so fully shown the necessity for giving a strong top flange to the ship considered as a girder, that builders now take steps to supply such a flange in iron ships; and we shall afterwards illustrate some of their plans. In many recent wood ships, too, a similar object has been aimed at, and to some extent attained; but before describing this modern practice it will be desirable to glance at the usual arrangement of the deck-flat in ordinary wood ships.

Wood ships with wood beams have their deck-flats formed by planking laid upon and fastened to the beams, as shown in Fig. 54, p. 36; hence the term "deck-flat" is commonly used instead of "deck-planking," although we have given it a wider meaning. In combining and fastening the strakes of deck-planking, care is taken similar to that described for the skin-planking. The strakes are almost always placed longitudinally, crossing the beams at right angles. Their butts are placed upon the beams, and shifted so that three passing strakes may come between consecutive butts on the same beam; the shift of butts is consequently identical with that for outside planking, shown in Fig. 27 (Vol. III., p. 256). The fastenings are also somewhat similarly arranged, only in the deck-planking they consist of nails or dumps (short bolts) driven into, not through the beams. With broad planks, double fastening is used in each beam; with narrower planks, double and single fastening is sometimes employed; single fastening is rarely used. Each of the butts is generally secured by two bolts driven into the beams.

We have already described how the deck-flat is bounded by the thin water-way, near the ship's side; and it will suffice to add here that towards the bow and stern, where the decks narrow rapidly, the strakes of plank lying nearest the side are ended successively. Nearer the middle of the deck, and stretching along by the sides of the principal hatchways, there are usually fitted several thicker and stronger strakes of planking, termed "binding strakes." These planks are carefully fastened to the beams (by scoring or dowelling), and running throughout the whole length of the ship, they form a valuable longitudinal tie. The remainder of the deck planking is usually of uniform thickness.

Where the hatchways occur special arrangements are required. The side-framing of these openings is formed, as said before, by longitudinal carlings let down between the beams, which form the foremost and aftermost boundaries of the hatchways. Upon these carlings "coamings" are fitted to enclose two sides of the hatchways, and upon the beams other pieces, named "headledges," of the same depth as the coamings, are secured to complete the enclosure. The inner binding strakes of the deck-flat fit against the sides of the coamings; and between the headledges of adjacent hatchways, the deck-plank has to be fitted in short lengths. In fact, this latter portion of the flat must be regarded chiefly as forming part of the deck, considered as a watertight platform; and it does not contribute much to the structural strength. It is impossible, however, to enter into detail further, and attention must next be directed to the arrangements of the deck-flat in a wood ship with iron beams, such as is illustrated by Fig. 55, p. 36.

The main portion of the flat in such cases consists of deck-planking worked directly upon the beams, and arranged with similar care to that of ordinary wood ships. In order to add to the strength of the deck, especially against hogging strains, the stringer-plate S is worked upon the beam-ends; and being carefully butt-strapped, as well as fastened to the beams and to the side, it forms a most valuable longitudinal tie. It, of course, helps the deck-planking somewhat also against sagging strains tending to compress the upper part of the ship; but this is of less importance than its assistance against hogging strains, because the butted planks at any cross section—amounting to no less than one-fourth of the total number of strakes—are effective against compressive strains, but almost useless against tensile strains. Experience with vessels constructed on this plan has proved that the addition of the stringer-plate is a very considerable improvement; and the fact is becoming generally recognised, although the use of such iron strengthenings is not yet common. From the sketch it will be obvious that these desirable results have been obtained without sacrificing simplicity of workmanship, or encroaching upon the internal space; in fact, as regards the first-named feature, the use of iron beams and stringers has made it possible to greatly simplify as well as improve the beam-end connections. The stringer-plates, it must be added, run throughout the whole length of the ship, and those on opposite sides of a deck are brought together and secured to each other at the bow and stern. By this simple arrangement the necessary connection is secured between the two sides of the ship, and all the elaborate devices of "ekings," "deck-hooks," "transoms," etc., required in a ship with wood beams are dispensed with. This is a matter of some importance, and it will not be out of place to illustrate it more fully. The ordinary practice in ships having beam-end connections similar to those shown in Fig. 54, p. 36, is to stop the shelf-pieces a little short of the bow and stern, the ends being rounded off just beyond the second or third beam from each extremity. For the remainder of the length a longitudinal timber named an "eking" is secured to the ship's side, the upper surface being well with the upper surface of the beams, and forming a support for the deck-planks. Close to the stem the eking is associated with a massive timber "breast-hook" or "deck-hook," which is bolted to and strongly connects the opposite sides; and right aft a corresponding timber known as a "transom" is fitted. In many cases the connection thus made is strengthened by large iron "crutches," forged so as to fit upon the inner surfaces of the deck-hooks and transoms, and bolted through them and the timbers of the frame. Contrasting this elaborate arrangement with the simple stringer arrangement possible with iron beams, it will be seen that the advantages attaching to the later plan are considerable.

The deck-planking in cases such as Fig. 55, p. 36, is secured to the beam-flanges by nut-and-screw bolts; but in wake of the stringer-plate the fastenings of the planks should be brought away from the beams, and placed in the intermediate spaces. By this means the beam-flanges are only weakened by the holes for the rivets securing the stringer-plate, and the deck-planks are enabled to aid the stringer against buckling under compressive strains. Sometimes the flanges of the beams are too narrow to receive the bolts securing the butts of the planks, and then it becomes necessary to rivet a small butt-plate to the beam under the butt.

Passing on to ordinary iron ships, we meet with an arrangement of deck-planking precisely similar to that just described, associated with some description of iron strengthenings. The most common forms of the latter are stringer-plates on the beam-ends, longitudinal tie-plates on each side of the principal hatchways, and diagonal tie-plates stretching from side to side between the hatchways. It is most desirable that the stringer-plates should be directly secured to the outside plating, with which they have to act in resisting bending strains, and to

accomplish this involves some trouble on some of the decks. For example, Fig. 56, p. 37, illustrates the kind of connection that would be employed on the main or lower deck of an iron ship. Notches have to be cut out of the stringer-plate in wake of the reversed frames, in order that it may be "fitted home" to the outside plating, and the connection of the two is made by means of short pieces of angle-iron. A continuous stringer angle-iron is fitted inside the reversed frames, in order to strengthen the connection with the side. This plan answers every purpose as long as it is not required to make the stringer watertight between the frames; but when the reverse is true, which is not commonly the case, other means are adopted. One of the simplest plans for securing watertightness is to fit short pieces of plate in the spaces between the frames, and to secure them by forged "staple" angle-irons, fitting accurately against the frames and plating; the stringer-plate proper running along inside the frames, and being secured to the short pieces of plates either by a lap-joint, or by a flush-joint with a covering edge strip.

The frames commonly end beneath the upper deck stringer-plate, so that it can be secured to the outside plating, or "sheer-strake," without difficulty, by a continuous angle-iron. Such a connection is obviously of greater importance on the upper deck than it is on either of the others, because failure is most likely to begin at the upper part if it occurs at all. In cases where exceptional strength is considered necessary, it is usual to obtain it by increasing the breadth and thickness of the stringer-plate, and by doubling the sheer-strake; and a similar course is often followed when ships display signs of weakness. Longitudinal and diagonal tie-plates are also fitted upon the upper decks of iron merchant ships to give greater strength—the former being intended to act with the stringer-plate in resisting bending strains, and the latter to lend some aid against such strains, in addition to preventing any "racking" in the deck. There is no doubt that these tie-plates are useful when so fitted; but it is questionable whether the material thus disposed might not be better placed in the form of an addition to the stringer-plate. This point has been much discussed by ship-builders, particularly as regards the use of the diagonal ties; and now Lloyd's Rules permit the disuse of diagonal ties, provided a certain additional strength is given to the stringers. The longitudinal ties at the sides of the hatchways are, however, still made compulsory by the Rules, although strong arguments may be advanced in favour of their disuse. Supposing, for example, that the iron used in these longitudinal ties were added to the stringer-plate, it would be intimately associated with, instead of being distant from, the skin-plating with which it is required to act; and, moreover, the stringer so formed would be likely to form in itself a more efficient longitudinal strengthening than is formed by the widely-separated stringer and tie-plate, which may or may not act jointly. On the other hand, it must be admitted that these longitudinal tie-plates form excellent strengthenings to the deck in wake of the principal hatchways, which are of considerable size; but the special strength required at these places can be obtained by other means of a simple character, in cases where no tie-plates are fitted. It may be interesting to add that in the unarmoured iron ships recently built for the navy tie-plates have been entirely dispensed with, and strong stringers alone fitted. One other matter of importance must be mentioned. In arranging stringer plates care should always be taken to make their butts give good shift to the butts of the strakes of skin-plating in wake of the stringers; and the butt fastenings of the stringer-plates and angle-irons should be made sufficiently strong.

Nearly all the preceding remarks apply with equal force to composite ships of the ordinary construction. In them there is an iron sheer-strake to which the stringer-plate is attached; and longitudinal and diagonal tie-plates are also employed. On all except the upper decks, however, it is usual to fit the stringer-plates within the reversed frames; and the reason is obvious, seeing that there is generally only a wood skin in wake of these decks. In some cases, however, strakes of plating are worked in wake of the beam-ends of all the decks, and then the stringer-plates are scored in between the frames and secured to the iron plating. No other points of difference in the deck arrangements of iron and composite ships demand notice.

Stringers and ties such as have been described give sufficient strength to the decks of most merchant ships, but in iron vessels of great size and length additional strength is needed, at least on the upper decks. This want has been met in many cases by adding considerably to the breadth of the stringer, and consequently forming what is termed a "partial iron deck;" and in other cases a "complete iron deck" has been formed by plating over the whole surface of the deck from the line of the hatchways to the ship's sides with continuous strakes, the middle-line spaces between the hatchways being either left unplated or else covered with thinner plating. Complete iron or steel upper decks have been long recommended by some of the greatest authorities on ship-construction; and they have been for many years employed in the iron-clad ships of the navy. Only recently, however, have they found much favour in the merchant service, although a few ships have been so constructed; but with the great increase in the lengths and proportions of ocean steamships, has come the conviction that nothing but advantage results from covering the upper deck with iron or steel plating, and the practice seems likely to become common.

A very brief description of the mode of fitting deck-plating will suffice. The plates are usually flush-jointed at both edges and butts, and consequently rest directly upon the beams, no liners being required. The edges are secured by continuous strips, single-riveted; the butts are covered by double or treble riveted straps. All the joints can be caulked, and the whole plating made watertight if required. In some cases the plan of lap-jointing is resorted to, and the plating arranged just on the same plan as the skin-plating, but this necessitates the use of liners under the alternate strakes which do not fit upon the beams. The butts of the plates are carefully shifted with regard to each other, and also with respect to the butts of the sheer-strake; in fact, the latter precaution is almost as necessary here as it is when only stringer-plates are fitted, if the best possible disposition of the material is aimed at, as it should be, by the ship-builder.

Wood planking, arranged in the same manner as on the decks of ordinary wood ships, is almost always fastened upon the iron deck-plating, and secured by nut-and-screw bolts, which should be kept clear of the beam-flanges, in order that they may be only weakened by the riveting of the plates. Formerly this was not done, but the fastenings of the deck-planks were placed in the beam-flanges just as they would have been if there had been no iron deck. By placing them between the beams, the planking is also secured with greater ease, and it prevents the plating from buckling down under compressive strains. Intimately connected as they are, and each possessed of considerable strength in itself, these two assemblages of plates and planks mutually aid each other in resisting longitudinal strains. The iron or steel deck is of the greater importance when hogging strains have to be resisted, but even against these the wood deck is of considerable service; while the wood deck is most valuable in itself resisting sagging strains, and enabling the plating to develope its strength without buckling. Proposals have been made to give up wood decks when iron or steel decks are fitted, and some ships have been so built. Hitherto, however, it is the general opinion of ship-builders that the use of wood decks is most desirable, mainly on account of the greater comfort gained thereby; and to this must be added the foregoing considerations relating to the joint action of the wood and iron.

This simple arrangement of deck-plating is found to meet every requirement in ordinary iron vessels, and will doubtless lead to the entire disuse of the various detached strengthening pieces—such as "box-stringers," and "vertical stringer-plates"—formerly common in long iron ships. Special requirements, however, have to be met by special arrangements. For instance, in the *Great Eastern*, where extraordinary strength was needed, the upper deck was formed by two iron skins with deep longitudinal girders between; constituting, in fact, a cellular structure in itself capable of resisting great tensile and compressive strains. Again, in the iron-clad ships of the navy it not unfrequently happens that the deck-plating is arranged rather with a view to its powers of resisting penetration by projectiles, than with regard to the strength of the ship considered as a girder. All these exceptional cases must, of course, be considered independently; but in all of them the ship-builder must take care, while giving prominence to the special features, not to overlook the requirement of structural strength, securing both to the utmost extent possible.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXXVI.—HENRY MAUDSLAY.

BY JAMES GRANT.

Henry Maudslay, who was the leading workman of Joseph Bramah, and the inventor of the slide rest and the leather collar for the hydraulic press, was born on the 22nd of August, 1771, in an old house opposite the gates of Woolwich Arsenal. Though his father, William Maudslay, was but the storekeeper of the dockyard, he was the lineal representative of an ancient Lancashire family, to whom belonged old Maudslay Hall, near Ormskirk. Through some unfortunate love-affair he enlisted in the Royal Artillery, and served in the West Indies, where he was several times engaged in action, and on the last occasion received a bullet in the throat. After being invalided, he was discharged at Woolwich, but obtained some humble employment in the Arsenal, and ere long had the office of storekeeper assigned him.

When his son Henry was twelve years old, he was employed as a "powder-monkey" in making and filling blank and ball cartridges, and in 1785 he obtained employment in the carpenters' shop of the arsenal, and there first became acquainted with the use of tools and with working in wood and iron. "From the first," we are told, "the latter seemed to have had the greatest charm for him. The blacksmiths' shop was close to the carpenters', and Henry seized every opportunity that offered of plying the hammer, the file, and the chisel, in preference to the saw and plane. Many a cuff did the foreman of carpenters give him for absenting himself from his proper shop and stealing off to the smithy. His propensity was indeed so strong, that at the end of a year it was thought better, as he was a handy and clever boy, to yield to his earnest desire to be placed in the smithy, and he was removed thither accordingly in his fifteenth year."

He rapidly became an expert artisan, and was particularly skilful in forging light iron work, but his favourite employment was to cut "trivets" out of the solid, work which only the most finished hands in the shop could do. These were made out of Spanish iron bolts, which, "though exceeding tough, forged like wax under the hammer." The old workmen, with whom he was a great favourite, were wont to crowd about him when forging these trivets, which he did so quickly and neatly as to excite their admiration. This manufacture of apparatus for supporting toast-plates before the fire was not exactly required at the arsenal, and was strictly forbidden by the superintending officer, so that Maudslay's secret work had to be concealed every time he entered the shop.

He was always fond of any unusual piece of forging, or of having difficulties to overcome, and turned out many beautiful pieces of workmanship in the form of ornaments; but his dexterity as a smith became eventually directed to machinery. His fame as a handy and expert mechanic became known even in London, and his father, the old artilleryman, who was very proud of him, was wont to point to the old military leather stock, which had partly saved his throat from the bullet, and which he carefully preserved, and say—

"But for that bit of leather, there would have been no Henry Maudslay."

He now quitted Woolwich Arsenal and obtained employment in Piccadilly, with Joseph Bramah, who speedily made him foreman in his manufactory, and who was greatly indebted to him for the contrivance of many of those tool-machines which enabled him to carry on the business of lock-making with such profit and advantage. Bramah was inspired by an indefatigable spirit of invention, and the great success of his lock, which he patented in 1784, stimulated him to fresh efforts. His first invention, with the view of creating a motive power, was his hydrostatic machine, founded on the doctrine of the equilibrium of pressure in fluids, as exhibited in the "hydrostatic paradox."

This machine has been used on many occasions in preference to other methods of applying extraordinary power, where such was required, such as when Stephenson hoisted the giant tubes of the Britannia Bridge into their bed, and Brunel launched the *Great Eastern* from her cradles—the weight raised by a single press in the first instance being 1,144 tons! The chief difficulty of Bramah in the construction of the hydraulic press arose from the tremendous pressure exercised by the pump, which forced the water between the solid piston and the sides of the cylinder in such quantities as to render the press, at first, useless for practical purposes, and he found himself completely baffled by this result.

"In this dilemma," says Mr. Smiles, "Bramah's ever-ready workman, Henry Maudslay, came to his rescue. The happy idea occurred to him of employing the pressure of the water itself to give the requisite water-tightness to the collar. It was a flash of common-sense genius—beautiful itself in its simplicity."

Maudslay's invention is thus described :—

"A collar of sound leather, the convex side upwards and concave downwards, was fitted into the recess turned out in the neck of the press-cylinder, at the place formerly used as a stuffing box. Immediately on the high-pressure water being turned on, it forced its way into the leathern concavity and flapped out the bent edges of the collar, and in so doing caused the leather to apply itself to the surface of the rising ram with a degree of closeness and tightness so as to seal up the closer, exactly in proportion to the pressure of the water, in its tendency to escape. On the other hand, the moment the pressure was left off, and the ram desired to return, the collar collapsed and the ram slid gently down, perfectly free and yet perfectly watertight. Thus the former tendency of the water to escape by the side of the piston was, by the most simple and elegant self-adjusting contrivance, made instrumental to the perfectly efficient action of the machine; and thus, from the moment of its invention, the hydraulic press took its place as one of the grandest agents for exercising power in a concentrated and tranquil form."

Maudslay's father died soon after he entered the employment of Bramah, and every Saturday night he walked down to Woolwich, to hand over to his mother the largest share of his week's wages. His fellow-workmen considered him as the hero of the shop, and as he was tall and handsome, on gala days, when the men turned out for a procession, they insisted that he should march at their head, immediately behind the band, and carry their flag. As manager of Bramah's extensive works, Maudslay quite won the heart of his master; but he did more, for he won the heart of the housemaid, a pretty girl named Sarah Tindal, whom he married, and who made him an admirable wife.

Maudslay was eminently successful in the ingenuity with which he devised tools for the most delicate and difficult parts of lock-making; and with his own hands he constructed that identical padlock which so puzzled and tested the powers of Mr. Hobbs in 1851. That lock had then been made for more than half a century, without any of the modern improvements, hence its power was doubly creditable to the skill and dexterity of the artisan who made it. With all the skill and activity displayed by Maudslay in the service of Bramah, his highest wages as manager of his works never exceeded thirty shillings per week. The expenses of an increasing family requiring more, his application for it was bluntly refused. Mortified by this unexpected result, he quitted Bramah and started in business on his own account, in a small workshop and smithy in an alley off Oxford Street. This was in 1792.

There his first customer was an artist, who ordered the ironwork for a large easel, embodying some new and complicated arrangements, and the work was done punctually and to satisfaction. Other orders followed fast. His fame as a skilled workman became as great as that of the master who had lost him, and many who used to do business with Bramah now followed Maudslay to the alley off Oxford Street. He was particularly careful in the style and finish of his work, and it was with this end that he aimed at the contrivance of so many improved machine-tools, which should be self-acting and self-regulating; and hence he invented that important mechanical instrument, with which his name is more usually identified—the slide rest. In this lathe the slide rest and frame were movable along the traversing bar, according to the length of the work, and could be placed in any position and secured by a handle and screw underneath. The rest, however, afterwards underwent many important alterations, but the principle of the whole machine was Maudslay's own invention.

One of the first uses to which he applied it, after he had commenced business in Margaret Street, Cavendish Square, was the execution of the requisite tools and machinery required by the future Sir Mark Isambard Brunel, for the manufacture of ships' blocks. He was then assisted only by a single journey-

man, but he speedily required many more, after the working models were ready for the inspection of Sir Samuel Bentham and the Lords of the Admiralty, in 1801. After being fully approved of by them, Mr. Brunel was authorised to proceed with the execution of the machinery requisite for the manufacture of the ship-blocks of the Royal Navy. The whole of this machinery was executed by Henry Maudslay. It occupied him nearly six years, so that the cutting of blocks by the new process was not begun until the close of 1808.

Many machines were requisite in the manufacture of a single block. Among these may be enumerated the straight-cross-cutting saw, the circular-cross-cutting saw, the reciprocating-ripping saw, and the circular-ripping saw, the boxing and mortising instruments—the latter for cutting stream holes, and furnished with numerous chisels, each making from 100 to 150 strokes per minute; and then came the corner saw, the shaping machine, and the scoring engine, for cutting grooves round the longest diameter of the block. With this new machinery ten men could perform the work which before had required a hundred and more to execute, and not less than 160,000 blocks of all sizes were turned out yearly, at a cost of not less than £541,000, the annual saving to the Government being estimated at £17,663.

This brought fresh accession of fame and business to Maudslay, who removed his works to the Westminster Road, Lambeth, 1810, and established there the famous co-partnery of Maudslay, Field, and Co. There he continued to improve his old tools and to invent new ones, until the original slide-lathes used for making the block machinery became antiquated, and thrown into the shade by the more gigantic machines of the present day. Among other work to which he turned his attention was the construction of plane and saw mills, mint machinery, and steam engines of all kinds; and the *Regent*, the first steamer that plied between London and Margate, was fitted with engines by Maudslay in 1816. He invented the machine for punching boiler-plates, and for many years held the contract for supplying the Navy with ships' tanks. As wealth and years came upon him, he never allowed himself to forget his skill in the use of the hammer, and to the last he took a pleasure in handling it, sometimes in the way of business, but more often through sheer love of his art and the memory of his early days. Among the last works executed by the firm during Maudslay's lifetime, was the famous shield employed by his friend Brunel in the excavation of the Thames Tunnel, the completion of which he did not live to see, as he died on the 14th of February, 1831.

By his own desire he was buried beside his parents in the parish churchyard of Woolwich, a district for which he ever had a great regard, and which he was fond of visiting from time to time. "He liked the clangour of the arsenal smithy," says the historian of industrial art, "and all the busy industry of the place. It was natural therefore that, being proud of his early connection with Woolwich, he should wish to lie there; and Woolwich on its part has equal reason to be proud of Henry Maudslay." A cast-iron tomb, designed by himself, is erected over his remains.

MUSEUMS: THEIR CONSTRUCTION, ARRANGEMENT, AND MANAGEMENT.

BY SAMUEL HIGHLEY, F.G.S.

XII.—NATIONAL MUSEUMS (*continued*).

General Details, etc. (*continued*).—Another convenient arrangement, especially when delicate specimens have to be isolated for close examination in the studies, is that of the glazed boxes round and square, with corked bottoms. Usually, these are supplied "nested," consequently of various depths; but sets of subdivisions of a standard size, of a uniform height, afford the neatest arrangement for museum purposes. These may also be glazed on both sides, which like frames glazed on both sides are useful for the display of rare objects that require examination, both on their upper and lower surfaces. Flat bottles (Fig. 16), such as are employed by Mr. Twining, are useful for the display of seeds, powders, etc. Next in convenience are the ebonised bowls (Fig. 17), closed by glass discs that drop into a rebate in the rim. These are useful for the display of sands, grains of metals, small nuggets, etc. Where small quantities of material have to be made the most of, the bottoms of such bowls may be filled up with lenticular shaped blocks, A (Fig. 17), which bring the sand, etc., up to the covering glass. Allied to these are the specimen glasses (Fig. 18), covered with flat plates or watch glasses, that are specially suited for separate crystals, chemical products, etc. Cast rods of metals, etc., can be well displayed in tubes, the stoppers of which form stands as in Fig. 19. The hermetically sealed tubes in which the alkaline metals potassium, sodium, etc., are supplied are best mounted on an ebonised wooden foot that conceals the unsymmetrical portion, as shown in Fig. 20. Gems, crystals, etc., may be supported in shallow cups or on the points of ebony or ivory conical pegs, as in Fig. 21, or be held in the grasp of double or triple limbed tweezers (Fig. 22), with pointed ends that allow of such objects being placed at any angle that best catches the light to bring out its play or colour, etc. Preparation jars are round or oval, as shown in Fig. 23, are made of various sizes, but when filled with preservative fluids have the disadvantage of producing optical distortion, so that unless the object is very large, it is better to display dissections in flat cemented cells, built up of glass slips, slabs, and covers, or, better still, made from sections of square, oblong, oval, or round bottles, cemented to base and covering glasses, as shown in Fig. 24. Where objects are unsuitable for display in a public gallery, such as jelly fishes, microscopic objects, etc., they may be represented by transparent photographs which may be coloured with great delicacy, and a more perfect rendering of hyaline aspect than can be given in water-colour drawings. Such paintings on glass must be supported on tin frames of the form shown in Fig. 25, the upper half being japanned dead black, the lower half white; as this is for the purpose of reflecting light through the transparent illustrations, the tin allows of the glass being adjusted to the most suitable angle. In the elementary collections such photographs may be utilised as magic-lantern slides for the illustration of lectures to large audiences when colossal diagrams of objects described are essential to a clear comprehension of details of structure. This is the only way of showing lettered classifications, so as to be discernible in a large lecture theatre.* A very useful arrangement has of late years been introduced into museum fittings by Mr. Twining, shown in Fig. 26, that consists of an iron standard on a tripod foot, to which are hinged a series of iron frames that may be fitted with specimen bottles, trays, herbarium cards, diagrams or photographs, which may be turned over like the leaves of a book. These hold a great number of specimens, while they occupy little space, and would be of especial service in the botanical gallery. Strong iron cradles, frames, etc., made of iron, are required for the support of special objects, such as the tusks of the mastodon, carapace of the glyptodon, restored skeleton of the great extinct sloth, etc., at the British Museum.

Fig. 27 shows a convenient form of label. In tropical countries it is necessary to protect specimens from moth, white ants, and other destructive pests, by preserving them in tight-fitting metal cases, which, if required for public exhibition, may be glazed on the top side; attention being given to the way in which the glass is cemented into its fitting.

Details of Rotunda of Elementary Natural History.—As a small collection is found to be more readily understood and made available for the uneducated classes, and those who have not studied very profoundly—numerous specimens of species rather confounding than assisting such persons—the arrangement of this supplemental building is specially disposed for the display of an epitome of natural history or index collection, introductory to the systematic series, and for the same being open for inspection in the evening as well as during the day or even, as recommended by Dr. J. E. Gray before the Parliamentary Committee on the British Museum, on Sundays also. The elementary collections in this department should illustrate by external form, skeleton, skulls, dental formulæ, internal and microscopic structure, developmental phases and embryology, the characteristics of the classes and orders of the animal and vegetable kingdoms, zoological, botanical, and mineralogical terminology; and the classification being illustrated by the collections of British natural history, interspersed with the most important exotic species which have not representatives in the British series. All such specimens should be arranged so that they could

* See Vol. II., page 244.

be utilised for popular lectures on the general principles of natural history. As the typical collection would embrace a similar series to that which should form the basis of every local museum, I shall defer a detailed description thereof till I have to treat of museums of the latter class. The ethnological and geographical distribution collection should form one series, and be arranged in large groups, artistically arranged with scenic backgrounds in cases at least 10 feet deep, so as to convey a just idea of the natural association of plants and animals with the human race in geographical regions, and of the representative species of different countries, and distribution of life in oceanic

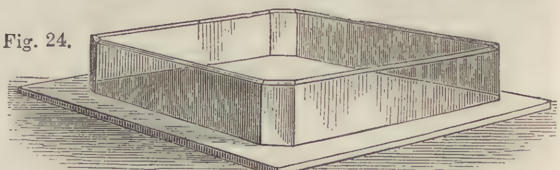

Fig. 24.

depths after the manner foreshadowed by the lamented Edward Forbes at the Crystal Palace, though such illustrations can only be regarded as sketches of what ought to be worked out in detail at the new Museum. Each case might be conventionall divided *in idea*, as indicated in Fig. 28, so that the species of every associated geographical group should find its place according as its maximum of development was to the north, east, south, or west of the geographical region illustrated. In the same room, the position of our earth in the solar system should be shown by a simple orrery, which should also indicate the relative diameters of the planets, their mean distances from the sun, and such other details as the huge dome of the Rotunda would admit of.

The floor of the ethnological and geographical gallery might be occupied with cases containing small models, such as those shown at the Exhibition of 1862 by Montanari and Heiser to illustrate varieties of the principal types of the human race, and the costumes of the inhabitants of the various regions of the globe. The life-like illustrations of bathymetrical distributions might be displayed in tall but shallow cases, artistically arranged to give an idea of sub-aqueous life, vegetable and animal.

Such a gallery would be one of the most popular as well as the most instructive in the elementary series, as being most readily comprehensible by the uneducated.

Details of Lecture Theatre.—This would be seventy feet in diameter, lighted by day from a glass ceiling opening into the dome of the Rotunda, after the manner of the theatre at the Museum of Practical Geology, and by night by a "sun-burner," which would also be an active element of ventilation. The thick glass ceiling could be guarded in the upper floor by a circular range of cases, serving the place of a balustrade without material loss of space. The theatre should be arranged to accommodate at least 1,000 persons, and provision should be made for the illustration of the lectures by monster diagrams, tables of classifications produced by aid of the demonstrating lantern, which is the only method of making structural details and lettered diagrams distinctly visible to the whole of a large audience, a method that year by year is gaining favour, and rendering the old magic lantern in its modernised form a powerful instrument of education, by the way in which it conveys information through the eye; and as long as we can teach well and quickly, "sight knowledge" is a thing not to be sneered at.

WOOL: ITS INDUSTRIAL APPLICATIONS.

By Professor T. C. Archer.

I.—THE NATURE AND PROPERTIES OF WOOL.

The term *wool* is applied to that particular kind of hair which reveals, by aid of the microscope, a peculiar transversely imbricated structure, upon which chiefly depends its value as a textile material. Besides this peculiarity, wool possesses another which increases its usefulness: it is longitudinally waved.

These properties cannot be well understood without the aid of drawings, and these must be somewhat exaggerated in their details, as well as in their size. They exist in the greatest perfection in the fleeces of the cot-fed Merino sheep of Bohemia and Hungary, a tuft or lock of which is represented of rather more than its full length in Fig. 1. If from this we draw out a single hair, we shall find it is extremely thin, finer even than the thread of the gossamer spider, and that it is regularly waved in the manner shown in Fig. 2.

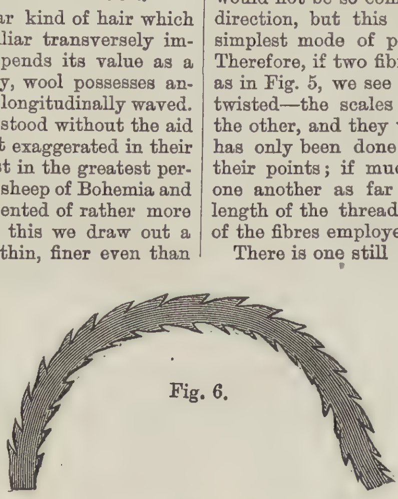

Fig. 6.

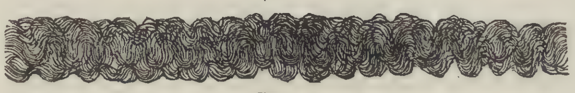

Fig. 1.

Fig. 2.

Fig. 3.

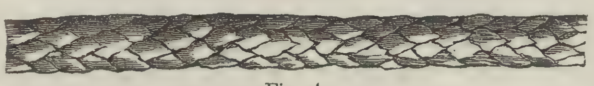

Fig. 4.

Fig. 5.

As we have before stated, this represents the highest perfection of one class of wools, which from their shortness are called *short-stapled;* but there are some other kinds in which this type is very widely departed from, in which the wool is very much longer, and the curves are altogether different, as in Fig. 3, which may be taken to represent the class called *long-stapled.* Between the extremes shown in these figures there is every possible gradation, and these qualities are more or less visible to the eye and touch of the experienced *wool-stapler*, and also to that of the manufacturer; but the other and more remarkable quality of wool, its imbricated structure, cannot be seen by the unassisted eye. As with the waves or curves, so also with the imbrications or scales, differences exist, which are distinctive of the short and long-stapled varieties. If we magnify a single hair of the finest *short-stapled* kind to about 150 diameters, we shall find that it is marked transversely by very distinct and apparently irregular striations, which will be seen on further examination to be the edges of scales overlapping each other, after the manner of tiles on a roof. Fig. 4 gives an exaggerated view of a fibre so magnified, and Fig. 5 an imaginary longitudinal section of two fibres laid in opposite directions. That the scales are free except at their bases, can be easily seen by examining one when bent, as in Fig. 6, when the scales will be lifted up at their points. These may appear very trifling matters, but they are of so much importance that without them wool could not be applied to the purposes of weaving by any of the processes now known. Besides the special form and arrangement of these scales, their number is also a matter of great importance, and this varies quite as much, or even more so, than the length of the curves; thus, in the very finest of the *short-stapled* kinds, as many as 4,000 have been counted in the length of an inch, whilst in the long staples they rarely exceed 2,000, and are often not more than 1,200 in number.

Now, if we take a few hairs not possessed of these qualities, human hair for instance, and twist them together, we find that they will not retain the twist, but straighten themselves, as soon as the ends are liberated; but a similar number of wool fibres so twisted retain that condition and form a thread. This arises from the fact that the scales hook into each other whenever they are forced into contact, and thus the fibres become inextricably interlocked: this will be the more complete in those varieties in which the scales are most numerous; and the curves will of course aid much, as when twisted they cause the individual fibres to form spirals. Of course, this interlocking would not be so complete if all the fibres were laid in the same direction, but this is practically impossible with wool, as the simplest mode of preparing it is sure to prevent such a result. Therefore, if two fibres come in contact in opposite directions, as in Fig. 5, we see at once what must be the result if they are twisted—the scales of one will slip under or over those of the other, and they will be thus held together. If the twisting has only been done slightly, the scales will only be held by their points; if much twisted, the scales will be inserted under one another as far as they can go. In the former case the length of the thread produced will not be much less than that of the fibres employed; in the latter it will be much shorter.

There is one still more minute quality in these scales, which is not generally noticed, but it is of very great importance; it is that the under side is not perfectly smooth, and this offers some resistance to the interlocking of the scales. This is proved by the fact that when a lubricating fluid like soap and water is used, the interlocking is rendered more complete and permanent.

This peculiar property of wool is called *felting*, and it will be seen that this causes the shrinkage of woollen clothing when washed; the rubbing, the soap and water, and the wringing, are all operations which are sure to make the fibres of wool work together to the fullest extent they are capable.

So remarkable is this property of felting, that with many kinds of wool it is only necessary to mingle the fibres, wet them, and beat them gently, to get them to combine and form a fabric, which is used in various ways for clothing, under the name of *felt*, which will be hereafter described.

So far, sheep's-wool has been the type before us, because no animal produces wool so perfect in all its essential qualities; indeed, so perfect is it, that without a full knowledge of the physiology of this most useful of animals, it is a matter of no little wonder that the immense mass of wool which constitutes the fleece of a single sheep, does not, from the movements of the animal and other causes, felt into a compact mass upon its back. We find, however, a provision in the economy of the sheep which secures it from such an evil.

A large portion of the skin of the sheep exudes a secretion known by the name of *yelk*, which is a kind of natural liquid soap, as it contains both oil and the alkali potash. This lubricates the fibres, which on the skin of the animal are all held in one position; hence, they are kept freely moving upon one another during the motions of the animal, and do not, consequently, *felt.* So abundant is this secretion, and so large the amount of alkali present in it, that it has been suggested that the waters from sheep-washings should be used as a source of potash; and at the Cape of Good Hope and in France, this valuable and not very abundant alkali has actually been recovered with profit from the water in which sheep have been washed.

Most animals which are clothed with hair have two kinds: one smooth and unprovided with the scales which distinguish wool; the other, usually the undergrowth, which either has such scales or some modifications of them. The latter is called either *wool* or *fur;* the term *wool* is, however, very limited in its application, whilst the number of fur-bearing animals is very considerable. For technical purposes, it is convenient to dis-

tinguish them thus:—*Wools*, those animal fibres which can be both spun into yarn and also felted. *Furs*, those which can only be felted.

The true wool-bearing animals are the sheep, the Cashmere goat, the alpaca, the llama, the guanaco, and the camel. As no animal in an absolutely wild state produces wool in such abundance as these, there is some reason to suppose that it is largely due to the changes produced in the animals by domestication. The guanaco might almost be excepted, for it is so wild that it has to be hunted; nevertheless, it yields an inferior kind of wool used only by the Indians and Mestizos of Peru.

The chief of all wool-producing animals, the sheep, is so remarkably connected with the history of man, that no fossil remains of the animal have ever yet been discovered which are not clearly referable to times coeval with the human race; at least, this is the case with respect to Europe, and leads to the inference that it has been introduced from some other part of the world by man in his migrations. And it is equally interesting to find that it is associated with the history of our race as far back as any historical records exist, and this association is due to the use of the animal both for food, and in furnishing materials for clothing. Throughout the Old Testament, allusions to the rearing of sheep and their uses continually occur, and they are equally numerous in the old classical writers, from whose writings we gather that, from the earliest times, a pastoral life was common to all the inhabitants of Persia, Mesopotamia, Syria, Palestine, and Arabia, and extended into Scythia and Tartary. Indeed, there is no want of evidence to prove that the culture of the sheep for its wool, as well as its flesh and milk, was common throughout the greater part of Asia Minor and Scythia before Greece planted its colonies in those districts; and in very ancient Græco-Scythian antiquities discovered on the site of the colonies of Panticapæum, representations are found showing the highly pastoral character of the people, and the perfection of their woven clothing, which was doubtless of wool.

The Greeks and Romans, from the commencement of their respective histories, were familiar with the wool of the sheep, and reared varieties of different qualities. The wools of Miletus and of Phrygia were famous for ages, and form themes for their historians and poets; and so famous were the fleeces of the Attic sheep, that the shepherds covered them with skins in bad weather to preserve and improve them, whilst the district of Arcadia has obtained an immortal celebrity for its pastoral life. Moreover, from the times of the most ancient Greeks to the later Romans, the trade in wool was considered under the especial protection of Mercury.

Amongst the Romans wool was held in high esteem, and various breeds had great celebrity—a celebrity which exercised the pens of their most famous writers. Virgil and Pliny, Varro, Tertullian, and Columella, have all left abundant evidence in their writings that the subject was considered worthy of such celebrated writers, and that the shepherd's life was regarded with great favour in their days; for we cannot class their writings with those of the poets of our own country, who make the pastoral life the basis of many of their amatory songs and poems.

But however abundant the evidence of the use of wool, and consequently the rearing of sheep, by the nations of classical and Biblical antiquity, we are entirely without information respecting the introduction of the sheep to Britain. As before stated, the negative evidence of the absence of true fossil remains forbids the assumption that the animal was indigenous; and although assertions have been made that sheep were introduced by the Phœnicians, that wonderful people who are made to account for so many difficulties, yet there is no actual proof that our forefathers had seen the sheep when Cæsar landed on our shores, or for a hundred years afterwards. In all probability, we are indebted to our conquerors for this useful animal, and we certainly are for the first establishment of a woollen manufactory, which was founded at Winchester in the time of Agricola. From that time we know from various sources that the trade flourished, and that it also became a female accomplishment of the highest character (whence the term *spinsters*) to work the wool up into fine yarns, and even to weave it into garments; whilst those men who were engaged in rearing sheep, although sometimes called shepherds, were held to be persons of distinction, and their daughters could mate with kings, as in the case of King Edward I., whose first wife, Egwina, was the daughter of a shepherd; and the princesses his daughters were skilled in spinning wool. In subsequent papers will be given the various methods employed in those primitive times, as well as at the present, for preparing the wool for the various purposes to which it is applied.

Next in importance to the wool of the sheep is that of a species of goat (*Capra hircus*), a native of Cashmere and the elevated table-lands of Thibet, where it thrives at an elevation of from 12,000 to 16,000 feet. It also abounds in the mountainous districts of Asia Minor, and one of its varieties is reared in vast numbers in the neighbourhood of Angora, whence it is called the Angora goat, the fine, long, silky hair or wool of which forms a very important article of commerce, so much so that the imports to Great Britain alone represent an annual value of over half a million sterling. The greatest quantity comes to us from the various ports of Turkey, from which alone we receive the enormous quantity of between nine and ten thousand tons annually.

In ancient times we know that the common goat, the European variety, was shorn of its hair, which was manufactured into various textile fabrics of the coarsest description, such as sailors' clothing, coverings for tents, and especially for such coarse bags as we now call sacks; in fact, we derive the word sack from the Hebrew name of goat-hair cloth, which was *shac* or *sac*. From the fact that the Romans obtained the best goats'-hair from Cilicia, cloths made from it were also called Cilicias, and we still use the term slightly altered for a class of fabrics made from sheep's-wool. The fine wool yielded by the goat of Cashmere and Thibet, and the beautiful material which, combining the qualities of wool and hair, is yielded by the Angora goat, were both unknown to the Greeks and Romans, and our acquaintance with them is comparatively very recent. Fifty years ago the imports of this material only amounted to a few hundredweights per annum, and it was not until many important modifications in the machinery for spinning it had been perfected, that it attained to the great importance which it now has in our manufactures, under the name of mohair. The wonderful improvements which have been made in that time in carding machinery, have led to a vast extension of the trade in mohair, and to the use almost equally extensive of another beautiful wool, that of the alpaca (*Auchenia pacos*) and its allied species (*A. llama* and *A. huanaco*). These animals are natives of the Peruvian Andes, where, besides two of them being useful as beasts of burthen, they all yield a peculiar kind of wool which, besides being very long, is exquisitely soft, and beautiful in lustre. In the time of the Incas beautiful cloths were made from the wool of these animals, specimens of which are still occasionally found in their tombs; but it was not until about 1840 that its usefulness was fairly recognised in this country. Now the annual importation is over three millions of pounds, and the value nearly half a million sterling, giving employment to many thousands of people in the production of beautiful fabrics, which will be more fully described in a subsequent paper. The only other animal which yields hair which has the properties of wool, and is used as such, is the camel. This creature is ordinarily covered with a thick coating of soft brown wool, amongst which are sparingly mixed long smooth hairs. When these are separated, they are of great use in the making of small paint-brushes for artists, and the wool can be spun and woven into cloths of beautiful quality, as to softness and durability. Eastern nations use it extensively, but it has not been employed in Europe, except in Russia, where it is in great favour for military clothing, and is as much in fashion as the scarlet woollen cloths are in our military service.

Besides the true wools, and those varieties of hair which also have the properties of wools, all the true furs possess the property of *felting* in a remarkable degree; they are very numerous, but only a few of them are sufficiently abundant and cheap to be used in making textile fabrics by the process of felting. Chief amongst those which are so employed are the hare and rabbit, called in commerce coney-wool; the beaver, though very little, compared with its former extensive use in the manufacture of hats; the musquash (*Fiber Zibethecus*); the nutria or coypu (*Myopotamus coypus*). These materials are very extensively employed in the manufacture of felt hats, usually, however, in a state of mixture with sheep's-wool. In

the next article on woollen manufacture will be described the fabrics made from these materials in the earliest times, as an introduction to subsequent papers on the modern manufactures.

CAPITAL AND LABOUR.—IV.

By J. E. Thorold Rogers, M.A., Tooke Professor of Economic Science.

CAPITAL AND WAGES.

There is a very general opinion that the amount of wages procurable by those who labour depends on the amount of capital which is capable of being employed in the payment of wages, and some writers have thereupon discovered what they have called a labour-fund, meaning by this the quantity of property in the hands of those who employ labour, concluding that this property is the sole cause why labour is employed at all. It is further imagined that as this fund increases and diminishes, so the condition of labourers is bettered or made worse; and a quantity of ingenious reasonings have been propounded, and a number of ingenious precautions suggested, which have for their object the sustentation of this labour fund, and the prevention of those direful consequences which might be expected to ensue, were the fund curtailed, or rendered less manageable for the purpose to which it is to be devoted. If, however, we are able to show that this labour-fund is a mere creation of fancy, which has no reality, all these alarms will be shown to be as baseless as their object is.

There is always a foundation of truth in any wide-spread delusion. The truth may be very small, and it may be used for the development of such vast errors, that it may become mischievous by its incidental or inveterate connection with these errors, and thereby it may do much more harm than good. In the matter immediately before us the truth as to the relations of employer and workmen is that the manifest convenience of such relations is so considerable that they are frequently supposed to be all important. Again, any interruption of these relations brings about so serious an inconvenience that people may well be pardoned for exaggerating the significance of such facts as really exist. For example, the wide-spread distrust which prevailed for some months after May, 1866, when an eminent house of business in London was proved to be wholly bankrupt, was so serious, that infinite injury was done to every branch of industry by the recklessness and deception of the persons referred to. People did not know on whom they might rely, and in consequence business was paralysed; for credit is so very delicate an instrument, that though it is capable of most astonishing feats of power, it may be deprived of all its energies and collapse.

Labour is not set in motion by the property of the employer, but by the demands of the public. Houses are not built, cloth is not woven, books are not printed, because builders, spinners, and printers have property, but because the public is prepared to purchase each of these articles. If no such desire existed on the part of the public, the property of employers would cease to be productive, and the action of employers would cease. This position is so plain that it needs only to be stated in order to be immediately acknowledged and admitted. No industry can exist or continue unless the public requires the product on which the industry is exercised. Nay more, if for some reason the product in question may be obtained more cheaply and conveniently from some other source besides that which has hitherto supplied it, and the public is allowed to obtain it from that source, the industry which is now made less effective will be discouraged, and, unless it can accommodate itself to the altered circumstances, will finally come to an end. However abundant the property of the employers may be, nothing but public demand can keep an industry alive.

Now the capitalist employer, when such a demand exists, performs two important services. He interprets or measures the extent of the demand for the object in which he trades (not always exactly, for he frequently produces too much, and may produce too little of the article), and he keeps the price of the article pretty steadily up to the cost of producing it. Much time would be lost if the workman were seeking the customer or consumer of the article which he produces, and much labour would fail of occupation were there no person who found out, as his proper business, the means for bringing producer and consumer together. Again, the workman has constantly very little beyond his labour to sell. If he employed himself on producing articles which he took to market himself, the price of that which he makes would be liable to sudden and frequent changes, as his necessity forced him to sell, and the wants of the customer were unsatisfied. Now there is nothing which a producer desires more than as uniform a price as possible for that which he makes. It is this result which the employer brings about. He is able to hold goods back from the market, because by the possession of his property he can wait till a fair price can be obtained for the article in which he deals. His position, then, is essential towards the true interpretation of public demand and its regular supply. But he does not set the labour in motion. This result is obtained because the labour can do something which is useful, and so will be purchased or employed.

The employer, then, buys labour, which he sells again, either by hiring out the labourer to the customer, or by disposing of those articles in which labour has been condensed. Sometimes the service which he does to the labourer in relation to the two points just adverted to is very slight. For instance, the master baker has probably sold, and has been paid for the service which his journeymen perform long before he has paid them for the work which they have done. But in the great majority of cases the work of the labourer is paid for some time before the price of the work has been recovered from the public. Occasionally the work or service to be performed is of such a character that a very large sum has to be laid out, and laid out permanently, before any payment can be obtained. The cost of constructing a railway is very great, and must be incurred before any charge can be levied for the conveyance of passengers and goods. Were it not for the capital of the employer—*i.e.*, of the railway shareholders, acting through the managers or directors—no service whatever could have been done. The shareholders have rendered it possible that workmen should be employed in rendering the service. But when the road is laid down, and the carriages and engines are supplied, the trade of the shareholders is characterised by even more rapid returns than that of the baker referred to above. The railway receives the payments for passengers and goods long before it pays those persons whom it hires to do the work for the public. In other words, after the first outlay, the demand of the public finds the means for paying the wages of the railway servants to a far more notable extent than is the case in any other trade.

The inaccurate and unphilosophical language often used about the relation of labourer and employer, under which the former is made to appear as though he owed his employment and subsistence to the latter, has led to very serious inconveniences, for it has constantly estranged workmen from their employers, and has given an impression that the relations between them are those of patron and dependent. Rightly considered, there is no more dependency between the two than there is between the miller and the farmer. In order that a farmer may sell his corn it is no doubt necessary that the miller should be at hand to buy and prepare it for the public. But similarly, in order that the miller should set his mill going, it is necessary that there be a farmer who shall supply him with corn to grind; and much more important still, neither the farmer would find a market, nor the miller get his living, unless the public were prepared to use the corn of the one, and employ the services of the other.

The employer, then, is a dealer, or go-between. His real value in the economy of society is not disparaged by pointing out what his true position is, and by stripping it of those pretended powers which it never possessed, and never could assume, if its real meaning were investigated. Like every other person who gets employed, he has a use, and a very important one. He would not, indeed, occupy the position which he does, if there were not a notable use in the office which he fills. But like the labourer whom he employs, he is paid for his labour, and because his labour is acknowledged to be useful. Similarly, just as any kind of manual labour may be superseded if some machinery may be found to supply its place, so it is possible that the office of the employer may be superseded, if a better and cheaper substitute can be found for it. I say *possible*, for as far as human understanding can determine, the relative conditions of employer and employed will exist, like rich and poor, as long as the world lasts.

TECHNICAL DRAWING.—LXXVIII.

DRAWING FOR CABINET-MAKERS (*continued*).

THE first example given in this lesson (Fig. 610) represents a small mahogany wardrobe, drawn to the scale of $\frac{3}{4}$ inch to the foot. It consists of a drawer and two compartments, the one of which may be fitted with trays and the other arranged for hanging.

In commencing to draw this object, erect the central perpendicular, and draw the ground-line. Set off on each side of the perpendicular, A, half the width of the plinth, the entire width of which is 3 feet 6 inches; and at these points, B and C, erect

The bead covering the meeting of the doors is now to be drawn, half its width being set off on each side of the centre line. Within the two rectangles thus formed draw the panels. It will be seen that the curve uniting the top with the sides of the panels is a quadrant, the centre of which is at *a*.

Fig. 611.—The next example here given represents a small bookcase with closets at bottom, drawn to the scale of $\frac{3}{4}$ inch to the foot.

Above the closets is a drawer for music, manuscripts, etc. The top of the lower case projects on the front and sides, and is moulded with a quarter-round and fillet. The moulding of the cornice is the *cyma recta* (Fig. 116, Vol. I., page 200).

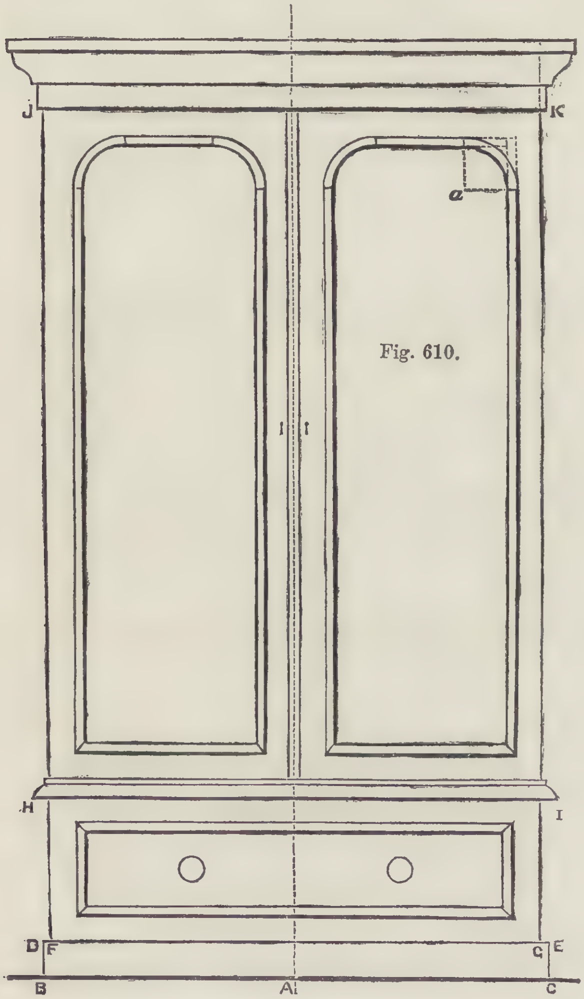

Fig. 610.

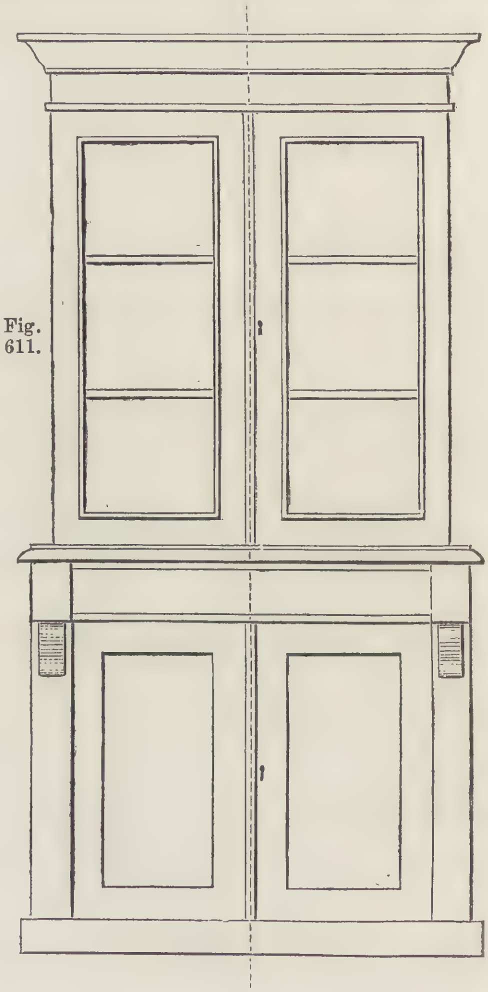

Fig. 611.

perpendiculars 3 inches high. Join these by the horizontal line D E, the upper line of the plinth.

Now the width of the body of the wardrobe is 3 feet $4\frac{1}{2}$ inches, the plinth projecting $\frac{3}{4}$ inch in the front and on the two sides. Having set off half this measurement on each side of the centre line, draw the perpendiculars F and G: these may be indefinitely high, as they form the sides of the entire wardrobe.

Draw the horizontal line H I, for the lower line of the small cornice which separates the drawer from the closets above. This projects 1 inch on the front and sides, and is $1\frac{1}{4}$ inch thick, including the fillet. The height of the closets is 4 feet 10 inches to J K, and the entire cornice is 6 inches high.

Draw the horizontal line J K, and the others required for the cornice, which may then be completed. It will be seen that the moulding is that shown in Fig. 120 (Vol. I., page 200), viz., the *cyma reversa.*

The measurements of this object may be obtained from the example, the method of drawing which is so precisely similar to the last that no further directions are deemed necessary.

PERSPECTIVE FOR CABINET-MAKERS.

The subject of Perspective is one of much importance to the cabinet-maker. We do not mean that this particular branch is used in the workshop; there, Practical Geometry and Projection form the fundamental methods by which the working drawings are made, whilst freehand drawing, of course, occupies in the ornamental portions of the trade a very high position.

By means of Perspective, however, drawings of the various articles of furniture are made in order to enable the customer to judge of their appearance, and it will be easily understood how, in a business point of view, the power of making such drawings may benefit the artisan, and how valuable to his employer a man may become, who, when calling on a customer, is

able from his oral description, to sketch out the article on the spot, in such a manner that the artist employed in the establishment can make a finished drawing, from which the working drawings are subsequently to be made. And, further, by means of a practical knowledge of model drawing, which is the freehand application of perspective, a young workman who carries with him a small sketch-book and pencil may lay up a store of sketches, which will be invaluable to him on a future occasion.

As Perspective is treated of in a separate series of lessons, to which (Vol. I., page 292 of THE TECHNICAL EDUCATOR) for details of the principles the student is referred, we here proceed to show the application of these principles to the special branch of trade which forms the subject of the present course.

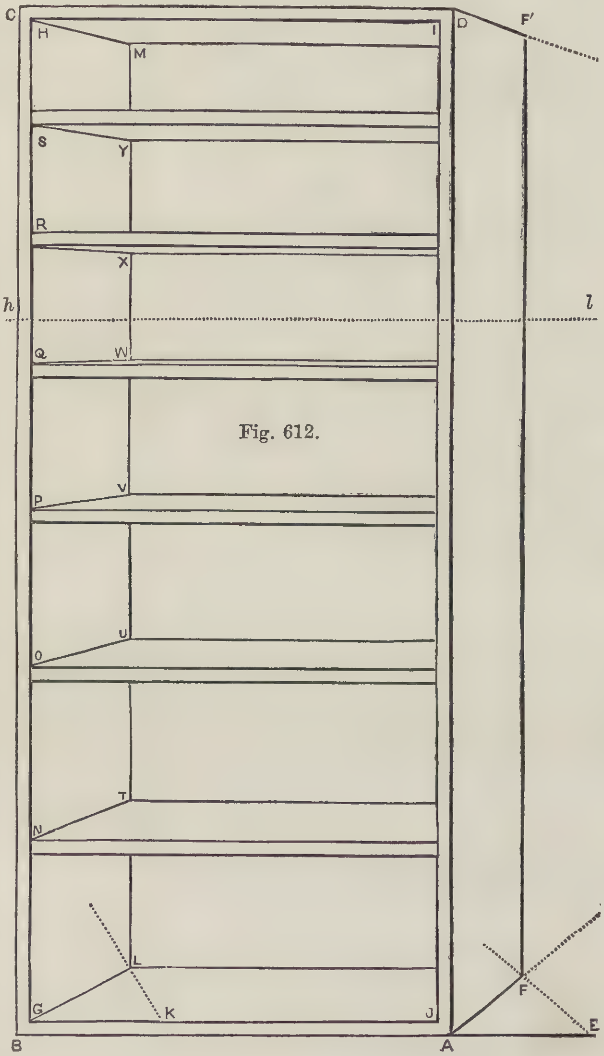

Fig. 612.

A mere glance at the earlier lessons on "Practical Perspective" will therefore suffice to remind the student who has gone through them, of the general principles; and having done this, he can at once proceed to the advanced studies. He is, however, urged not to be content with this, but to take up the subject as a separate study, of which he will find the advantage as he proceeds with the other branches of his art. Indeed, it may be said that the workman, however expert and ingenious he may be in the use of his tools or implements of his craft on the one hand, and in forming contrivances for facilitating his work and imparting to it stability of form or beauty of structure on the other can never consider himself entitled to be classed among those who are at the head of their vocation until he has acquired a knowledge of perspective, which is not only the foundation of success in the higher walks of art, but the basis also of well-doing in all the vocations, be they what they may, to which the art of drawing is ancillary.

Fig. 612.—The subject of the present lesson is a rack of book-shelves, drawn to the scale of $\frac{3}{4}$ of an inch to the foot.

The external width of this case is 3 feet, and the total height is 7 feet 1 inch, made up as follows:—

	Inches.
The top, bottom, and six shelves, made of wood 1 inch thick	8
The 1st space from the bottom	14
" 2nd " "	13
" 3rd " "	12
" 4th " "	11
" 5th " "	10
" 6th " "	9
" 7th " "	8
	85 in. = 7 ft. 1 in.

Having, therefore, drawn the rectangle bounding the front of the entire case—viz., A B C D (3′×7′ 1″)—mark the point of sight and the point of distance.

Now the height of the spectator is supposed to be 5 feet, and thus the horizontal line (h l) is to be drawn at that distance from the picture line, and as the object is to be represented as standing at 6 feet on the left of the spectator, the point of sight is to be set off on the horizontal line at that distance on the right of the perpendicular, A D. The distance of the spectator—viz., 11 feet—is then to be set off from the point of sight on the horizontal line on the other side of the object.

In order to economise space these points are not placed within this figure.

The depth of the case externally is 1 foot. To show this, draw lines from A and D to the point of sight, set off 1 foot on the picture line from A—viz., A E—and draw a line from E to the point of distance, cutting the line drawn from A to the point of sight in F. At F erect the perpendicular F F′, which will be the back line of the case, thus rendered as a mere block.

The thickness of the wood of which the entire case and shelves is made is 1 inch, and this is now to be represented by the inner rectangle G H I J.

The interior of the case next claims attention, and to project this draw, in the first place, lines to the point of sight from G and H.

Now it will be remembered that to obtain the depth of the case *externally* 1 foot was set off from A—viz., A E—and a line drawn from E to the point of distance, intersecting A, gave the point F, the place for the distant perpendicular F F′.

The same system is now to be pursued; but the *interior* depth is 1 inch less than in the previous case, the back of the case being made of wood 1 inch thick; therefore,

From G set off G K (11 inches by scale), and from K draw a line to the point of distance, which, cutting the line drawn from G to the point of sight, will give the point L. From L draw a perpendicular, cutting H in M; from L and M draw horizontal lines, which will complete the representation of the carcase of the case, the shelves only remaining to be drawn.

On J I set off the respective heights of the spaces and thickness of the shelves, and draw horizontals, giving the front edges of the shelves.

It will now be evident, that as some four of the shelves are below the horizontal line, their upper surfaces will be seen, whilst of the two which are above the level of the eye of the spectator, the under side will be visible. Therefore from N, O, P, Q, R, and S, draw lines to the point of sight. From the points where these cut the perpendicular, L M, viz., T, U, V, W, X, Y, draw horizontals, representing the distant edges of the shelves, and the drawing will thus be completed.

The learner need scarcely be told that as the figure under consideration affords a correct representation of the rack of bookshelves only according to the point of sight and point of distance that has been used in this case, it will be a useful exercise for him to vary these points, and so form a series of representations of the same object from different points of view.

FARMING AND FARMING ECONOMY.—XVI.

By Professor Wrightson, Royal Agricultural College, Cirencester.

MANAGEMENT OF CATTLE.

DIVISIONS OF THE SUBJECT—TERMS EMPLOYED—ADAPTATION OF BREEDS TO THEIR LOCALITIES—MANAGEMENT OF THE CALF—OF YEARLINGS—OF TWO-YEAR-OLDS.

Cattle management may be divided into three branches—breeding, rearing, and fattening. Occasionally they are followed separately, but more usually are practised upon one and the same farm. The occupiers of high-lying moorland or of mountainous tracts raise "store stock," which are purchased by the graziers of the richer and lower grounds. Hence in this case there is a division of labour between the breeder and the beef manufacturer; but more commonly the ordinary farmer keeps a few cows and brings up a lot of calves every year, which eventually find their way into his feeding stalls.

Cattle are classified according to sex and age. All are spoken of as horned stock, neat cattle, and beasts. Calves are either *bull calves* or *heifer*, *quey*, or *cow calves*. Yearlings of either sex are called *stirks*. Subsequently they are spoken of as *two* and *three year old bulls*, *steers*, or *heifers*. The female is called a cow after she has dropped her first calf; the male, if castrated late in life, is termed a *stag*, and the castrated male or *steer* becomes a *bullock* or *ox* when he has arrived at the age of four years. Such are the terms by which cattle are usually designated on the farm and in the market.

The selection of a breed of cattle is usually decided by the previous experience of the neighbourhood. As a general rule, worthy of the gravest consideration, there is an adaptation in the case of every breed to the soil and climate of the district over which it has spread. This remark is applicable to sheep as well as cattle, and attempts to rashly introduce new breeds of either into a district often fail. The hardy West Highland cattle and black-faced sheep exactly suit the severe circumstances under which they exist; the heavy Lincoln and Romney Marsh sheep require the flat luxuriant pastures upon which they graze; and the shorthorn requires rich meadows and liberal management to maintain him at perfection. The fact that a race of animals exists in a locality is a strong argument for its continuance. Safe and reasonable as is the opinion above stated, notable exceptions to its truth might be given. Thus, the shorthorn has made his way to the detriment of many native established breeds. The Leicester and Shropshire sheep have supplanted many of the older ovine races, and at the present day there is a tendency for certain dominant and improved races of live stock to intrude into districts up to this time occupied by native breeds. All we demand is caution, as sweeping and ill-considered changes are liable to end in loss to the too-enterprising agriculturist.

CATTLE BREEDING

may be divided into the breeding of high-bred or pedigree stock and the breeding of good useful cattle intended for the production of beef and milk. The first division represents the breeding of animals with the object of improving the race generally; and the second, while it participates in the improvements effected by the first, has for its object the immediate supply of the consumer. In the first, a perfect form, fine quality, and unspotted lineage are essential; in the second, a "good sort" is all that is asked for—cows which give plenty of milk—healthy, growing young stock, and steers which will yield a good return for the food they consume. Such animals are very frequently the produce of ordinary "useful" cows and pure-bred shorthorn bulls. We have already given sufficient space to the principles of breeding pure-bred stock, and we now turn to the management of more ordinary cattle, such as are to be met with on all well-managed mixed husbandry farms.

The calf is affected, previous to its birth, by the treatment of its mother. Cows should not, therefore, be milked when within six weeks of calving, if we wish to obtain well-nourished and well-grown calves. This first precaution having been enforced, we shall, without entering into all the difficulties incident to parturition, suppose the calf to be naturally ushered into the world. This important event usually takes place in the spring. Calves are dropped at all seasons of the year, but many reasons may be given for preferring the spring for this purpose. First, the young animal has the summer before it, and will have gained sufficient strength previous to winter to enable it to stand its rigours; secondly, the mother is brought into the best condition for yielding milk just when grass is most abundant. Where the farmer supplies the demand for new milk, he requires cows to calve at various seasons of the year; but where cheese is the staple produce of the dairy, summer is the only time during which the manufacture proceeds briskly.

The subject of bringing up calves is one on which much might be written, but our space being restricted, we are necessarily compelled to treat it with brevity. What, then, is the method to be adopted? We may allow the calf to suck its dam, a plan which has the recommendation of being natural; we may teach the calf to drink, and bring it up by hand on new and old milk; or we may adopt the system of feeding upon substitutes for milk, such as gruel or mucilaginous substances. Each of these plans has its advocates, and each must detain us for a short time. The writer objects to the first plan, unless in the case of high-bred stock, or of cattle which are intended to be forced forward from their birth and fattened at a few months old. Under any other circumstances this method is open to the following objections:—The quantity of milk the calf receives cannot well be controlled; the diet exclusively consists of new milk, and the thrifty farmer is debarred from introducing any other cheaper material, such as Iceland moss, linseed mucilage, and gruel, all of which are excellent foods for young calves. We must also remember that, where the land is poor, and where the yearlings and two-year-olds have to do as well as they can upon somewhat bare pastures, it is very questionable policy to pamper calves, and thus unfit them for the hard life which lies before them.

These considerations clearly point out the expediency of limiting the amount of new milk, and this can only be done by bringing the calf up by hand. Immediately the calf is born, it is removed to a suitable hutch or crib, and rubbed dry with straw. It should receive its first meal immediately after this operation, and during the first day it should be fed every four or five hours. The meals are speedily reduced to three, and afterwards to two per day, until weaning time. A calf requires to be taught to drink. Its natural inclination to suck is satisfied by placing one or two fingers of one hand in its mouth, while with the other hand the head is lowered, by gentle pressure on the crown, into a vessel containing milk, until the mouth of the animal is immersed. The sucking proceeds, and by gradually withdrawing the fingers, the calf is soon taught to drink. A very young calf is for this reason sometimes spoken of as a "finger calf." The following dietary for calves from birth to weaning is employed upon a well-managed farm in Northumberland with great success:—

1st day . .	1 pint of new milk every $4\frac{1}{2}$ hours.		
2nd day . .	2 pts. in the morning;	2 pts. at noon;	3 pts. at night.
3rd day . .	3 ,, ,,	3 ,, ,,	4 ,, ,,
4th and 5th days,	4 ,, ,,	2 ,, ,,	4 ,, ,,
6th and 7th days,	5 ,, ,,	2 ,, ,,	5 ,, ,,
8th and 9th days,	6 ,, ,,	0 ,, ,,	6 ,, ,,
10th to 30th days,	8 ,, ,,	0 ,, ,,	8 ,, ,,
2nd month . .	8 (old milk) ,,	0 ,, ,,	8 (old milk).
3rd month . .	8 (old milk) ,,	0 ,, ,,	8 (old milk).

Eight quarts per day is thus the maximum amount of milk given, and the increasing appetite of the growing animal is satisfied by grass, hay, finely-chopped turnips, meal, ground cake, etc., which it soon begins to relish if they are properly introduced to its notice. Mr. Bowick, manager of Mr. Howard's (Biddenham) farm and herd, in an admirable essay on calf management, gives the following allowances of milk as requisite for calves:—

1st week, with the dam, or 4 quarts per day, given in two meals.
2nd and 3rd weeks—5 to 6 quarts, given in two meals.
4th and 5th weeks—6 to 7 quarts, given in two meals.
6th to 12th weeks—8 quarts, given in two meals.

"If really good, creditable beasts are wanted—such as will realise £25 per head from the butcher when turned two-and-a-half years old—a little cake or meal will be found a desirable investment." Further, Mr. Bowick makes the following alterations from new to old milk:—New milk is given the first fortnight; the third week skim milk is substituted to the extent of one-third of the allowance; and at the fourth week the new milk is reduced to one-half, and boiled linseed gruel is added,

five pounds of linseed being enough to provide seven gallons of gruel, and to suffice for five calves. Mr. Bowick recommends the plan of tying up calves, but the more general and healthy plan is to keep them in cribs or hutches in a light, well-ventilated building. The cribs vary in size from 4 ft. × 4 ft., and 4 ft. high, to 4ft. × 8 ft. × 4 ft., and are "sparred" with slips of tile-lath and provided with a small wooden wicket to afford access to the calf. The floors of the cribs may be earth, but the passage between them should be flagged or of asphalte (Scott Burn). Each calf crib must also be provided with a trough and rack.

Mr. Henry Ruck (Cricklade, Gloucestershire) described an excellent plan for bringing up calves with a minimum quantity of milk, which he had successfully carried out for some years. His experience was communicated to the Cirencester Chamber of Agriculture, and was reported in the *Agricultural Gazette* of August 25, 1866. Calves are purchased at ten days old for about 30s. each. For the first three or four days they receive a milk diet, after which their food is gradually changed to a prepared gruel. This gruel is made as follows:—First, seven pounds of the best bruised cake is stirred into two gallons of hot water; next, two gallons of a watery infusion of hay (hay tea), diluted with a further addition of two gallons of water, is added; lastly, seven pounds of mixed meal, formed of equal parts of oat, wheat, barley, and bean meals, and the whole is well incorporated by stirring. More concisely, the gruel is composed of the following ingredients:—7 lbs. of linseed cake, 7 lbs. of mixed meal, 2 gallons of hay tea, and 4 gallons of water. Two quarts of this fluid, with two quarts of water, are given to each calf twice a day, and the young animals thrive well upon it at a cost of from 1s. 3d. to 1s. 6d. per week. The foregoing directions must be supplemented by very careful supervision, a point which is strongly insisted upon by Mr. Ruck, otherwise failure will be the inevitable result. Calves will be out at grass during their first summer. After weaning they may receive a small quantity of artificial food—say 1 lb. of linseed cake: they should be provided with a shed during the hot summer months, and as the nights become cold, towards the middle of October, they will be brought into fold-yards.

MANAGEMENT DURING THE FIRST WINTER.

Too often a starvation system has been followed in the wintering of young cattle. While we discountenance pampering, we certainly recommend a liberal plan of feeding, regulated by the quality of the grass land into which the young stock will be turned the succeeding summer. It would be the height of folly to feed young animals with expensive forcing foods in the winter, and then to turn them into poor bare pastures in the summer. Rather let us keep the future in view, and secure a steady, healthy growth from first to last. The usual system is to place the stirks in a fold provided with a shed; to give them a fair allowance of roots, barley or oat straw, and hay, cake, or corn, according to the liberality of the farmer who owns them. Mr. Ruck recommends 1 lb. of cake, 2 lbs. of crushed barley, cut straw, and pulped mangold as sufficient. Mr. Lawrence, of Cirencester, has given 1 lb. of cake and meal and 15 lbs. of pulped roots mixed with chop (cut straw). These figures sufficiently indicate the quantity of food which may be given. The stirks, meanwhile, should be well cared for, regularly fed, gradually changed from poorer to richer fare, supplied with fresh water, and placed in warm, dry, well-ventilated, quiet sheds. With such feeding and surroundings, every particular of which is of great importance, we may hope to see well-grown, healthy yearlings, ready for turning out to grass in the spring.

MANAGEMENT DURING THE SECOND SUMMER AND SECOND WINTER.

This is simple enough. The second summer the young cattle will be out at grass. The second winter they will again be brought into the yards, and fed according to the purpose for which they are intended. If to run once more on poor land during their third summer, straw and a few turnips will suffice; if to be brought out as "fresh beasts" and offered to the graziers of good land, then they will be proportionately better "done." Straw and about 3 lbs. of rape cake will keep such cattle alive and healthy. The "Farmers' Calendar" (page 46) recommends 1 lb. to 2 lbs. of linseed meal and a small handful of salt to be added to 1 gallon of water and boiled in a copper. The resulting liquid is then poured over chaff, at the rate of 1 gallon to 2 bushels, and this is given to the cattle twice a day. The two-year-old cattle, after their third summer's grass, are generally disposed of at two-and-a-half years old, to be fattened in the winter, and brought out as fat cattle at or about three years old.

THE LATHE.—XI.

By Henry Northcott.

HAND-TOOLS FOR TURNING IN VARIOUS MATERIALS.

The hand-turning tools for soft woods consist of gouges and chisels. The gouge is shown at Fig. 32, and the flat-edged chisel at Fig. 33. With tools of this sort almost any kind of work can be produced when one knows how to use them. They are employed of many different sizes, and sometimes the flat chisels have different angles for more convenient application to the work; but these two tools are the soft-wood turner's most powerful auxiliaries. Indeed, they may be called the only soft-wood turning tools, because they are not only applicable to almost every kind of soft-wood turning, but they are in form, cutting edges, and mode of using, quite different from all other tools employed by the wood-turner. It may sometimes be advisable to use a tool of some other shape; but in all such cases the tools will be similar to those used for turning hard woods, with the cutting angle ground rather more acute. The gouge is used for taking off the first or main portion of the superfluous wood, technically termed "roughing down." An expert workman will very considerably reduce the size of a piece of wood at a single cut, and will raise a heavy shower of shavings which fly in all directions from the tool's edge. He will first roughly and rapidly reduce the article in this way to nearly the required shape, and then with a sharper tool of the same sort, and with more care, will go again over the turned surface, and with a few light cuts leave the whole article very nearly the proper shape and size. The chisel is then carefully applied to the work, and the comparatively rough surface left by the gouge is replaced by the smooth glossy surface of the well-turned article.

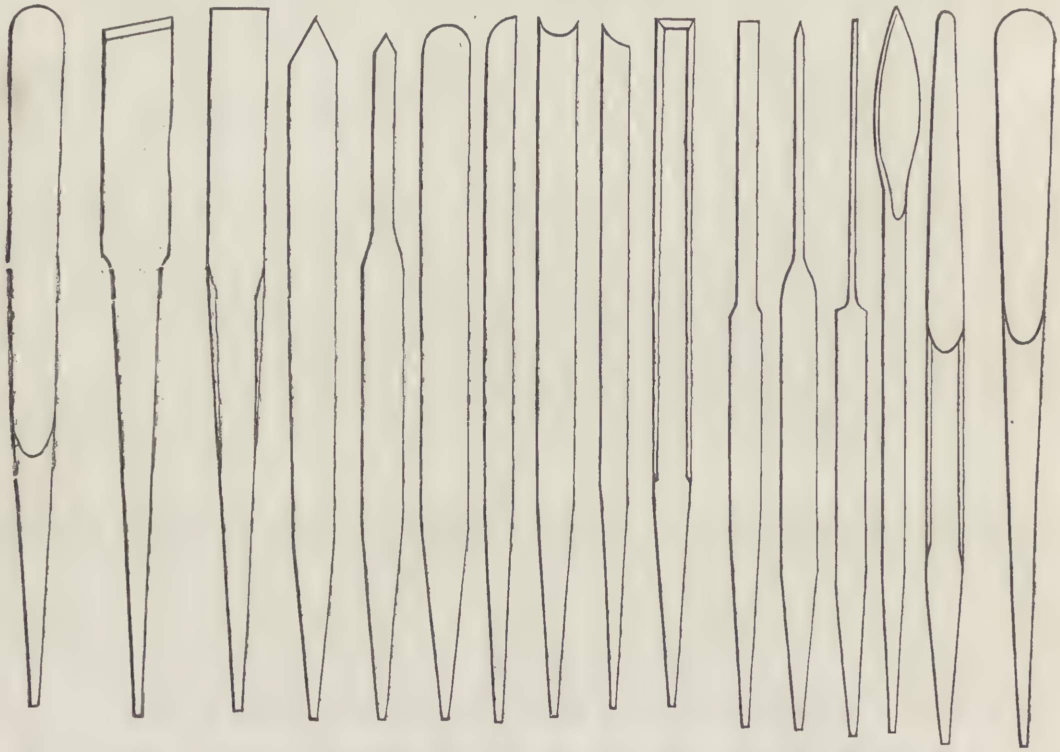
The hand-turning tools for hard woods are shown at Figs. 34 to 70. These tools are nearly all known as chisels, and are only distinguished by the shape of the cutting edge. Fig. 34, for instance, is the flat chisel; Fig. 35 the diamond-point chisel; Figs. 37 and 38 the round-nosed and half-round chisels; and so on with the others. Fig. 34 is chiefly used for turning cylindrical articles; Figs. 35 and 36 for turning angular shapes, corners, and flat surfaces. Figs. 37 and 38 are useful to produce curved forms, round grooves or channels; and Fig. 37 is also generally used for roughing down the harder woods. Fig. 39 is not a very useful tool, because it will only produce one particular form and shape. Fig. 40 is rather more useful. The two last are employed to produce round beads or mouldings. Figs. 42, 43, and 44 are sometimes called "parting" tools. They are useful for very small work, but chiefly for "parting," or cutting off pieces of work from the main cylinder or log. Figs. 45, 46, and 47 are termed "internal tools," as they are chiefly used for turning out holes, and for hollow work. Tools of this sort, but with a keener cutting edge, are sometimes useful for turning soft woods. Figs. 48 and 49 are "holing tools." They act more like drills than turning tools; but they are very useful instruments. Figs. 50 to 54 are chiefly useful for internal work and for side cutting. Some of them cut towards the right, and some to the left, and they are distinguished as right-handed or left-handed side tools according to the direction of the cutting edge. Figs. 55 to 61 are cranked tools, and are very useful for turning internal grooves, and otherwise shaping work not accessible to the straight tools. The hard-wood turner uses them of several sizes, and cranked towards both the right and left hand. Of these tools Figs. 56, 57, 58, and 61 are the most often in request. Figs. 55, 59, and 60 are less useful. Figs. 62, 63, 64, and 65 are also very useful tools. They are employed for turning fancy work, and for touching out corners difficult of access. Figs. 66 to 70 are beading or moulding tools. They are used for producing definite forms or set mouldings upon the turned articles. Any of these forms can, of course, be produced by the ordinary turning tools, and it

is only when many articles of the same shape are required that it becomes worth the workman's while to obtain these special tools for the work. Mouldings produced by these tools are, of course, more correct, and more likely to be uniform, than if the curves were separately turned out with the ordinary tool.

The figures show most of the tools in general use, but many of them may be dispensed with altogether: indeed, it is surprising how few tools some workmen use, and it is very often the case that the largest assortments of tools and instruments are found in the workshops of the least efficient turners. For soft-wood turning the gouge and flat chisels (Figs. 32 and 33) are quite indispensable. For hard-wood turning Figs. 34, 35, 37, 44, 45, 47, 48, 56, 57, and 58 are the most necessary tools. Many of the others are sometimes very useful, but most of them can be dispensed with. For fancy and ornamental turning it is often necessary to have tools made expressly to suit the work, and such tools are generally useless except for such

Most of these tools are used after the same manner, but the efficient use of some of them is much more difficult to learn than of others. The two soft-wood tools are truly cutting instruments. The tools for turning hard woods and brass are scarcely of this class, as their action upon the materials is more akin to scraping than cutting. Some of the turning tools for iron also act incisively. Figs. 71 to 76 are of this class; but the tools used upon cast iron act chiefly as scraping tools. As a rule, the tools which act by cutting are more difficult to use than those that act by scraping.

The gouge and flat chisel for soft woods are held with the cutting edges above the centre of the work, and with the handles of the tools lower than the cutting edges. The hard-wood and brass-turning tools are nearly all held with the cutting edges just level with the lathe-centres, and with their handles also on about the same level. All the tools are supported against the cuts by a tool-rest of some sort, and this



Figs. 32. 33. 34. 35. 36. 37. 38. 39. 40. 41. 42. 43. 44. 45. 46. 47.

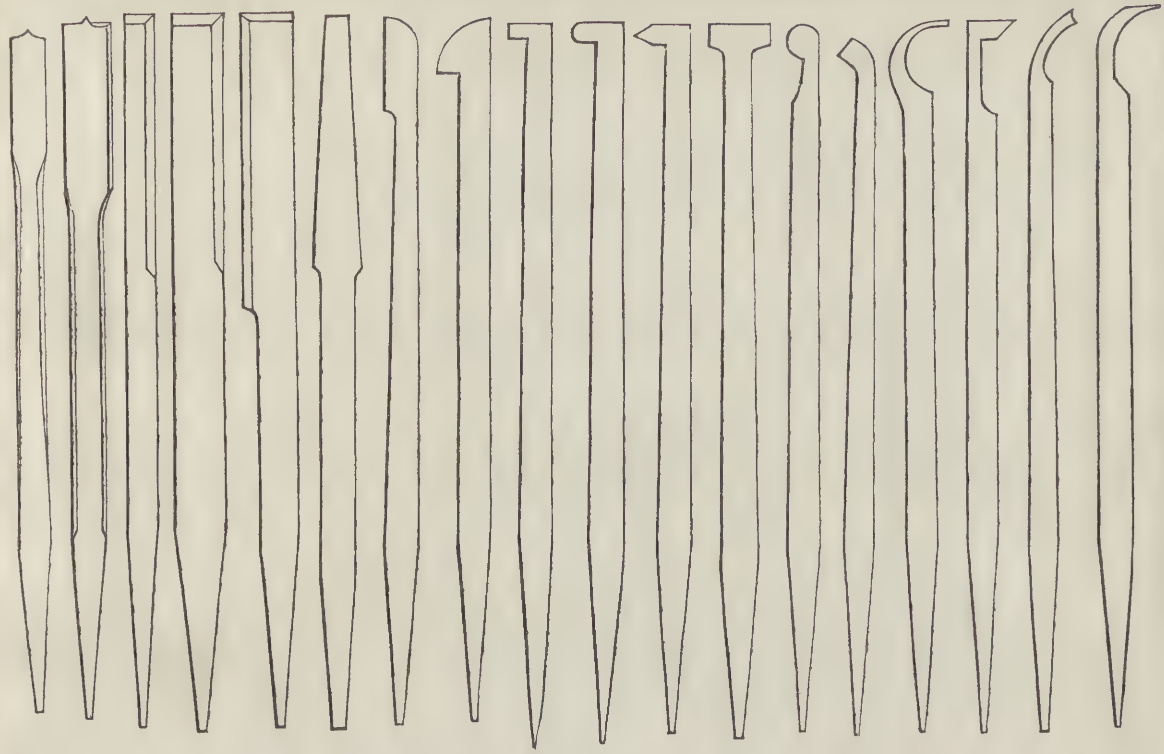
work. Some of these special tools will be illustrated in connection with the work they are designed to effect, and these will be sufficient to indicate how special tools for other work should be formed.

The tools used for turning wrought iron and steel are given at Figs. 71 to 76. Figs. 71 to 74 are used for roughing down the article. Figs. 75 and 76 are side tools for turning ends and side surfaces. The finishing cuts are usually taken by chisels somewhat similar to Fig. 42, but made much deeper and stronger, to withstand the increased strain put upon them.

Fig. 74 is also used for taking the roughing cuts off brass articles, and the finishing cuts are taken with the tools shown at Figs. 77 to 81. These tools in outline are much the same as those used for turning hard woods; but the angle of the cutting edge is, in the tools for brass-turning, made more obtuse than in the tools for wood. The blades also are made stouter towards the handle, and the steel is tempered rather harder. In addition to these tools, the brass-turner occasionally requires the use of cranked tools, and special tools of much the same shape as those already given amongst the wood-turning tools, but with a cutting angle adapted to brass, and which is about 90 degrees.

support is generally placed as near the work as possible. The tools are held by both hands, and generally the left hand is employed to guide the edge along the work in the required direction for shaping it, whilst the right hand is employed to regulate the height and inclination of the tool's edge, and the depth of its cut. It should be explained that the term "scraping," applied to describe the action of some of the tools, is, to some extent, an incorrect term, or rather, a term likely to be misunderstood. All of the tools act by cutting the substances they work upon, but in some of them the incisive action is more marked than in others. The chief points to be observed in the use of hand-turning tools are, first, that the tools shall be properly shaped, and kept in good order; second, that the tool-rest or support shall be placed near the work, so as to reduce the leverage acting against the workman as much as possible; third, that the tools shall be maintained in proper position upon the rest, and kept firmly up to their work.

The first point is very frequently neglected even by old hands at turning. The tools are first of all, perhaps, properly shaped and in good order; but as they wear dull on the cutting edge, they are sharpened by removing a small portion of metal near this edge. And as no metal can be removed from the cutting



Figs. 48. 49. 50. 51. 52. 53. 54. 55. 56. 57. 58. 59. 60. 61. 62. 63. 64. 65.

edge alone without gradually altering the shape of the whole tool, it follows that the tools in a short time become much injured. The proper plan is to grind the whole cutting part of the tool when *any* part requires grinding; but the keenness of the edge may be maintained by slight applications of the oil-stone.

The position of the tool-rest should especially be attended to by young workmen, as the whole operation of turning is rendered much easier by having the tool properly supported. The steadiness of the tool is chiefly affected by the position of the rest, and to produce good work it is obviously necessary that the tool shall be perfectly under the turner's control.

CIVIL ENGINEERING.—XX.

BY E. G. BARTHOLOMEW, C.E., M.S.E.

LIGHTHOUSES (*concluded*).

We must not conclude our notice of lighthouses without referring to that important subject, the method of lighting them. In order that a beacon may be of value, it is absolutely necessary that it should be visible in all states of the atmosphere, at a distance sufficient to give timely warning to vessels it is intended to warn off from a danger, or direct to a harbour. In ancient times a blazing coal fire was frequently employed for this purpose, or, better still, torches smeared with pitch. But the improvements of modern days have, in the matter of artificial light, far outstripped all the ideas of the ancients. As soon as it became known that combustion depended upon the presence of oxygen, which, as our readers are probably aware, forms more than one-fifth part of the atmosphere, attention was directed to the best means of supplying this gas to the flame. The flame of a common candle receives its supply of oxygen upon its exterior surface alone; but if it were practicable to introduce air into the interior portion of the flame, its brilliancy would be greatly increased. Now this has been accomplished in the case of the Argand burner. This form of burner consists of a circular ring, around which the fuel is supplied. If it is intended to burn oil, the substance usually employed in lighthouses, the wick which abstracts the oil from the reservoir, or which is saturated with it, is made circular, and the thin ring of flame which proceeds from it whilst burning is freely supplied with air upon its interior as well as its exterior surface. A glass chimney is placed over the flame, by means of which the combustion is rendered more complete.

If gas be employed, it is supplied through holes pierced in the ring, and in doing so it is necessary that the holes should be placed at equal distances, and be equal in diameter. The size of the holes is an important point, for if they are too large the gas will flow so rapidly that it will not mix in the proper proportion with the atmospheric air to render the combustion complete, and the result is that a quantity of smoke or carbon is produced, which affects the brilliancy of the light. If, on the other hand, the holes are too small, the gas will not flow in sufficient quantity to produce the necessary quantity of light; it is also generally observed that the burners which contain the greatest number of holes within a certain space afford the most brilliant light. A few rules founded on observation may not be out of place. The rings of burners which have 10, 15, 20, or 25 holes, should have their diameters respectively $\frac{3}{8}$, $\frac{1}{2}$, $\frac{3}{5}$, and $\frac{13}{20}$ of an inch; the breadth of the rim being $\frac{12}{100}$ of an inch. The height to which flame may be raised without smoking is as follows:—If with 8 holes, 4 inches; 10 holes, $3\frac{1}{2}$ inches; 15 and 20 holes, $2\frac{1}{2}$ inches; and 25 holes, 2 inches.

The most economical, and at the same time the most brilliant light from common gas, is produced by a burner in which the jet-holes are very numerous, the aperture for admitting air small, and the diameter of the chimney narrow; and when several jets are combined, as in the Argand burner, the light increases in a greater ratio than the expenditure of gas. The chimneys for the burners mentioned should be respectively $\frac{8}{10}$, $\frac{12}{10}$, $\frac{13}{10}$, and $\frac{15}{10}$ of an inch in diameter, and 6 inches high. The equivalent of light obtained from sperm oil and gas is as one gallon of the former to 29 cubic feet of the latter, both being pure, and both being utilised to the utmost. The presence of sulphur in gas as sulphuretted hydrogen is detrimental to the purity of the light produced by its combustion; this is readily detected by passing a stream of it through a solution of acetate of lead. If sulphur be present, a black precipitate or a dusky hue will be produced in the solution; if the gas be pure, the colour of the solution will be unchanged. The necessity for producing a brilliant light in the lantern of a lighthouse will be obvious, from the fact that light diverges in every direction from its source, and that its intensity decreases in proportion to the *square* of the distance; that is to say, at two yards' distance the light will only be *one-fourth* of what it was at one yard, or at three yards only *one-ninth*, and so on, the atmosphere being clear. Amongst the various sources of light which have been used for illuminating lighthouses, may be enumerated oil, tar (as in Beale's light), gas, the Drummond or lime light, and electricity. Although we are now able to boast of splendid lights exhibited by many of our lighthouses—a matter in which our neighbours, the French, are in no way behind us—it is a singular fact that for fifty years after the Eddystone lighthouse was completed it was lighted only by *tallow candles*, and so recently as 1801 the lighthouse at Harwich had a *flat plate of brass* placed at the back of a *coal-fire* to guide the mariner on his course.

With reference to the employment of oil, we have already shown how best to utilise its flame—namely, by the employment of an Argand burner and a glass chimney. The apparatus for obtaining light from the combustion of tar is of the following description:—A copper reservoir, similar to that of an Argand lamp, is partly filled with refuse tar from gas-works, a suitable apparatus being attached to prevent an undue amount of tar being admitted. Leading from this reservoir is a pipe which bends vertically upwards and terminates in a hollow burner, up through the centre of which passes a fine jet communicating with a vessel containing atmospheric air under a pressure of $1\frac{1}{2}$ lb. per square inch. As soon as the tar is lighted, a small lambent flame is obtained; but immediately the compressed air is admitted, the flame is changed into a very brilliant light.

The employment of coal-gas in lighthouses involves too many difficulties to render it a practicable means of illuminating them. Could it be utilised, it would doubtless be preferable to oil, both in economy and brilliancy. Equal, or indeed greater difficulties present themselves in the employment of the Drummond light. This exceedingly brilliant light, called after its inventor, was suggested by him for employment on the Trigonometrical Survey of England, in consequence of the difficulty he often experienced in observing the signals between very distant stations. It had already been ascertained by experiment that a piece of lime when heated by the flame of the blow-pipe emitted a very brilliant light, and the higher the temperature to which the lime was heated, the greater its brilliancy. In the *Philosophical Transactions* for 1826 and 1831 are two papers upon the subject. The apparatus for the production of the light consists of a lamp, which admits at the same time through two separate tubes oxygen and hydrogen gases, in the proportion of one of the former to two of the latter by volume. These tubes terminate in a small chamber, and there become mixed. As in their combined state they form a highly explosive mixture, the greatest care is necessary to prevent the flame from the jet from passing back to this chamber; and to secure this end the tube or tubes which convey the *mixed* gases to the point at which they are ignited, is filled with very fine wire gauze, which impedes the passage of the flame. The jets passing from the chamber are two in number, and the flames issuing from them impinge upon the opposite sides of a ball of lime. The intense heat produced by the combustion of the mixed gases raises the ball of lime to an extreme point of brilliancy, and in order to prevent the too rapid wasting of the ball, it is made to revolve about once in a minute. With even this precaution, however, so great is the heat that the ball has a deep groove cut all round it in the space of about forty-five minutes, and it then has to be changed. An ingenious but complicated piece of mechanism is arranged to effect this change at the right moment, the object being to permit no intermittence of the light, which might be mistaken by a passing vessel.

The brilliancy of the *electric* light is well known, and many of our readers may have seen it. It may be regarded as excelling all other artificial lights at present known, even the magnesium. The ordinary source whence this light is obtained is the voltaic battery, and when required for a short period it is probably the most economical. The mode of obtaining the light from the battery is simply to terminate the wires which lead from its

extremities by carbon prepared in a peculiar manner, and shaped like a pencil of ¼ inch square. The circuit of the battery being completed by contact of the points, they may be withdrawn a certain distance apart, and the electric flame will continue to burn through the space of air between. Care must be taken not to withdraw the points too far, otherwise the flame will cease, and contact must be again made before it will re-appear. The *distance* to which the points can be separated without extinguishing the flame is dependent upon the *number of elements in series* in the battery, and the *volume* upon the *size* of the plates. A self-regulating apparatus is usually employed with the electric light, by which the distance is maintained between the points, allowance being made for the combustion of the carbon. We do not consider it necessary to explain the character of this apparatus in detail now.

The employment of electricity derived direct from a battery has its objections. The expense is very considerable when the time is prolonged, owing to the waste and consumption of some of the materials; and the power of the battery is by no means uniform: for these and other reasons attention has been paid to *magnetism* as a source of electricity. To Faraday is due the merit of discovering that magnetism could be made to develop electricity, and the now common medical coil which is sold by surgical instrument makers affords a familiar type of an apparatus for the purpose.

Professor Holmes has designed a very powerful and effective apparatus, by means of which he obtains an exceedingly brilliant and regular light. It has been employed at Dungeness for a considerable period, and more recently at the South Foreland. The advantage of this method of obtaining electricity for lighthouse purposes lies in the *constancy* of the current, so long as the helices revolve with the same speed.

To quote from a paper read by Professor Holmes before the Society of Arts, in December, 1863, he says:—

"The electricity derived from a magnetic machine is induced in coils of wire, by the changing of the magnetic polarity of pieces of soft iron enclosed within the coils or helices; and the quantity or intensity of the induced current depends, first, on the amount of magnetism induced in the soft iron; secondly, on the facility with which the poles of the magnetised soft iron can be reversed; thirdly, on the velocity with which the change of polarity takes place; and, fourthly, on the length and diameter of the wire forming the helices. The amount of magnetism induced in the soft iron depends on the size and force of the steel magnets employed, and on the weight and softness of the iron in the helices; but in practice the weight of the soft iron is limited by the weight of the steel magnets, for if too heavy the steel magnets will be slowly deprived of their magnetism. To facilitate the change of the poles, the soft iron cores of the helices are not solid pieces of iron, but are tubes, single, double, or treble, as it is found by experiment that the same weight of iron, when divided in this manner, loses or takes magnetism in much less time than when in a solid form."

"There is a limit to the velocity to be employed when the maximum of electricity is required, for this reason. The amount of electricity depends on the amount of magnetism taken up, and the soft iron takes time to become saturated with magnetism: hence, if the velocity with which the cores move from the poles of one magnet to those of another be too great, there will not be sufficient time for the cores to become saturated. But since the quantity of electricity increases with the velocity, it is necessary to ascertain this maximum point exactly, either by experiment or calculation. The length and diameter of the wire must vary according to the current required; a short thick wire for the helices represents a battery with plates of large area, but limited in number; whilst a long thin wire will represent a battery having plates of small area, but very numerous. From these facts certain known laws are deduced, founded upon which a magneto-electric machine can be made capable of giving a current of any given amount of electricity."

An important feature in Holmes's machine is the method of converting every alternate current into one and the same direction with the intermediate currents. In order to explain this point, it is necessary briefly to state that the electrical currents induced from magnets are very brief in duration, and that the currents are obtained at each change of polarity in the iron cores within the helices, and moreover that the direction of the successive currents so obtained is alternately reversed. The result of this reverse character in the currents is, that one tends to destroy the other if produced in the same wire, unless by some plan all the currents can be thrown in the same direction in that wire.

Professor Holmes explains his arrangement thus:—"The helices are connected in two, four, or more series; and in doing this, care must be observed that the direction of the coil of every alternate helix is in an opposite direction—that is, if one is wound right-handed, the next is wound left-handed; or what amounts to the same thing, supposing all wound in the same direction, then the two inner ends of the helices of, say, Nos. 1 and 2 must be joined to the two outer ends of the helices of Nos. 2 and 3, and so on through the series; and lastly, the ends of the series are soldered to two insulated discs against which two springs press. . . . One half of the helices are arranged so as to arrive on the poles of the magnet at the same instant that the other half are exactly midway between the poles. Thus there are two distinct currents, and what may be called the 'dead' point—that is, the point when the current inverts in one series—occurs exactly at the time when the other current is at its maximum, so that if now the inverted currents can be again inverted in both of these distinct currents, and the two which now flow in one direction can be united as one compound current, it is evident that the result will be a current nearly as uniform as that from a galvanic battery, with the advantage of equable continuity. This is done by the two commutators, which consist each of two insulated rings of metal, of such a form at the periphery, that two rollers or rubbers change sides from one disc to the other at the same instant that the current is reversed; then, by combining the two commutators, a compound current is obtained which produces *a constant white light.*"

We cannot now enter into a description of the professor's regulator. Suffice it to say that he has succeeded in producing a most intense light, which may be maintained for any length of time, which does not require to be trimmed or extinguished for a second, and which has all the steadiness and uniformity required for lighthouse purposes. The intensity of this light has a power of penetrating haze only equalled by the sun, and its cost, light for light, is far less than the cost of oil.

We regard this invention of sufficient importance, in connection with our subject, to render any apology for having devoted so much of our space to it unnecessary.

It only remains for us now to describe the methods which are employed for utilising all the illuminating rays from the flame—from whatever source it may be derived—for the object intended, namely, that of projecting a ray of light upon a belt of water at a given distance from the lighthouse.

Since the rays of light issue from an illuminated point in *all* directions, it is obvious that a great proportion of these rays are useless and wasted if only required in *one* direction, unless some means can be adopted for bending or *refracting* them in that direction. There are two distinct methods which have been adopted for this purpose, the *Catoptric* and the *Dioptric* systems. There is also what may be termed a third system, in which these two are combined. This is the *Catadioptric*, or, as some call it, the *Holophotal* system.

The Catoptric arrangement is that in which the rays which form the one half of the illuminated sphere are thrown back upon the other half by means of a parabolic reflector. This system was first applied at Dieppe, by Borda, in 1784; although reflectors, probably spherical, had been employed at Marstrand, in Sweden, a short time previously. A first-class catoptric arrangement consists of, say, three sets of Argand burners, three in a set, with a highly polished silvered parabolic reflector behind each burner; the entire system being caused to revolve, by the intervention of clock-work, round a centre, the space between the sets producing the occultation or eclipse necessary, supposing the light is intended to be a revolving one. The reflectors are of sheet copper, plated in the proportion of six ounces of silver to sixteen ounces of copper. They are moulded to the requisite form by beating them with mallets and hammers of various forms, and are frequently and carefully tested. After they are formed to the paraboloidal curve, they are stiffened round the edge by means of a strong bezzle. The form of the reflector is tested by trying a burner in the focus, and measuring the intensity of the light at various points of the reflected conical beam.

The Dioptric arrangement is that in which the rays issuing

from the flame are collected and refracted in a given direction by a lens placed in front of the light. So far back as 1752 a lens was tried at the South Foreland, but abandoned, owing to some mechanical imperfection. In 1819 Fresnel constructed a lens which may be said to have produced a revolution in the method of illuminating lighthouses. Previous to the date mentioned, Condorcet in 1773, and Brewster in 1811, had suggested the idea of *building up* a burning lens in separate pieces. This was the plan which Fresnel devoted himself to perfect in order to apply it to lighthouses, he being at the time secretary to the French Lighthouse Commission, under the presidency of Arago. In a plano-convex lens the rays of light falling upon one of its faces are refracted in lines *nearly* parallel to its axis, but the parallelism becomes less the further the rays lie from that axis, and this aberration is excessive when the lens is very large. It was to obviate this defect, and obtain full command over *all* the rays falling upon the lens, that Fresnel designed his lens. In Fig. 45 we give a diagram of one of Fresnel's lenses in section, showing its action upon the rays it receives. A B is a section of the lens, which it will be seen consists of many separate pieces or rings concentrically surrounding a small central lens L, the whole having their flat surfaces arranged in one plane. S is the source of light, the rays from which falling upon the system of rings, are refracted in parallel lines A A′, L L′, B B′, according to a well-known law. The advantage gained by a Fresnel lens is twofold. In the first place, by combining calculation with experiment, the precise curve of each separate ring is so arranged as to ensure *perfect* parallelism in the refracted rays. Now supposing it practicable to grind a plano-convex lens to such an exact curve as that the refracted rays should be perfectly parallel, we should obtain a lens whose thickness in the centre would be several inches, and the absorption and consequent loss of light by transmission through this mass would be serious. Here then we have the second advantage gained by a Fresnel lens. Looking at it irrespective of the curve, we may regard a Fresnel lens as a plano-convex lens cut into slices parallel to the plane surface, having a disc cut out of the centre of each slice. Our meaning will be better understood by a reference to the diagram (Fig. 46).

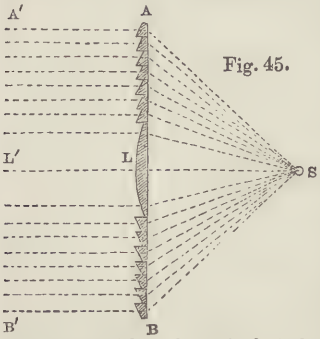

Fig. 45.

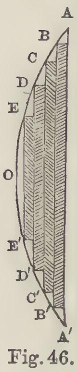

Fig. 46.

Let A A′ represent a section of a plano-convex lens, and imagine it cut into slices by the lines B B′, C C′, D D′, E E′, parallel to the face A A′. Now, since the whole of the refractive action of the entire lens lies in the angle formed by the two lines A A′, A O A′, of which the latter line is curved, it follows that if the various slices be separated from each other, their respective faces being kept parallel, there will be in each slice a central portion bounded by the point at which the curve commences, of which the two faces are parallel, as shown in the diagram by the shaded portions, and to which, in consequence of the parallelism, no refractive action is due. The whole of this portion can therefore be cut away, and the rim remaining—almost precisely similar to a quoit in shape—will exert just as large a refractive action without the central disc as with it, with the advantage of dispensing with a mass of glass whose only effect is to absorb light. If then in each slice the central discs be removed, the several rims remaining can be pushed forward, so that they assume the position shown in Fig. 45.

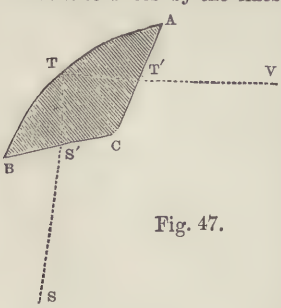

Fig. 47.

In a light of the first order, the central lens is about eleven inches diameter, with a focal length of rather more than 36 inches, and the concentric rings surrounding it (the slices without their discs) gradually decrease in breadth from $2\frac{3}{4}$ to $1\frac{1}{4}$ inches as they increase in diameter. A lens of this description, made of crown glass, will possess a refracting surface of about 1,300 square inches.

A very brief allusion to the *Catadioptric* arrangement is all we can afford space for. This, as its name implies, combines the Dioptric and Catoptric systems in one. The diagram (Fig. 47) will illustrate the arrangement.

Let A B C represent the section of a catadioptric ring, and S the source of light. The ray S S′, falling upon the surface C B of the ring, is refracted at S′ in the direction S′ T; it then becomes completely reflected at T on the curved surface A B, in the direction T T′, and finally emerges in the horizontal line T′ V.

It is easy to perceive that if due care be taken in the grinding and fixing of these rings, they may be so arranged as to *gather up*, so to speak, *all* the luminous rays from S, and throw them into a horizontal direction.

FISH CULTURE.—X.

By Greville Fennell.

OYSTER BREEDING, REARING, AND FEEDING.

Very much of late years has been written upon oysters and their culture, more especially since the great failures around Great Britain and Ireland, and on the Continent, where miles and miles of hitherto prolific parks, both natural and artificial, existed, have become, from various causes, either wholly unprolific, or entirely depleted.

It would be therefore a somewhat profitless work, more particularly where space is of value, to go back for information to books and documents which treat of the past history of these once famed oyster parks as a permanent success. We must therefore take as our guide the latest most reliable authority upon this interesting subject—the Report of the Commission appointed to inquire into the methods of oyster culture in the United Kingdom and France, with a view to the introduction of improved methods of cultivation of oysters into Ireland. The Commission was an unpaid one, composed of J. A. Blake, Esq., M.P., George William Hart, Esq., T. F. Brady, Esq., and Francis Francis, Esq.—the latter gentleman bringing his long practical experience to bear upon the inquiry. The instructions to the Commission are very discouraging upon the subject of oyster culture, more particularly in Ireland, it stating that in that country, out of nearly ninety licences granted by the Board of Works for oyster planting, which embrace an area of about 15,000 acres, scarcely half a dozen can be said to be successful. This is the more surprising, as Ireland is admittingly well calculated for the successful prosecution of *ostreoculture*. The favourable temperature of the sea, the large inlets and bays on the western coast, containing banks where oysters are already found in great numbers, the habits and tastes of the coast population, all show that this most valuable industry might be prosecuted with great success. The Commission was required to visit the principal places in France, England, and Ireland, where oyster cultivation is, or can be, carried on: they were to examine the best authorities upon the subject, and endeavour to ascertain the causes which have led to the many failures which have been experienced.

The young of the oyster, when perfectly formed, attach themselves immediately to the first clean, hard substance they meet with. It has been ascertained that the spat floating in the water for several days is that which from some cause has been ejected before maturity: such spat forms a large proportion of the whole, and during the time in which the spat is free, and is becoming fit for attachment, it is carried by tides and currents to great distances, is devoured by countless enemies, or is driven upon muddy and otherwise unsuitable ground, and so perishes. Under the most favourable circumstances, the proportion that never attaches is very considerable. In a natural state the oyster remains attached, during its lifetime, to whatever object it first adheres to; but after accidental removal it will sometimes again adhere to substances with a hard and tolerably clean surface. To save the bulk of the spat when free is the great object of oyster culture. It may be here stated that the young of all mollusks are apparently free for a longer or shorter term; of this fact the cockle, mussel, winkle, and balanus tribes afford proof.

In the British waters, and those of France, spatting usually takes place when the parent oyster is three to four years old, although it is not uncommon to find oysters milchy at a much earlier period. It has not been clearly ascertained how often during life breeding takes place, but there is no reason to suppose that it does not frequently occur in the lifetime of the same oyster, although it is believed that not more than 10 per cent. of the stock on any bed will usually spat during any one season. As oysters, however, from various causes, have been known to spat very late in the year, it is impossible with accuracy to state the proportion of full-grown oysters that breed annually. The young oyster, when sufficiently matured, rises immediately to the surface upon its emission from the parent, after which it adheres to the first clean hard substances it meets with: this motion is effected by what is termed a swimming pad (Figs. 21, 22, 23), but which is, in truth, but the protruded lobes of the mantle, and not an organ specially formed for locomotion, seeing that by it the shell is secreted. It is by this organ also that the oyster attaches itself, and this, too, in the same way that it forms its shell. Swimming with open shells, and extended mantle uppermost, on meeting with a clean, hard substance, it remains in close contact with it, and secretes over that part of the substance which it touches a coating of the same material of which its shell is formed. The first coating is followed by other layers, and so the once free oyster becomes

Fig. 21. Fig. 23.

Fig. 22.

SWIMMING PAD OF THE YOUNG OYSTER.

fixed, and by a repetition of the process from time to time the necessary increase of shell is made to meet the requirements of the fish. By the same means, also, young or adult oysters, it is said, re-attach themselves to stones or other substances when removed from the places to which they first adhered. That oyster-spat invariably rises when first emitted is a fact to be appreciated in cultivation.

The nature of the bed or soil on which the oyster rests is a matter of the greatest importance, conferring as it does upon the oysters there bred or deposited special flavour or other qualities distinguishing them from all other oysters in adjacent grounds; and this influence prevails to so great an extent that dredgemen can in a fog or dark night readily recognise their position by the shape, size, or colour of the oysters brought up by the dredge; and although the distance between such beds is often small, they are enabled accurately to steer for the harbour from information of this peculiar kind. The nature of the soil is important in another aspect. Many circumstances highly favourable to the growth and fattening of oysters are the reverse for successful breeding.

Growth and fattening will proceed where there may be a large amount of fresh water and a strong current: the former would prove prejudicial to spatting, and the latter tend to prevent the adhesion of spat—at least in the locality at which it is voided.

Good spawning grounds have, on the other hand, been found less suitable for purposes of fattening—pure sea-water, and a clean bottom, essentials for successful spatting, not being always advantageous for the other purposes; hence it is usually found in rivers and estuaries that oysters breed better at the mouth, and fatten best higher up. There are, however, instances where the two processes are found to thrive simultaneously on the same banks.

The present diminution in the supply of oysters appears to have commenced some seventeen or eighteen years ago. Since that period a greatly increased demand for oysters has resulted from the greater facilities of transport to places where previously fresh oysters had seldom reached. Another circumstance has also added considerably to the demand—viz., the more frequent use of oysters, owing to the fashion prevalent both in England and France, among the wealthier classes, of consuming them at almost every meal. This materially enhances the price, and has led to a vast increase in dredging. In 1855 the price of native oysters was 42s. per bushel; and in 1870 it was £8 to £9, while in 1872 it was £10 to £10 10s. A similar rise has taken place in seconds; while commons, in 1855, were 13s. to 14s. per bushel, they were, in 1870, 18s., and in 1872, 20s.

Considerable difference of opinion exists as to the cause of this decrease in oysters, some authorities contending that it is altogether due to over-dredging, others to failure in the natural production of spat. There is no doubt, however, that the principal cause of the scarcity is attributable, both in France and England, to over-dredging; and this we can deal with, and to a certain extent counteract its effects, by wise legislation.

No better illustration, says the Report, can be given than the advantageous position which Ireland occupies when compared with either of the other countries. That her natural beds have suffered much less from exhaustion may be attributed in a great measure to the enforced close time and other salutary regulations made by the Commissioners of Irish Fisheries, which are not in existence in England, and only lately came into operation in France.

The oyster fisheries may be divided as follows:—Firstly. Natural banks, where, without any action on the part of man, oysters are propagated. Secondly. Banks partly natural and partly artificial, as in the rivers of Auray and other places in France, and of Essex and other places in England, where the production is aided by laying down fresh cultch (oyster-shells, tiles, stones, etc., for the oysters to adhere to) and stock, and keeping the beds clear of dirt and vermin. Thirdly. Foreshore cultivation, where the spat from oysters on natural banks is saved or caught on collectors placed for that particular purpose. Fourthly. The method of cultivation in enclosed spaces, such as Lake Fusaro, in Italy; at Hayling, the Isle of Wight, and other places.

The process of collecting oyster spat on stones, etc., has been practised at the Isle of Oléron for upwards of half a century, without attracting much attention—a fact which has not been previously noticed by any of the writers upon oyster culture up to the appearance of the Report of the Commission, it having been erroneously supposed to have originated at the Île de Ré; whereas the park system, which Hyacinthe Bœuf introduced into that island, was but a modification of the system followed at Oléron. Bœuf's discovery is said to have been altogether accidental, arising from the storing oysters within a small stone enclosure, and finding some time afterwards that a large quantity of spat had adhered to the stones. Encouraged by this, Bœuf, in the ensuing year, made a larger enclosure on the foreshore, and laid down more oysters and stones. The result was most successful, and many of his neighbours seeing this, engaged in like enterprises, and were so well remunerated for their trouble and outlay that an extensive cultivation on this plan was soon in operation on various parts of the shores of the island. These layings do not extend beyond low-water mark, and in most places the water is retained by small embankments. The results were much greater the first few years than they have been latterly; indeed, we hear that they have lately been nearly, if not wholly, destroyed by mud and sand. In 1859 the number of oysters was 157,500, valued at £126; in 1863, 5,650,250 oysters, valued at £4,535; and in 1867, 879,713 oysters, valued at £1,245.

The young oysters are usually removed from the stones at one year old. They are then placed in claires to grow and fatten, the time they remain in claires varying according to circumstances in the different localities.

The cause assigned for the recent failures was the improvidence of the concessionaires in selling off all the stock as soon as it was marketable, and leaving none from which to replenish the beds. But to a large extent it is probably also attributable to the stones, tiles, or other collectors being in a cleaner condition during the first year than they were afterwards, sufficient care not being taken to keep them free from mud and weed, without the observance of which precautions the adhesion of spat to collectors is very doubtful.

In our next paper on this interesting subject we shall call attention to some of the principal localities in which oyster-farming has been carried on, and the different modes adopted in this branch of shell-fish culture.

SHIP-BUILDING.—XIX.

BY W. H. WHITE,

Fellow of the Royal School of Naval Architecture, and Member of the Institution of Naval Architects.

BULKHEADS.

HAVING considered the three great subdivisions under which the principal parts of the structures of ships may be arranged —viz., the framing, skin, and decks—it will not be out of place to devote attention to some parts which can scarcely be included under either of these heads, although they are far from being unimportant. Chief amongst these stand "bulkheads," *i.e.*, the transverse or longitudinal partitions fitted in the holds of ships, whose principal features we will proceed to describe.

The bulkheads, or partitions in the holds of ordinary wood ships, are built almost solely with a view to convenience of stowage, their positions being determined quite independently of any considerations of safety, and their construction being very commonly such that they are not water-tight. There have, we believe, been some few cases in which a different plan has been adopted, the bulkheads being made water-tight and placed at comparatively small intervals apart; but this arrangement has only been had recourse to where an exceptional degree of safety was considered desirable—for example, in ships sent to the Arctic regions, and liable to serious injuries from the ice.

The general use of water-tight bulkheads dates no further back with us than the introduction of iron ship-building. Mr. Charles Wye Williams was, we believe, the first to recommend their adoption as a means of gaining increased strength and safety in iron ships; and the practice of fitting them has since become common, although the full advantages possibly derivable therefrom are not commonly obtained. In nearly all cases they are placed transversely, but in some vessels longitudinal partitions are also built. They are usually formed of thin iron plating stiffened by numerous angle-iron or T-iron bars, and thus made more or less rigid, adding greatly to the transverse strength of the ships. Of late years similar bulkheads have been fitted in composite ships, and also in some wood ships, mainly with a view to structural strength, but also as a means of increasing safety. With a wood skin, however, it is difficult to secure the thorough water-tightness at the edges of bulkheads which can be obtained in iron ships; nor is this equally necessary, because thick wood planking is less liable to penetration than thin iron plating, and because a leak in a wood bottom can generally be stopped more easily than one in an iron bottom. Fortunately, therefore, water-tight subdivisions can be made most efficient in the class of ships where they are most required.

Experience has furnished ample evidence of the great advantages gained by a proper arrangement of the bulkheads in iron ships, and of the dangers incurred by neglecting such arrangements. On the one hand, numerous cases are on record where iron ships have been kept afloat and safely navigated into port after receiving serious damage by collisions, grounding, fire, and other causes: on the other hand, many instances might be referred to where iron vessels have been lost for want of efficient water-tight subdivision of the hold. There is no difficulty in ascertaining the reason why ordinary iron ships are left open to the chance of such casualties. The rules which govern the practice of private ship-builders state the minimum number of bulkheads required in different classes of ships, and leave it to the ship-owner and ship-builder to decide whether a larger number of bulkheads shall be fitted. The "classing" of a ship, together with her rate of insurance by the underwriters, not being affected seriously, if at all, by the provision or non-provision of additional water-tight subdivisions, it is not surprising to find that the cheaper but less safe and strong arrangement is commonly preferred. The decision in favour of this course is, moreover, partly due to the consideration that the stowage of cargo in a merchant ship is much facilitated when the hold is free from obstructions or subdivisions. But, while this is true, the fact remains that, as regards safety, the common plan leaves an iron ship with an insufficient number of bulkheads.

Take, for example, a sailing ship built of iron in accordance with Lloyd's Rules. She need only have one bulkhead, fitted moderately near the bow, and known as a "collision" bulkhead, because it provides against injury to the bow in case of collision. No doubt the dangers from this cause are greater, and of more frequent occurrence, than those arising from penetration of the bottom abaft the bulkhead; but supposing a leak to occur in the after portion of the vessel, and to overpower the pumps, her loss would be almost certain. Taking the case of a screw-steamer, built in accordance with the rules, a not much more satisfactory arrangement is met with. Such a vessel would have, in addition to the collision bulkhead, two others enclosing the engine-space, and another placed near the stern. The latter is intended to provide against chance of injuries to the screw-propeller and shafting, such as have caused the loss of some ships; and the engine-room bulkheads are designed to keep that space as free from water as possible in case of injury to the other compartments. These compartments are, however, frequently so large that if one of them be injured and filled, the ship cannot be kept afloat.

More satisfactory arrangements are made in many vessels than are rendered compulsory by the rules, and such arrangements are obviously most requisite in passenger or emigrant ships, wherein large numbers of people are embarked, as well as in war-ships, where the chances of penetration under water by projectiles, by torpedoes, or by ramming, are great. Taking, for instance, one of the iron-built armoured ships of our navy, we find that in addition to a water-tight double bottom, she has eight or nine transverse water-tight bulkheads by which the hold-space is divided into compartments of comparatively moderate size. A slight injury would, as was before explained, only admit water into a small compartment of the double bottom, and not result in its entry into the hold; and this is most important, because it would practically prevent any loss of efficiency in the ship. But in case of a more serious injury occurring, and leading to the penetration of the inner as well as the outer skins, the water-tight bulkheads would confine the water to the damaged compartment, and the ship would remain afloat. Merchant ship-builders, as a rule, do not care to incur the expense of fitting double bottoms, or to lose the hold-space, which would not be occupied by cargo if there were an inner skin, and consequently they have to depend for safety entirely on the bulkheads, the arrangement of which should, therefore, be most carefully considered.

Two principal objects should be kept in view in making such an arrangement. The first, that no single compartment should be left so large as to sink the ship if it were filled; and the second, that in case any compartment were filled the water from it should not find its way into other compartments. The first is so obviously necessary to efficient subdivision that nothing need be said respecting it; but as the second is sometimes overlooked, a few words in illustration may not be out of place. Ships have been built with a sufficient number of bulkheads, but with these bulkheads ended too low down; so that if a compartment had been filled, the consequent increase in the draught of water of the ship would have sunk the tops of the bulkheads below the level of the water outside, and have allowed the water from the damaged compartment to flow over into the adjacent compartments; thus leading to the loss of the ship. In order to prevent this, the simplest plan is to carry the bulkheads up to such a height as will keep them above the water outside, even when the ship has been sunk deeper than her normal draught by the filling of a compartment. And if this is not convenient, the same end can be obtained by fitting a water-tight deck of iron along over the tops of the bulkheads. It should be added that it is usual to end the bulkheads at the height of one of the decks, so that the last-named plan can be readily carried out when required.

Before proceeding to describe the ordinary methods of constructing transverse bulkheads, we desire to refer briefly to the longitudinal bulkheads sometimes fitted in iron ships. These are generally subordinate to the transverse bulkheads, and are primarily constructed as partitions in the hold to shut off the spaces required for stowing particular parts of the equipment, such as coals, chain cables, powder, shell, etc. etc.; or to enclose water-tight passages, such as the shaft-passages of steam-ships, and the passages between the engine and boiler spaces when they are separated. Such longitudinal partitions may, by care on the part of the ship-builder, be turned into valuable longitudinal strengthenings, and also be made to form further water-tight subdivisions in the hold. Probably the best examples of such care may be found in the armoured ships of the Royal Navy, wherein every longitudinal partition of any importance

is, by a small expenditure of material in the form of stiffeners, turned into a girder; and every space of any size enclosed for special purposes is a subordinate water-tight compartment.

There have, however, been cases in which longitudinal bulkheads have been used primarily as strengthenings of a ship's structure, and raised from their subordinate position into prominence. The *Great Eastern* furnishes the most striking example of this arrangement. For about half the length of this vessel two strong bulkheads are built, reaching from the inner bottom to the cellular upper deck. These bulkheads form the side boundaries of the engine and boiler spaces, and do not interfere with the stowage of the hold. Being strongly built, and well stiffened, in addition to receiving valuable support from the intermediate decks, these bulkheads form most efficient girders; and not only lend their own strength to the structure, but also help the sides in connecting the cellular upper deck, forming the top flange of the girder, with the cellular double bottom, forming the lower flange. In fact, we find in this arrangement another illustration of that admirable combination of strength with simplicity which distinguishes every principal feature in the structure of this remarkable vessel.

There have been many proposals to construct similar longitudinal bulkheads in ordinary iron vessels; but the plan which answers so well in the *Great Eastern* is open to grave objections when applied in smaller ships, where it would interfere with the internal arrangements, particularly in steam-ships. For instance, it would not be easy, in a ship of moderate breadth, to secure sufficient space, between such longitudinal bulkheads, for the engines and boilers; and the stowage of cargo in the hold would be made difficult. To remove these objections, it has been proposed in such cases to have one instead of two bulkheads, placing it along the middle line of the keel; but this plan also has serious disadvantages. In short, as sufficient strength can in ordinary vessels be secured by other means, and the ship-builder left with greater freedom in making the interior arrangements, the use of these longitudinal bulkheads has not found favour, nor is it likely to do so unless the size of ships should be much increased.

Reverting to the consideration of the transverse bulkheads usually fitted in iron ships, we will endeavour to describe briefly the principal methods of constructing them, and afterwards notice some of the plans for securing them to the skin-plating.

The plating of bulkheads is usually worked in horizontal strakes, with the butts shifted either on the brick fashion (illustrated by Fig. 35, Vol. III., page 305), or on the diagonal plan (Fig. 36). In a few instances, however, the plates have been worked with their greatest lengths vertical. The edge-joints, as well as the butts, are generally lapped and single-riveted, and are caulked on the plan followed for outside plating (see Fig. 40, page 351). At the places where the laps and butts cross each other the corners of the butted plates have to be hammered out to a thin edge, so that they may form but one thickness under the edge-lap of the plates above and beneath them. Some builders have preferred to work bulkhead plating flush at the edges and butts; but this is a more expensive plan, and is not commonly used, although it has some advantages as regards strength.

Considering the thin plating of a bulkhead as in place, and subjected to the strains resulting from the motion of a ship at sea, it will be obvious that it would be liable to buckle in various directions, and might cease to be water-tight. In order to prevent such buckling, and to render the bulkhead efficient in assisting to maintain the transverse form of the ship, the plating must be stiffened. This is usually done by means of angle-irons riveted to the plating, and either placed vertically or else arranged in two sets, one being horizontal and the other vertical. The latter arrangement is to be preferred, as it makes the two sets of stiffening bars cross at right angles, and by uniting them to the plating, enables it to resist most efficiently changes of transverse form. When vertical stiffeners only are used, the attachments of the bulkhead to the decks and platforms constitute its sole horizontal stiffening, and this may not always be sufficient. When bulkheads enclose comparatively long spaces, such as engine-rooms, or boiler-rooms, or cargo-holds, where the transverse strength of the decks is considerably reduced by the large hatchways required, it is especially necessary to secure rigidity in the bulkheads; and this is sometimes done by increasing the thickness of the plating; but it is preferable to have recourse to stronger stiffeners. As an example of one of these special arrangements, we may refer to the bulkheads fitted amidships in the armoured ships of the navy. The plating is worked flush, at both the edges and butts, the latter being secured by plate-straps single-riveted. The horizontal joints of the plating are covered by T-iron stiffeners, stretching from side to side; and on the opposite surface of the plating vertical iron stiffeners are fitted at intervals of about four feet. Proposals have been made to use T-iron stiffeners vertically as well as horizontally, but we are not aware that the plan has been applied in practice.

Respecting the construction of the various subordinate longitudinal and transverse bulkheads in the hold, it is only necessary to say that the plating is usually arranged similar to that of the main transverse bulkheads, and stiffened by vertical bars of angle or T-iron.

The modes of securing transverse water-tight bulkheads to the skin-plating of iron ships next claim attention. One of the earliest and simplest connections is that where a single angle-iron is riveted to the edge of the bulkhead, and to the skin-plating; and another, still largely used, differs only in having two connecting angle-irons instead of one. Both these plans, however, are considered by many ship-builders to lead to too great a localisation of the connection between the skin and the bulkhead, and it is urged that means ought always to be provided for distributing the strength of the bulkheads over parts of the skin not immediately in wake of them. These objects are realised better by the connection illustrated in Fig. 57, which is much used in merchant ships. A single angle-iron forms the main connection between the bulkhead and the skin; but additional strength of attachment is obtained by means of the horizontal "bracket-plates" (a, b), which also distribute the support of the bulkhead over two frame-spaces. These brackets are placed alternately on the fore and after sides of the bulkheads, and are near the middle of the strakes of the outside plating. They are very simply formed of plates and angle-irons, and are of considerable service in ordinary iron ships with transverse framing.

This sketch also enables us to refer to the practice of fitting broad liners to the outer strakes of the skin-plating in wake of transverse water-tight bulkheads. In the plan in Fig. 57, it will be seen that the liner stretches from the frame before the bulkhead to that abaft it, and this is the common practice in merchant ships; narrower liners are sometimes used, and may be made to answer the same purpose. These broad liners are fitted because the rivets in the angle-iron connecting the bulkhead with the skin have to be spaced very closely in order to secure water-tightness, their pitch not exceeding five or six diameters. Consequently, the plating is much more weakened in wake of the bulkheads than it is in wake of the transverse frames where the pitch of the rivets is greater; and in order to do away with this inequality of strength, the liners in wake of the bulkhead are broadened so that they may act as *butt-straps* to the specially weakened lines on the plates. The plan is simple, but thoroughly efficient, and its use prevents a recurrence of disasters similar to those which occurred with some of the earlier iron vessels, where, in their anxiety to make the bulkheads water-tight, the builders so weakened the skin-plating that the vessels broke down the sides when severely strained at sea.

In addition to these common methods of securing water-tight bulkheads reference might be made to other plans; but as most of these have rarely, if ever, been employed, we must pass them by unnoticed. Respecting the bulkhead connections in ships built on Mr. Scott Russell's longitudinal system, it will suffice to say that when there is no double bottom the edge of the bulkhead is secured to a belt of plating worked inside the longitudinal frames for the purpose; and when there is a double bottom, the edge of the bulkhead is directly connected with the inner skin. The latter mode of attachment is also employed in the armoured ships of the navy built with double bottoms. In both cases it will be remarked that the longitudinal frames act as most efficient distributors of the strength of the bulkheads over the intervening spaces, and render the use of bracket-plates, such as a, b, in Fig. 57, quite unnecessary. Mr. Russell relies, in fact, principally on the bulkheads for supplying transverse strength to his ships, and experience shows that under ordinary circumstances his expectations are realised, and the

forms of the ships are maintained. He uses also "partial bulkheads," as before described, in order to further strengthen the structure; but does not make his transverse framing so prominent as that of the iron-clads built on the bracket-plate system. The latter system, however, has been shown to possess considerable advantages as compared with Mr. Russell's system, especially as regards the efficient support of the bottom plating; and while in the iron-clads the bulkheads are made to supply the greater portion of the transverse strength, they are not left so unaided as in ships built on the longitudinal system.

When fitted in wood ships, transverse iron bulkheads are secured to the inside of the timbers and ceiling by single or double angle-irons riveted to the bulkheads, and bolted through the ship's side; but in composite ships similar bulkheads would simply be riveted to one of the frame angle-irons. In neither case, however, can the water-tightness of the bulkheads be ensured so thoroughly as is possible in an iron ship.

Longitudinal strengthenings, such as keelsons, hold-stringers, etc., ought not to be stopped short at bulkheads, but either continued through them, or otherwise arranged so as to form continuous ties. Supposing them to be run through the bulkheads, which is the simpler plan, it then becomes necessary to make them water-tight. This can be done readily by fitting forged angle-irons closely around the keelson or stringer, and against the bulkhead. After riveting these angle-irons it is possible to caulk all the joints, either on the lap or flush system.

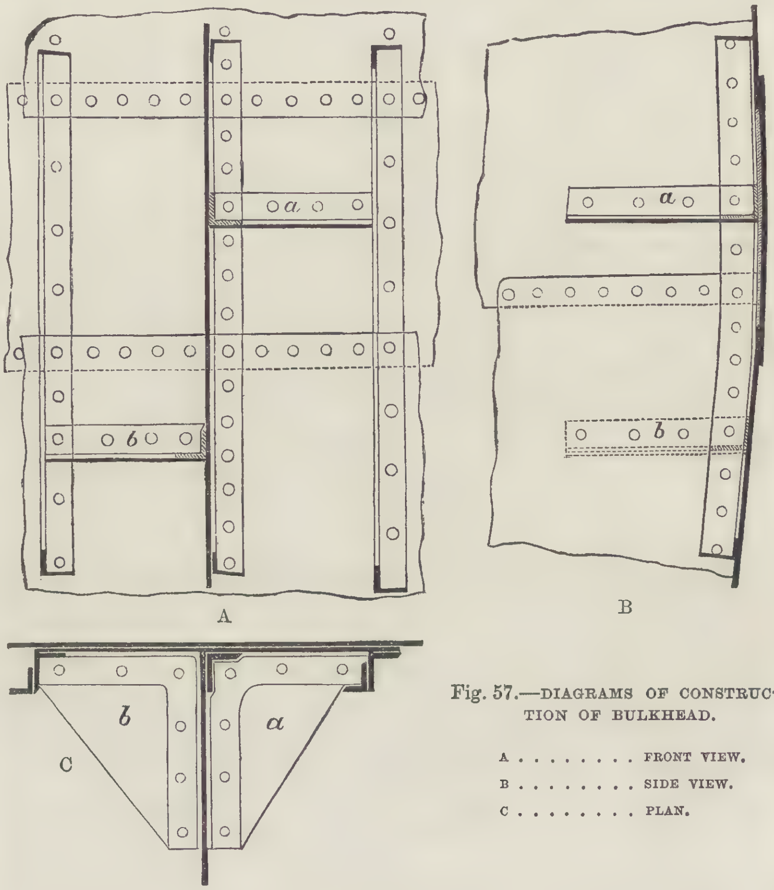

Fig. 57.—DIAGRAMS OF CONSTRUCTION OF BULKHEAD.

A . . . . FRONT VIEW.
B . . . . SIDE VIEW.
C . . . . PLAN.

Care must also be taken to test the water-tightness of the bulkheads after the work is completed, if efficiency is to be ensured. One mode of testing is to fill the compartments with water, in order to detect any leaks that may exist; but this involves much labour and expense when the compartments are large, and a more common plan is to pump water upon the bulkhead (by means of a fire-engine and hose) with considerable velocity. In testing the compartments of the double bottom in the iron-clad ships of the navy, it is usual not only to fill the compartments, but also to put the water in them into communication with a stand-pipe, also filled with water, and leading up to the height of the loadwater-line. By this arrangement it is ensured that there shall be no leak under the maximum pressure to which the boundaries of their respective compartments are subjected when the ship is afloat.

For the purpose of facilitating communication between the different parts of the hold, openings are frequently made in the water-tight bulkheads, and water-tight doors are required. These doors are usually formed of cast or wrought iron plates, and are made to slide either vertically or horizontally in grooved framework fixed on the bulkhead plating. The edges of the door are commonly wedge-shaped, and so also are those portions of the grooves in which the door rests when it is shut; so that a close fit of the bearing surfaces of the door and framework is ensured, and water-tightness is secured. In order to give the necessary sliding motion to these doors, vertical shafts or rods are generally fitted, being made to extend up to one of the decks, where they can be turned by means of a spanner or other device worked by hand. If the doors slide horizontally, their motion is generally caused by pinions on the shafts gearing with racks fixed on the door. If the doors move vertically, there are usually screw-threads cut on the lower ends of the shafts, and these work in nuts secured to the doors. All these arrangements, however, are open to endless modifications; but what is really important in all of them is to give the crew of a ship the power of closing the water-tight doors from the deck above, even after the rush of water into a damaged compartment has begun; and to enable them to ascertain, without actually going down into the compartment, whether the doors are closed or not. Similar precautions are necessary in fitting "sluice-valves" to water-tight bulkheads. These valves are usually opened or shut by means of rods leading up to one of the decks, and are intended to allow the bilge-water to flow from one compartment into another when the pumps are at work.

In the iron-clads of our navy the bulkheads extend up to the main deck, and it is very important that ready means of passage fore and aft should be provided on the lower deck. For this purpose light hinged doors, formed of plate-iron, stiffened on the edges, have been fitted to the bulkheads. When closed, these doors fit closely into a rabbeted frame fixed to the bulkhead plating, and are pressed tightly (by means of wedged catches) against a "beading" of india-rubber fitted in the rabbet for the purpose of making the joint water-tight. This plan is simpler and much less costly than that followed for the water-tight doors in the hold, and it answers perfectly in the places where it is used, because, being at such a small depth below water, there is every probability, in case of an in-rush of water, of sufficient time being obtained to close these doors and secure them by hand before the water rose high in the compartment. In the hold, as we have already remarked, the case would probably be different, and the doors must therefore be so fitted as to be closed by some simple train of mechanism worked from above; besides which they must be made capable of sustaining a considerable pressure of water without leaking. It need hardly be added that the water-tightness of all such doors, wherever placed, should be carefully tested; and this is usually done when the bulkheads themselves are tried.

MINING AND QUARRYING.—XXVIII.

BY GEORGE GLADSTONE, F.C.S.

LEAD (*continued*).

RED LEAD OR MINIUM—CHLORIDE OF LEAD—WHITE LEAD OR CERUSE—DUTCH PROCESS—THENARD'S PROCESS—LEAD-POISONING.

In addition to the oxides of lead described in the last article, there is another of very extensive use in the arts, and the manufacture of which forms a special trade. It is commonly known as red lead or minium. The very finest metal is used for the purpose, especially if the red lead is intended for sale to the flint-glass makers, as the presence of other metals will prevent the glass from being so clear and lustrous as it would otherwise be.

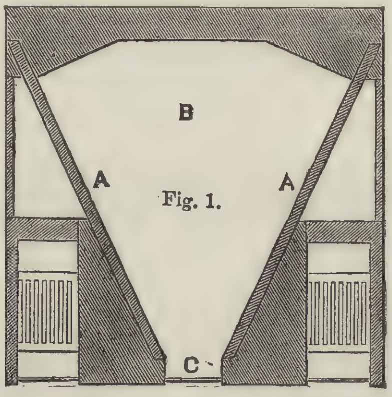

Fig. 1.

The first step in the manufacture is to convert the lead into the familiar protoxide, which is more usually called "dross" by the workmen than litharge or massicot. The drossing-oven is on the reverberatory principle, but it is generally made with a fire on both sides of the hearth, as shown in the diagram (Fig. 1), and without a chimney, the waste gases escaping from the top of the working-door. The heat required does not exceed dull redness, and some ovens are even made without fire-bars, there being sufficient draught from the charging-doors to keep lumps of free burning coal alight. The flames from the fires pass over the fire-bridges, A A, and circulate over the hearth B, which is about flat, and is so shaped that the whole area of it can be rabbled from the working-door, C. Just inside the latter a dam is made to prevent the lead when it melts from running out, and then the charge, consisting usually of something over a ton of lead, is introduced. If the minium is not intended for the glass manufacturers, about 1 cwt. of slag lead is added, the antimony which the latter contains having the effect of greatly expediting the oxidation of the whole mass. As soon as the lead has melted, rabbling is commenced and kept up vigorously, so as to expose the lead as much as possible to the action of the air; and as the oxide forms it is pushed up in a heap at the back of the oven. This process is continued for several hours, and then the dam is removed, and whatever lead remains unconverted is run out and put aside to be added to the next charge. The "dross" is then raked out from the back of the furnace and left to cool. It is next taken to the grinding-mill, where it is ground under millstones to an impalpable powder, or rather made into a fine paste as it is ground with water. From the mill it flows into the puddler, where it is agitated in water, and the finer powder is afterwards separated from the coarser in settling tanks. From these it is taken (after being dried) to the colouring-oven, which, in some works, is the same as the drossing-oven above described, and it remains there exposed to a moderate heat, varying from 550° to 600° Fahrenheit for about forty-eight hours. During this time it is frequently rabbled, and by the period named it will have acquired the full red tint characteristic of red lead. It is finally re-ground and sifted, when it is ready to be packed in casks for the market. The product should show an actual gain in weight of 7 or 8 per cent., due to the absorption of oxygen.

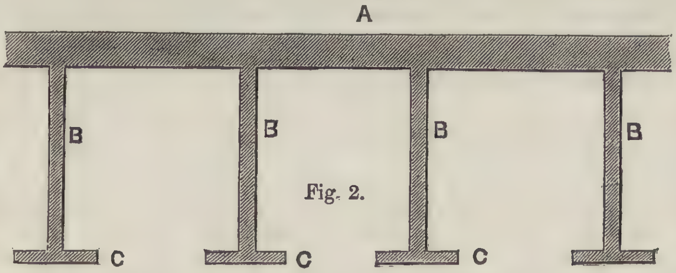

Fig. 2.

Minium is used for very similar purposes to litharge; but as a pigment it furnishes a much superior colour: ground in oil it forms a paint which possesses in a high degree the faculty of drying rapidly in the air. In the glass and pottery manufacture one of its chief values consists in the readiness with which it combines with silica and alumina, forming with them a vitreous compound or glaze. The acetate of lead has been already described in the series on "Chemistry applied to the Arts," No. XV.

The chloride of lead is a salt which has only recently been manufactured on a large scale. It is used by painters, and has the advantage over the carbonate of lead, which is generally used, in not being blackened by the sulphide of hydrogen, which so often causes the discolouration of white paint, especially in large towns.

The carbonate, generally called white lead, flake white, or ceruse, is, however, the almost universal foundation for all lead paints, and is therefore an article of very extensive manufacture both in this country and on the Continent. Some of the German makers used to be very celebrated for the superior quality they produced; but now our own manufacturers leave nothing to be desired in this respect.

The usual plan, commonly called the Dutch, consists in exposing lead for a prolonged period to the gentle action of the vapour of acetic acid and carbonic acid gas. The effect of this is to produce an acetate of lead, which is converted in its turn into a carbonate. The mode by which this chemical change is brought about is somewhat peculiar. The factory consists of a large building having the sides, one of which is represented by A (Fig. 2), divided by brickwork partitions, B, B, into a series of recesses or chambers, which are partially open towards the centre of the premises. The dimensions of these chambers are about fifteen feet each way for the area, and the height from the floor to the roof about twenty feet. As a matter of convenience, the floor of the recesses is generally sunk some feet below the rest of the building. These are the receptacles for the stacks, which are built up in the following manner:—The sides are lined all round with spent tan for about sixteen inches, and a layer to about a similar depth is spread over the bottom; upon this a quantity of earthenware pots, containing a little acetic acid or vinegar, are set in regular rows as close as they can stand, and on the top of the pots slabs of lead are laid; a floor is then made of planks, and upon this another layer of tan, pots, and lead; and so on until the stack is complete. A stack will thus contain a series of eight to ten beds, one above another.

In Fig. 3, B will represent one of the partitions, and D the floor of the recess; E E, etc., the tan; F F, the pots; and G, the lead slabs. Of these, however, a few more details must be given. In some manufactories stable dung is used instead of tan; the functions performed by either the one or the other are the same—that of creating a considerable warmth which assists the evaporation of the acetic acid, and of evolving the carbonic acid which is necessary to convert the acetate into the carbonate. The use of dung is, however, objectionable, because it also evolves some sulphuretted hydrogen, which is liable to destroy the perfect whiteness of the product. The pots, it will be observed, are of two sizes and shapes: the larger ones taper very much to the bottom, while the smaller do so very slightly, if at all. In some works they are just the shape of common jam pots. The larger pots are about eight inches high, and made with a ledge running round the interior; the part below the ledge is filled with weak acetic acid, and a spiral coil of lead is placed in the upper part, and rests upon the ledge, so as not to touch the acid. In each of the smaller pots a little acid only is poured; except here and there, where one or two of them are nearly filled with common vinegar. Upon the top of the smaller pots are laid the slabs of lead. The metal for this purpose is melted in an iron pot at a low temperature, from

which it is ladled out and poured upon an iron slab grooved with longitudinal and transverse gutters an inch apart, into which the lead runs: it thus forms a perforated slab resembling a grating or trellis-work. For the coils put into the larger pots, the lead is cast into long narrow strips, which are afterwards rolled up into coils. The slabs of lead are made in the form selected in order to allow of a free circulation of air around them, and also to admit of their expansion, as during the process they swell up to about three times the size of the original metal; additional space for this purpose is allowed between them and the planking, H H, which rests upon the rim of the larger pots and supports the next bed. The uppermost bed of all is covered with the tan or dung to the depth of about two feet; and as the beds are built up above the floor of the workshop, the open side, C (Fig. 2), is filled in with planking. In this condition the stack is left for six to ten weeks. If stable litter is used, the former time will be long enough, as it heats more than tan—sometimes, indeed, too much, as the acid then evaporates too rapidly, and the produce is not so satisfactory. Each stack will contain ten or twelve tons of metal. By building up each stack in succession the work of the establishment can be kept going uninterruptedly, as the first one will be ready to be dismantled as soon as the last is completed.

In taking down the stack the top covering is removed, and then the slabs and coils of lead are carefully lifted off and put into boxes to be carried away to the unscaling apparatus. The lead, partly corroded, is thickly covered with the carbonate, a flaky white substance, consisting of particles so finely divided that unless handled with care some of it is apt to get into the air, when it would exercise a very injurious effect upon the health of the workmen. They even wear leather gloves in some factories, so as to avoid touching it with their hands. The removal of the carbonate from the metallic core is done by passing the pieces under grooved rollers, and agitating them under water, and the metal is returned to the melting-house. The carbonate, while still wet, is passed under a series of millstones, from which it issues in a pasty state, and is conducted into the settling vats. When the water has separated and become perfectly clear it is drawn off, and the carbonate is put into flat dishes and ranged on shelves in the drying-room. This is heated by a close iron stove in the centre, which is supplied with fuel from the outside, and here the carbonate of lead is thoroughly dried in the course of a few days. It then only remains to knead it up with oil, and pack it in casks.

It is seldom, however, that the white lead made for painters' use is pure. There are mixtures well recognised in the trade, which bear specific names. Venetian white consists of equal parts of carbonate of lead and sulphate of baryta; Hamburg white, one-third of the former and two-thirds of the latter; and Dutch white, one-fourth and three-fourths respectively.

There are other modes of preparing white lead, most of which are modifications of the principle first carried out successfully at Clichy in France, whence the article produced by this process is often called "Clichy white." Thenard's system, which is the basis of all these, consists in preparing a solution of basic acetate of lead, and then passing carbonic acid gas through it, producing the carbonate of lead and a neutral acetate. The apparatus used at Clichy consisted of a large vat furnished with a rotatory stirrer for dissolving litharge in acetic acid, and when the acetate of lead had attained a proper strength it was drawn off into another vat to settle. The clear liquor was then drawn off again from this into the converting vessel, a long shallow tank, over which depended a series of twenty horizontal pipes connected with a main, and from each of these forty smaller pipes extended perpendicularly to a depth of thirteen inches below the surface of the acetate of lead. The main was connected with a pump, which was supplied with carbonic acid from the kiln in which it was made. When at work, therefore, 800 jets of carbonic acid gas were injected into the lead solution, and the carbonate thus formed was thrown down to the bottom of the converter as a fine white powder. The neutral acetate left in the converter was then drawn off into the first vat to dissolve up more litharge, and the carbonate of lead transferred to a vat to be washed, after which it is ready for drying and packing.

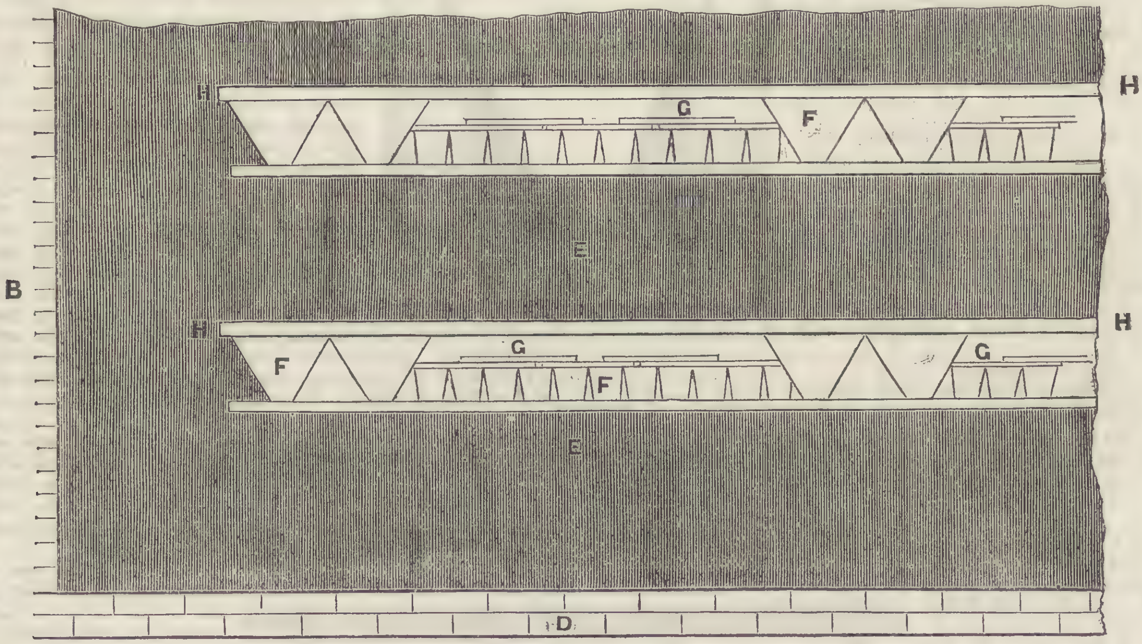

Fig. 3.

In the course of this and the preceding papers on lead the deleterious character of its salts has been referred to several times, and painters' or lead colic is unfortunately but too well known. Indeed, with the exception of the sulphides, sulphates, and phosphates, which are very insoluble, the whole series of lead salts may be considered more or less poisonous. Except in certain manufactures, and especially where the carbonate is dealt with in the dry state, such precautions are generally taken as to prevent active lead-poisoning; but the cases are not rare where the slow action is continued through long periods of time, producing at length distressing symptoms. This often arises from the water used for drinking or cooking being conveyed through leaden pipes, and held in cisterns lined with lead. Spring water may generally be brought in contact with lead without any bad effect, as the mineral matters contained in it

will most probably form an insoluble compound with the oxide of lead; but rain-water, or any surface-water which contains nitrogen, or any organic matter which will evolve nitrogen, exercises a most pernicious effect, as this element acts immediately on the lead. Fortunately, the presence of even the smallest trace of lead in water may easily be detected. It may be done by putting in the water two or three drops of acetic acid, and then adding about one-twentieth of its bulk of an aqueous solution of sulphuretted hydrogen. On looking down through a tube containing a column of water so prepared, 10 inches in length, upon a white surface, and comparing it with a similar tube containing the water without addition, a brown discolouration, more or less intense, will be seen in the one containing the sulphuretted hydrogen, if lead be present. By taking a standard solution of lead of known strength, the quantity of lead in water may be ascertained very correctly by comparing the depth of colour. The deleterious action of nitrogenous substances in water held in leaden cisterns may be prevented by the insertion of some coils of iron wire, for which the nitric acid has great affinity; but the safest plan of all is to substitute pipes and tanks of some other material.

MUSEUMS: THEIR CONSTRUCTION, ARRANGEMENT, AND MANAGEMENT.

BY SAMUEL HIGHLEY, F.G.S.

XIII.—LECTURES AND DEMONSTRATIONS.

Lectures and Demonstrations.—It would at first sight appear obvious that lectures should be given on the collections of the several departments of a national museum, to ensure the public deriving the full advantage of its scientific wealth; but there is great diversity of opinion on the subject, and many eminent men hold a different opinion. Thus Professor Huxley considered that a museum may be regarded as a consulting library of objects, and that lectures on the objects are not more necessary than on the books in a public library.* Others considered that teaching should be accessory only, and chiefly for demonstrating the character of any newly-acquired remarkable specimens. At the Jardin des Plantes, the lectures have not been appreciated as fully as might have been expected, and their ablest lecturers have found that after their first and second lecture, their auditors have diminished to six or seven constant attendants, *but then those six or seven afterwards became men of repute!* In our own country we have met with similar experience. Thus, at Oxford, Professor John Phillips gives an annual free course on some subject of geological interest: a few years since it came to my knowledge that he had prepared a most interesting series of demonstrations on fossil echinodermata, but after the first lecture he had only *one* regular attendant—a well-known palæontologist; but Professor Phillips went manfully through the entire course to the satisfaction of himself and his solitary auditor, as he dropped university formalities, and both went into the subject *con amore, tête-à-tête.*

Cuvier and Geoffroy complained of the injury often inflicted on choice specimens by their removal to the lecture-theatre; and further, that the utilisation of the Museum specimens for lecture purposes, entailed loss of the curator's time in having to derange and re-arrange the cases. Such objections may be obviated by giving demonstrations in the galleries in place of lectures in a theatre, which would not entail the removal of the specimens; but Dr. J. E. Gray is of opinion, from what he has seen at the British Museum and College of Surgeons, that from the crowding of the auditors on the demonstrator, and the manner in which the specimens are obstructed from the view of a great number of persons, such a system does not give promise of a successful method of imparting instruction, but that catalogues are the most convenient guides for the general public. From the evidence we have before us in the "Report of Committee on Public Institutions" as to the manner in which the public lectures at the School of Mines have been appreciated by the working and middle† classes, and the wide-spread increasing taste for scientific knowledge, especially in the department of Natural History, the success of the Quekett Club and similar microscopic and natural history associations in London and the provinces to wit, together with the commencement in earnest of science-teaching in our public schools, affords justification for believing Professor Owen's inclusion of a lecture-theatre in his plan for a National Museum of Natural History, an act of sound policy, with the view of extending sound information among the people on "the extent and variety of the Creative power." He considers that, during the year, at least nine courses on as many branches of Natural History should be given in connection with the museum; popular evening lectures in the theatre on the Elementary, British, and Geographical* collections; and advanced lectures three times a week on the special departments by their keepers to a limited number of persons who have attained a certain standard of scientific knowledge, but without establishing any restriction as to class. Twelve to twenty lectures to be given by each keeper. Probably it would be better if the advanced lectures were given in the galleries to which each subject pertained in the form of demonstrations, as then the specimens, with exceptional instances, need not be removed from their cases, thus meeting the objections raised on the score of possible damage to the systematic collection, which would include the rarer objects of the Museum. Such demonstrations should be given from four to five o'clock, after the closing of the galleries to the general public. The objectionable crowding on the demonstrator could readily be provided against in a limited class, by portable barriers that could be removed from one spot to another, together with a diagram screen and blackboard. Such demonstrations by those whose duty it would be to be "posted up" in the latest knowledge pertaining to their special department, would be most advantageous and acceptable to working naturalists, and would generally tend to the extension of sound research among British students and naturalists.

The subject of lectures on our national collections raised the question as to whether it should become one of the necessary duties of a keeper or assistant keeper of a department to give a course of lectures. It was argued that the qualities for a good curator and a good lecturer are not always combined in the same person. The qualities calculated to attract an audience are by no means the qualities necessary to constitute a good curator. Patient research, constant attention to detail, care in the compilation of catalogues, taste and skill in arrangement, capacity for administration, are essential for the one; an easy delivery, and power of popular illustration, are chiefly required in the other. A good lecturer might not be a sound naturalist, but his acquired popularity might be brought to bear, and pressure put upon the appointing powers, to secure his election (though not the best man among the candidates) as curator of a department. Such an objection would naturally be raised by those curators who had never taken any position as lecturers; but we have among us men who have attained eminence in both capacities; and on the Continent, especially at the German universities, the professors are, as a rule, the curators of the collections in the University Museums, that illustrate their own subjects. Were the duties of curator and lecturer made distinct, it would deprive some of our most distinguished teachers of the control of the specimens that illustrated their lectures, and moreover might lead to want of harmony between the doctrines as enunciated in the lecture-room, and the arrangement of the collections in the Museum. Moreover, curators would naturally object to be made responsible for the safe keeping of specimens placed at the disposal of lecturers not on the Museum staff. If the demonstrating system were determined on for the systematic series, it would remove many of the difficulties that have been raised to the union of the two offices, as elegance of language, easy flow of words, and facile illustration, are not so essential for the terse and practical descriptions of the demonstrator. The keepers of a National Museum are really the only persons to whom naturalists, etc., could look for *information in detail* on all the great divisions of Nature, or in other departments of knowledge. Thus, at the present moment, the most extensive Government course on *general*

* Report on British Museum Committee.

† Evening lectures at a fee of five shillings a course have been provided for the middle classes, which have always been well attended.

* As the geographical groups would be unsuited for removal to the lecture-theatre, counterpart photographs could be shown on a large scale by means of the demonstrating lantern, and so the public could be familiarised with the detailed history of the groups themselves.

Natural History comprises forty lectures on Mineralogy, *none on Botany*, eighty on Zoology (embracing Comparative Anatomy, supplemented by demonstrations on Palæontology), and thirty-six on Physical and Stratagraphical Geology, which only admits of typical illustration.

TECHNICAL DRAWING.—LXXIX.

DRAWING FOR CABINET-MAKERS.

FIG. 613.—In the present study the bookcase is turned so that the front is at right angles to the plane of the picture, the narrow side (or depth) being parallel with it.

Draw the rectangle A D F′ F, representing the narrow side, and having drawn the horizontal line at the same height as in the previous lesson, set off the point of sight at eight feet (in this case) on the left of the perpendicular A, and the point of distance at eleven feet on the right of the point of sight, both of these points being, as in the last lesson, omitted from the illustration.

From A and D draw lines to the point of sight. From A set off A B, equal to the width of the front of the case, as shown in the last study, and from B draw a line to the point of distance, cutting the line drawn from A to the point of sight in B′.

At B′ erect a perpendicular, meeting the line drawn from D to the point of sight in C, thus completing the representation of the object rendered as a block.

From A set off A *a*, and from B set off B *b*, the real thickness of the wood, and from *a* and *b* draw lines to the point of distance, cutting A B′ in *a′* and *b′*; at these points draw perpendiculars.

Now on the perpendicular A set off A *i*, equal to A *a*, and set off the same length from D, viz., D *d*. From *i* and *d* draw lines to the point of sight, and thus the apparent thickness of the wood forming the carcase will be represented.

We have now to show the interior of the case; and in order to do this, it becomes necessary to render the narrow side A D F′ F transparent. Therefore draw (in dotted lines) the ends of the top and bottom, viz., *i k* and *d l*, and also the perpendicular *k l*, showing the thickness of the back of the case.

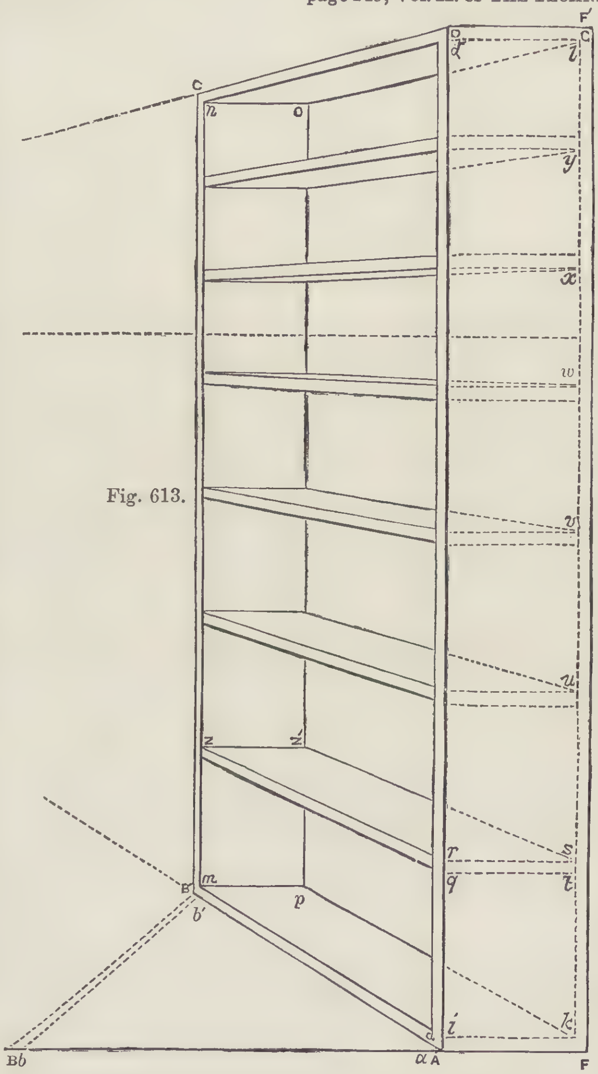

Fig. 613.

Now from *k* and *l* draw lines to the point of sight, and from *m* and *n* draw horizontals, cutting these in *p o*. Then the perpendicular *p o* will complete this portion of the subject.

We now proceed with the shelves. Mark the thickness of these at their proper places on A D, and draw lines from these points to the point of sight, observing, of course, that these lines are not to be drawn across the thickness of the framing, but only between the lines forming the inner edges of the walls.

Now from the points marking the positions of the shelves, as *q*, *r*, draw horizontal lines representing the ends of the shelves as they would appear if brought quite up to the plane A D F′ F. These ends, however, must not be carried as far as the line F F′, but only up to *k l*, which represents the inner line of the boards forming the back of the case, the shelves thus terminating as shown at *s t*.

From *s*, *t*, *u*, *v*, *w*, *x*, *y*, draw lines to the point of sight, cutting the perpendicular *o p*; then horizontal lines drawn from the distant ends of the shelves, as at *z*, meeting the others on the line *p o*, as at *z′*, will complete the view of the case of shelves when placed at right angles to the plane of the picture, and eight feet to the right of the spectator.

The subject of the next lesson (Fig. 614) is another view of the sideboard forming Fig. 51 in lessons on "Practical Perspective," page 149, Vol. II. of THE TECHNICAL EDUCATOR. In the present case the sideboard is turned, so that the end is parallel with the plane of the picture, and thus the horizontal lines of the front, being at right angles to the end, converge to the point of sight.

In commencing this figure, draw the side of the plinth which is on the picture line, *a b c d*, and from *a*, *c*, and *d* draw lines to the point of sight—viz., *a e*, *c f*, and *d g*.

Now on the picture line set off from *a* the length *a h*, representing the real width of the front of the plinth (equal to *a b*, the base of the plinth being square). From *h* set off *h i*, the width of the recess between the pedestals of the sideboard; and from *i* set off *i j* (*j* not shown in the figure), representing the width of the other plinth. These measurements may be taken from the front view (Fig. 51, Vol. II., p. 149). From *h*, *i*, *j* draw lines to the point of distance, cutting *a e* in *h′*, *i′*, and *j′*; and at these points erect the perpendiculars *h′ k*, *i′ l*, and *j′ m*. From *k*, *l*, and *m* draw horizontals to meet *d g*, and complete the distant plinth by the horizontal drawn from *i′*.

Draw diagonals in the upper surfaces of the plinths.

From *d* on *d c* set off *d* B*, equal to the distance at which the pedestal cupboards stand back from the front of the plinths, and from B draw a line to the point of distance. From the point at which the line drawn from B cuts *d g* draw a horizontal line, cutting the diagonal drawn from *c* in *n*. From *n* draw a line to the point of sight, which will cut the diagonal drawn from *k* in *o*, and being produced will give similar points in the distant plinth. At these points erect perpendiculars—of indefinite height, for the present.

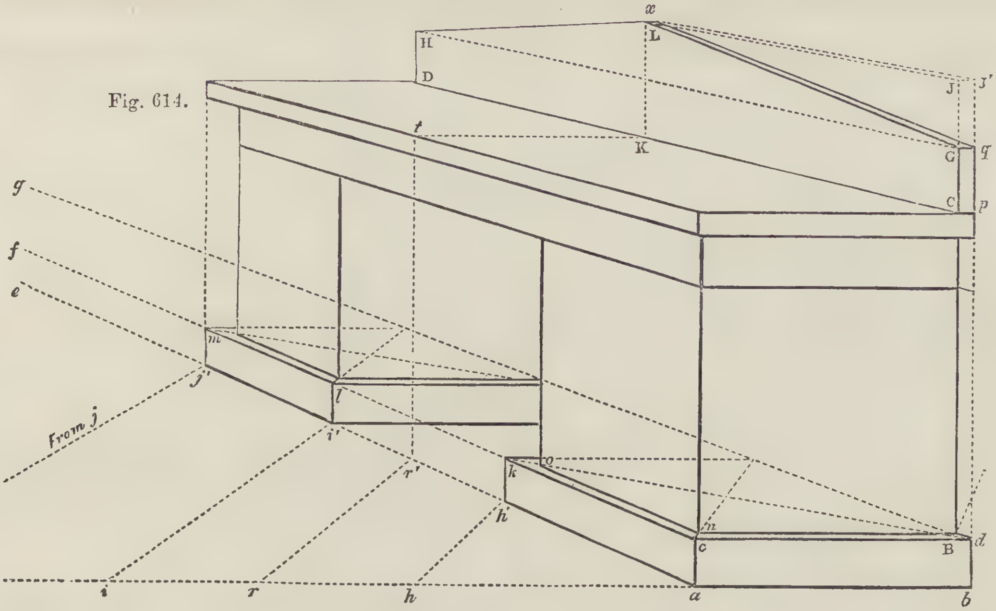
Now draw the slab of the sideboard at the height corresponding with that in the previous figure, its angles being formed by perpendiculars raised from those of the plinths, with which, as already stated, they correspond.

Draw the rectangle C G *q p*, representing the end of the back, and produce it to J, J′ indicating the section of the back at its highest point.

From C and G draw lines to the point of sight, and at D draw the perpendicular D H.

* The points indicated by small capital letters, correspond with those similarly marked in Fig. 51 (Vol. II., page 149).

Fig. 614.



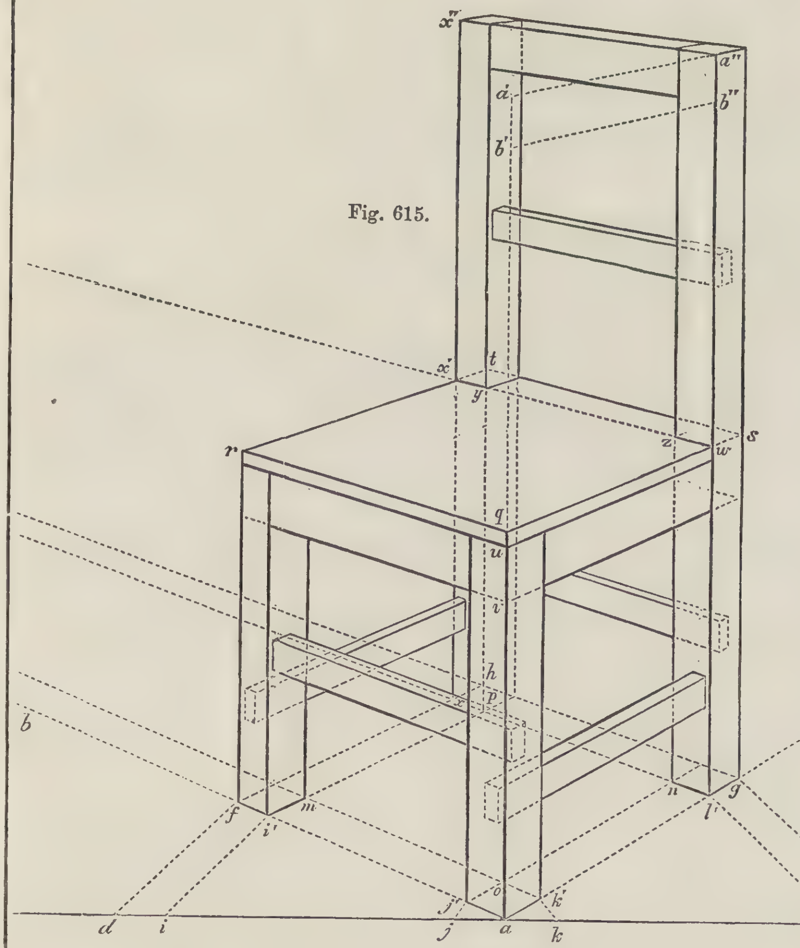


Fig. 615.

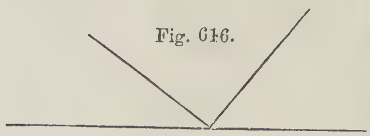

Fig. 616.

Half-way between h and i on the picture line mark r, and from r draw a line to the point of distance, cutting a-e in r'. At r' erect a perpendicular, cutting the upper edge of the front of the sideboard in t. At t draw a horizontal, cutting C D in K, and at K erect a perpendicular.

From J draw a line to the point of sight, cutting the perpendicular K in L, which will be the perspective position of the highest point of the back. Draw G L and H L. From J′ draw a line to the point of sight, cutting a horizontal drawn from L in x, which will give the point of the back behind L. Join this point x to q, which will complete the thickness of the slanting edge of the back. It is to be hoped that any further detail will be understood from the illustration.

On reviewing the subjects of the lessons in "Practical Perspective" hitherto given, it will be perceived that all have been rectangular, and so placed that their front and back have been parallel to the picture plane, whilst the other two sides have been at right angles to it. The horizontal lines of the surfaces parallel to the picture have thus been rendered horizontally, whilst the horizontal lines bounding the sides have been drawn to the point of sight.

The whole system of angular perspective, together with that of the perspective of polygons, is, however, fully given in the course already referred to in THE TECHNICAL EDUCATOR, and to these lessons the student is referred.

Fig. 615.—The subject here represented is a common kitchen chair, simplified in form as much as possible, in order that the leading principles of drawing may be rendered clear. Thus the general plan of the chair is here given as square, whilst in a real chair it would be rather narrower towards the back, and the top rail is rendered as thick as the uprights. The student will soon, however, be able to vary these proportions when he thoroughly comprehends the method of working as shown in this example.

The spectator is supposed to be standing a little on the left of the object, the level of his eye being thus above that of the chair, which is placed at the angles shown in Fig. 616.

The scale, height of spectator, distance, and all measurements, are left to the student to fix. He will thus be prevented from copying the diagram, and will be encouraged to work out his ideas, guided only by the general form shown in the example, and by the principles elucidated in the description.

The picture line, horizontal line, and the line of direction having therefore been drawn, and the vanishing points and measuring points having been found according to the angle at which the plan may be placed, commence the object at a (or any other point which may be determined upon as the position of the angle on the picture line), and from a draw a line to the vanishing points, viz., $a\ b$ and $a\ c$.

Set off on the picture line on each side of a, the length $a\ d$ and $a\ e$, representing the entire width of the plan, which, as already stated, is in this case supposed to be square.

From d and e draw lines to the *measuring* points, cutting $a\ b$ and $a\ c$ in f and g.

From f and g draw lines to the *vanishing* points, cutting each other in h.

The figure $a\ g\ h\ f$ will then be the perspective view of the square bounding the plan.

Now within the distances $a\ d$ and $a\ e$, set off the spaces $a\ j$, $a\ k$, $d\ i$, and $e\ l$, representing the real thickness of the legs and back of the chair.

From the points i, j, k, l draw lines to the measuring points, cutting $a\ b$ and $a\ c$ in i', j', k', and l'.

From i', j', k', l' draw lines to the vanishing points. These intersecting will give the points m and n, the inner angle of each of two legs, and the same of the other two legs, which are not really visible in the present view, but which are marked o and p. This then will complete the plan, and we can now proceed with the chair.

At a erect a perpendicular of indefinite height, and mark on it the length $a\ q$, representing the real height of the seat of the chair.

From f and g draw perpendiculars.

From q draw a line to each vanishing point, cutting the perpendiculars drawn from f and g in r and s.

From r and s draw lines to the vanishing points, cutting each other in t. The figure $q\ r\ t\ s$ is then the perspective view of the seat of the chair.

Beneath the point q set off on the perpendicular $q\ u$ the thickness of the board forming the top of the seat, and from u draw lines to the vanishing points.

At i', j', and k' erect perpendiculars as far as the lines drawn from u to the vanishing points, and at l' also draw a perpendicular, which, together with the perpendicular g, is to be drawn of indefinite height.

Beneath the point u set off in the perpendicular $u\ v$ the real breadth of the framing of the chair connecting the legs and supporting the seat.

From v draw lines to the two vanishing points, observing that the framing only extends from leg to leg, but the real breadth must be set off on a, which is the line of measurement for heights, being the only perpendicular which is in the immediate foreground, and on which, therefore, the true measurements are not altered. The lines from v should therefore be dotted across the leg, and only strengthened where the framing would really be seen.

It will now be seen that the line $q\ s$ is intersected by the perpendicular drawn from l' in the point w; from w draw a line to the vanishing point, cutting $r\ t$ in x'. At x draw a perpendicular.

Now it will be seen that the perpendicular at w, which gives the one edge of the back of the chair, is a continuation of the perpendicular rising from l'; and since the perpendicular x' stands in the same relation to the side $r\ t$ as w does to $q\ s$, it should be a continuation of a perpendicular raised upon the point x, which is to $f\ h$ as l' is to $a\ g$.

Perpendiculars raised from n and p will cut $w\ x'$ in y and z, and will give the inner edges of the back of the chair.

Now on the perpendicular a set off $a\ a'$, the real height of the back, and draw a line to the vanishing point, cutting the perpendicular l' in a''.

From a'' draw a line to the vanishing point, cutting the perpendicular x in x'', and of course the distant line of the top is to be drawn in a similar manner.

From a' set off $a'\ b'$ equal to the thickness of the top of the back, and draw a line to the vanishing point, cutting $l'\ a''$ in b'', and from b'' draw a line to the other vanishing point.

The foot-rails and that in the back are drawn in a similar manner. It will be seen that the tenons are not considered here, the general thickness of each rail being only required.

CAPITAL AND LABOUR.—V.

By J. E. THOROLD ROGERS, M.A., Tooke Professor of Economic Science.

ASSOCIATIONS OF CAPITAL.

IT has been stated that the assistance which capital gives labour—in order that labour may find its market, may be continuously occupied, and may be enabled to obtain an average remuneration, because it is not constrained to sell at a forced price, but may hold that which it produces till the market is better—varies with the nature of the operation on which industry is engaged. In some cases the assistance is so considerable that the labour would never be exercised if capital, in the hands of employers, were not forthcoming for the requisite purpose. In others it is so slight that the labourer can constantly dispense with the services of the employer, and deal at once with the public, or at any rate merely employ the occasional services of a middle-man or agent. The most obvious illustration of the latter phase is that in which a small occupier tills his own land by the labour of himself and his family. Here the only purpose for which he occasionally needs the office of the capitalist is to sell him such parts of his stock as he may wish to dispose of, and for the sale of which he finds it convenient to employ an agent in preference to going into the market himself.

But, on the other hand, there are certain kinds of industry in which it is impossible for the labourer to carry on his calling without the intervention of the capitalist employer. Such cases are (1) those in which great outlay is necessary previous to the exercise of labour in the service or production on which the labour is ultimately exercised; (2) those in which the economy of production, on a large scale, is so great that no individual labour would be able to compete against combined labour directed by the capitalist employer; (3) those in which it is

particularly needful that the turn of the market should be watched, in order to prevent great changes in the price of the article, and consequently great uncertainty in the amount of employment and the rate of wages.

One of the best illustrations which can be given of the first among these operations is that of the construction and maintenance of public roads, especially those with which we are familiar, in which the minimum of friction is overcome, and therefore the greatest speed can be obtained in travel, at the least possible expense. Now the construction of railroads is an operation of so much magnitude, that it is only in this country and the United States that railroads have been made by private and joint-stock enterprise. In every other country they have been constructed either wholly or partially by the State. In the wealthiest Continental countries it has been generally the custom for the State to supply the land, and for the company to construct the line. But in most cases the State has taken in hand the construction of railways, and of course has generally borrowed the necessary capital from foreigners. The magnitude of the operation has been so immense, and the resources at the command of the inhabitants have been so scanty, or the tendency to conjoined enterprise has been so feeble, that private agency would have been insufficient for the purpose. It may be added, too, that except in countries which possess great social and political freedom, and in which the use of this freedom has long been a familiar fact, it is very difficult to develop that spirit of mutual confidence which is requisite to the success of such undertakings. Even in countries where such confidence prevails, advantage has been taken of opportunity in order to abuse public trust for private ends. Both in our own country and in the United States a special kind of dishonesty and fraud has been practised in connection with railway enterprise, to the infinite disaster of those who have been interested in these undertakings.

Speaking roughly, English railways pay a dividend, at the present time, of about 4 per cent. on the capital invested in shares. The working expenses, on an average, and in the same general way, amount to nearly as much as the dividends. Hence the original outlay of the undertaking amounts to about ten times the quantity of the annual receipts—a proportion which is far in excess of that which rules in any other business. This fact will show why it would not be possible for private enterprise, apart from association, to have undertaken these roads, even if the magnitude of the undertaking had not been far beyond the resources of any private fortune. An individual trader expects that his capital will be replaced with its profit within a comparatively limited time, and would seldom, if ever, acquiesce in employing it in such an occupation as would return it only after an interval of ten years or more.

It may be worth while here to notice the fact that when persons invest their savings in undertakings to which they do not give their personal attendance, supervision, or labour, the advantage which they derive from such investments continually tends to the ordinary rate of interest. In other words, persons cannot get the profits of trade unless they take the risks and undertake the labour which trade implies. At the present time railways pay a somewhat higher per-centage than the ordinary rate of interest. But up to the beginning of the year 1871 they did not on an average pay a higher rate of profit to the shareholders than that which is obtained in public securities, and this profit was certainly liable to far more risk. I mention this partly because it is an important fact, the reason of which can be easily detected, and partly because it forms an illustration of the theory which I have already laid down, that the profit of such persons as are engaged in a business to which they give their personal labour is only wages under another name.

The office of the capitalist employer is also necessary when the calling on which labour is engaged is of such a kind that great economy may be effected by the division of employments, and therefore the individual labourer cannot compete against combined labour, directed by a capitalist employer. These economies are in the main twofold. In large undertakings of the class referred to it is constantly found possible to introduce labour-saving machines on the largest scale. Take, for example, the business of a man who is engaged in supplying builders' fittings—as doors and window-frames. Ordinarily, such work is the business of a joiner; but a wood-cutting machine will turn out a door or a window-frame—which would cost a day's work to the joiner—in a very few minutes, and will execute the work with almost mathematical precision. The planing machine of the machinist, employed to bring the surface of iron castings to the smoothness requisite for a well-constructed machine, is so prodigious an economy that no hand-labour could possibly compete against the machine. The second economy is that of classifying labour. In a great glass manufactory there are several classes of labour, the wages of which vary from pounds a week to shillings. If the industry were carried on by an individual, even if the individual were able to supply the costly plant and furnaces needed for the manufactory, it would be necessary for him to do the cheapest or meanest, as well as the dearest and mostly highly skilled labour himself. The waste of such a system is manifest.

In these callings, as the economy of a great as opposed to a small undertaking is manifest, there is a growing tendency to associate a large number of capitalist employers together, or, in other words, to turn private business into joint-stock enterprise. For the reason which I have given above this tendency will, I think, be temporary only, for it will very rarely be the case that joint-stock enterprise, unless it involves exceptional risk, will pay a much higher income than the ordinary rate of interest to those who engage in it.

Lastly, there are callings in which the turn of the market has to be carefully watched. Perhaps no better illustration of this kind of business can be given than the calling of a publisher of such books as are issued in order to meet the taste or caprice of the public. I cannot conceive the development of the joint-stock system among authors, or even among those who act as intermediaries between the author and the public. But it is quite certain, whatever may be the difficulties which lie in the way of any association of capitalists in this business, that there is no article in demand the value of which is so precarious as that of a book is, unless, of course, the reputation of an author is so great that he can afford to write nonsense.

PRACTICAL APPLICATION OF THE FINE ARTS.—XIV.

By P. H. Delamotte, Professor of Drawing, King's College, London.

THE ART OF BOOKBINDING.

CLASSIFICATION OF BINDINGS—MATERIALS FOR BINDINGS.

Leathers.—Bindings are classed according to the outside cover. This may consist of various leathers, cloth or paper. A book may be whole-bound or half-bound. The whole-binding naturally means that the whole of the cover of the book is covered with the same leather. The half-binding is understood to mean that the back and corners of the book are covered with some leather, whilst the side simply has cloth, paper, marbled or otherwise, pasted on the boards : we have seen a book half-bound in Russia, with vellum sides.

Paper is only used for the commonest and cheapest of books, such as cheap novels. These paper covers are usually printed and ornamented with pictures or titles, and they are most frequently pasted first on the boards and back, and the whole, boards, back, and paper cover, attached to the book after it has been stitched and cut. This, of course, is the cheapest and least useful kind of cover that a book can have. Formerly, books were commonly sold in what were called boards, that is, the cover was just covered with a thin kind of dark-brown paper. Since the introduction of cloth for the first covering of books, "boards" have disappeared. The Italians had a rough paper binding also, which was called *alla rustica*, but it wore out very rapidly, and soon became useless.

These various coverings were used as cloth is now used for publishers' bindings, that is, for the covers in which books are prepared for their first sale. Of course, in this case a large number are done at a time all alike, or all having much of their ornamentation in common. The process by which this is done is somewhat different from that of binding proper, in which each book receives individual attention, and is treated, as lovers of books would have it treated, like a pet child. We shall in a future paper describe the wholesale binding in cloth, so that we defer that process for the present, and treat only of the individual binding.

Morocco.—Of all the leathers used for bookbinding, morocco

is undoubtedly the best. It is a carefully-prepared goat-skin, tanned, tawed, dyed, and grained. It is stronger, more pliable, and lasts longer than any other skin. Of this leather there are various kinds, and it is prepared in various places; English, French, and Spanish moroccos all excel in their own way, either in grain or in colour. The French have the pre-eminence in the species of *levant** skins, which are called *gros grain*, and are marked with a handsome full grain of considerable size; shagreen is a smaller marked skin which they also make, but which is made in England as well; whilst the English excel in the straight grain, which appears something like the wrinkles on the back of a man's hand. This grain is made by passing a ball of boxwood, mode in which this done is unknown, and skins coloured in this manner are only procured from Spain. The effect of this style of pattern is pleasing, but it is seldom employed now, except for Spanish books. The thick, good, and strong skins of morocco frequently cost as much as £1 apiece, and they will after all serve only for the binding of one large book, as merely the best parts of the skin can be employed, though, of course, the scraps cut off can be applied to less important purposes. A thinner and cheaper kind of morocco is used for the pieces put on either as labels at the back, or for inlaying the sides of a book, but this is not suited for covering the whole of the back and boards. In working morocco after it is put on the book, it is found that

SPECIMEN OF BINDING, NO. 2.—FRENCH.

SPECIMEN OF BINDING, NO. 3.—FRENCH.

with grooves in it, over the skin many times. As regards colours, the French produce the best light colours, especially reds and blues; their reds are far better than any manufactured in this country; whilst for darker tints, especially olives, maroons, greens, and browns, the English skins are esteemed preferable. The Spanish skins are coloured in a peculiar manner which somewhat resembles marbling, one colour being laid on another, and sometimes a third added in a similar manner. The

* It is remarkable that both the terms *morocco* and *levant*, which now designate a peculiar kind of leather, manufactured in London or France, should have so far changed their original signification; but these are only two out of numbers of words, which from geographical names have become designations of manufactures, and the materials being cheaper elsewhere, the productions themselves are imported by the countries whence they take their names.

it should be prepared for the finisher by damping it. The reds are greatly improved by the addition of a little acid, whilst other colours work best when moistened with diluted vinegar, but if the colours are very light a little pure water is the best medium.

Russia.—Russia leather is prepared from various kinds of skin, and has a very pleasing odour; the appearance of the lines in it is agreeable, but it has the unfortunate peculiarity of requiring to be kept under cover; for if it is exposed to the atmosphere of London, combined with the results of the combustion of gas, it is observed that Russia very soon becomes discoloured; it dries up, and at last crumbles to powder. An instance of this kind occurred not very long ago at the Athenæum Club-house, where it was found that a large number of valuable bindings had completely gone. This is a great drawback to a species of binding that otherwise would be most agreeable.

Calf.—Calf is really what it is called, the skin of the calf, pre-

pared by the process called by tanners "tawing." The natural colour of the skin is a very light drab, but it turns darker in time, and becomes a light-brown. The uncoloured skin is pleasant enough to the eye, and is used in the peculiar style of binding called "Law," since it is commonly used for law-books. allowed to fall upon the cover, or upon a portion of the cover, the rest being protected by a covering. The copperas mixing with the tanning left in the skin produces a kind of ink, and so darkens the spot where it falls. Considerable variety may be caused by protecting various portions of the cover in patterns,

SPECIMEN OF BINDING, NO. 1.—GROLIER.

The skin, however, can be dyed any colour, and it has then an agreeable appearance, but as the mordants used in the dyeing are apt to attack the leather, and cause it to go more than it otherwise would have done, the best style of decoration for calf is the colouring of the natural skin by the binder. There are various ways in which this is done. It may be sprinkled wholly or in part. This is effected with a hog's-hair brush, dipped in a strongish solution of copperas (protosulphate of iron) in water; the brush is scratched with the nail, and the small drops are and graduations of the colouring can also be effected. Another mode of colouring is called *French catspaw*. This is produced by dipping a piece of wool, or similar substance, in the colouring matter, and dropping it on the cover, thus forming a more or less regular series of patches of dark colour. A third style of ornamentation is called "tree calf." The process by which this curious style of ornamentation is brought about is almost as remarkable as the marbling the edges of the leaves. The cover, which, of course, must not be too thick, is bent upwards away

from the book into the form of a channel. This is held slanting, at an angle, say, of thirty degrees: it is then sprinkled with pure water pretty freely, until the various spots begin to run into one another, and to find their way down to the central channel, and thus to fall off the cover. At this moment some very finely powdered copperas is dropped on the wet spots, and allowed to run down with the stream. Where the water is sufficient it carries off the iron, but where the leather is only damped it allows the colour to sink down into the skin. Some little experience and neatness of hand are required to give the desired effect, and to produce on the two covers a corresponding effect, which, however, should not be too closely alike.

Vellum.—Vellum, though scarcely a leather, is a preparation from skin which is not unfrequently used for binding, particularly classical works. The appearance at first especially is very pleasing, but it is apt to grow yellow, besides, from its colour, liable to show every stain or speck of dirt. Gold ornament stands out remarkably well upon the plain white, but for every-day use such a binding is almost painful. This covering lasts very well, and is very strong. There are various kinds—the English, which is the best and strongest; the artist's, which is the whitest; the Roman; and the commonest, which is called parchment. Vellum requires very different working from morocco and the other leathers; it will not admit of inlaying, for all leathers stuck on it peel off as soon almost as they are dry. If it is desired to have colour on vellum, it is necessary to paint it, and this can be done with plain water-colours. Vellum has to be moistened with pure water with only a very little gum in it; it requires a very clean workman, and the tools have to be much cooler than for the leather.

Sheep, etc.—The other skins used are sheep, roans, and skivers. *Sheep* may be had white, and of all colours. It is much thinner than those we have mentioned before, and much cheaper. It is greatly used for school-books and works of a like character, but naturally it will not last like morocco or even calf. Sheep-skins are sometimes prepared to imitate morocco, and so successfully, that they would take in the unwary. The grain and colour are perfect, and a man may often think that he has bought a cheap morocco binding, whereas he has been put off with a sheep-skin, which costs one-fourth of the price. Calf is imitated in the same way, and to the same effect. *Roans* are prepared much like the straight-grained morocco, but they have more varnish on them, and are much thinner. These are much used for binding and for half-binding periodicals, especially those of large size. Roans can be had in all colours. *Skivers* are split skins, and are very thin; they used to be much employed for Bibles, prayer-books, and school-books, and then frequently embossed—that is, stamped with a pattern before they are fastened to the covers. *American cloth* has been used, but it is very weak, and is now only employed in the cheapest forms of Bibles and prayer-books.

Velvet and Silk.—Occasionally velvet has been used for covers of books, but, naturally, this is rare, since it will not stand much wear. Silk also has been employed, but this is much more frequently found in the inner sides of the boards, which are sometimes as much ornamented as the outer. We have seen both vellum and morocco used for the interior, but the latter has the disadvantage, that it always contains some fat, which, after a time, works out and stains the opposite page. Several specimens of velvet and other rare bindings may be seen in the open cases in the King's Library, in the British Museum. Amongst others, there are some, of which the covers are embroidered; we may instance a Harmony of the Four Gospels, bound by Mary Collet, for Charles I., in 1635; twelve paintings upon vellum, by Julio Clovio, of the victories of Charles V., are bound in purple velvet, and kept in a blue morocco case; this belongs to the Grenville Library, the whole of which is preserved in excellent bindings. Of embroidered velvet we may instance Queen Elizabeth's copy of Archbishop Parker's "De Antiquitate Britannicæ Ecclesiæ."

We have now detailed all the various coverings ordinarily put upon books, except the commoner sorts used by publishers, viz., cloth and paper; but as the binding with these is a distinct art, requiring in many points a description to itself, we shall reserve this for a future paper, in which we shall also give some account of the stove and tools used by the "finisher" in ornamenting the back and sides of a book with lines and figures of various kinds in gold.

PATENTS AND PATENT LAW.—II.

By A Barrister.

A PATENT: WHAT IT IS, AND WHAT ITS SUBJECT MAY BE.

We now proceed to discuss what a patent is, and what may be the subject of a patent. According to ordinary acceptation, the word "patent" is taken to signify either the letters patent by which the monopoly is granted, or the subject-matter of the grant; but the best definition speaks of it as merely an abbreviation of "letters patent," that is, open letters (*patentes*). A patent, in this sense, therefore, is the grant by the State of the exclusive privilege of making, using, and vending, and authorising others to make use and vend an invention. The monopoly so granted may be unrestricted in geographical extent, and thus be co-extensive with the authority of the State or Government granting it; the period for which it is granted is now limited to fourteen years, subject to prolongation, by order of the Privy Council; and it may be either absolute, or subject to certain qualifications and conditions. The Patent Law Amendment Act provides that all letters patent for inventions shall be made subject to the condition that the same shall be void, and that the powers and privileges thereby granted shall cease at the expiration of three and seven years respectively from the date thereof, unless there be paid before the expiration of the three and seven years respectively certain stamp duties mentioned in the Act. These stamp duties are in substitution for the fees and duties which were previously payable on taking out a patent. Further, it may be limited to the patentee personally, or extend to him, his personal representatives and assigns.

The early statute of James I. used simply the word "manufacture" as the subject-matter of patents—manufactures which others at the time of making such letters patent did not use—and that word was generally understood to denote either a thing made which is useful for its own sake, and vendible as such, as a medicine, a stove, a telescope; or to mean an engine or instrument, or some part thereof, to be employed either in the making of some previously known article, or in some other useful purpose, as a stocking-frame, or steam-engine for raising waters from mines. The French law extends to every invention or discovery, and in any kind of industry; and yet the practical construction of the English, French, and American law, in regard to the kinds of inventions that are patentable, is substantially the same. It will be observed that utility is essential to the life of a patent, and the reason is obvious. The monopoly which is granted to the inventor, is not so much for his own benefit as for the benefit of the public, who encourage him by rewards to make known his secret discovery. There can, as a general rule, be little difficulty in deciding whether an invention is useful or not, but doubt may exist, as appears by a recent case before the Privy Council, where a prolongation of the monopoly was refused, the presumption as to utility being against the invention. And inventors may take it, that before incurring expense, they should be tolerably certain of the utility of their discovery, and that they shall be able to carry it into practical operation. The case in the Privy Council to which we refer had reference to improvements in electric conductors, and in the means of insulating electric conductors; but two large companies refused to adopt it, and for the whole of fourteen years it lay unused, the consequence of which was that the patent altogether lapsed.

The statute of James I., to which we have already referred, while it abolished monopolies generally, made an exception of existing letters patent and grants of privilege for the term of "one-and-twenty years or under, of the sole working or making of any manner of *new* manufacture within this realm to the *first and true inventor* or *inventors*, so they be not contrary to the law or mischievous to the State, or generally inconvenient;" and also an exception of future grants of letters patent for the term of fourteen years or under. Here we see that another essential of a patent is novelty. The subject-matter of a patent must be useful and new. But novelty must not be taken to mean new in all details, inasmuch as a patentable invention may be a new combination of materials previously in use for the same purpose, or a new method of applying such materials. This fact, however, must be made clearly to appear, as the mere application of a well-known process of casting to an article previously well known has been held not to be the subject of a patent. A very good illustration of legitimate operations in

this respect is afforded by the discovery of electricity, which has presented a variety of applications to practical purposes, and opened an immense field for the granting of patents.

An important consideration arises as to the period to which the term "novelty" is to apply, and it would seem sufficient if it appear that the thing patented had not been known or used before the *invention* by the patentee, as distinguished from the time of his application for a patent. The actual issue as to novelty is not so easily decided as might be supposed, and may present a difficult problem of mixed law and fact for solution by the judges. So closely may different descriptions apparently refer to the same subject, and yet in truth refer to inventions having different operations, that it is only by careful inquiry that novelty can be established or disproved. In one case, it was laid down, that even if there be identity of language in the specifications, yet if there be terms of art in one and also terms of art in the other, it is impossible to predicate of the two with certainty that they describe the same identical external object, unless it is ascertained that the terms of art used in the one have precisely the same signification, and denote the same external objects, at the date of the one specification as they do at the date of the other. Therefore, evidence must be forthcoming on these points. Further, an invention may be novel which is new in its practical operation, though the theory upon which it rests has been described in a prior specification. Thus, it has been distinctly held, that a notion that tin and lead might, by means of pressure, be so combined as to form a new and useful material, without giving information how to attain that object, is no ground for invalidating a subsequent patent giving that information. In delivering judgment in that particular case, the then Lord Chancellor was very precise, and well states the established rule, "that a barren general description probably containing some suggested information, or involving some speculative theory, cannot be considered as anticipating, and therefore as voiding for want of novelty, a subsequent specification or invention, which involves a practical truth, which is productive of beneficial results, unless you ascertain that the antecedent publication involves the same amount of practical and useful information."

An interesting illustration of what has been said on the subject of novelty has reference to chemical processes, and it has been distinctly held that where a patent has been taken out for improvements in the mode of producing a chemical substance, it is no bar to the legal validity of the patent that the subject of the patent is a product already known to scientific men, provided the patentee is the first person who has produced the substance in a sufficient quantity to make it a marketable article. And it was further decided in the same case that it is no bar to the validity of a patent for improvements in the mode of producing a particular substance that similar processes have been employed to produce analogous substances, where the subject-matter of the production is a chemical product, and the process is a chemical process. And further, that where the subject-matter of an alleged invention is an improvement of a chemical process for the production of a substance, a patent specifying a particular limit of temperature to be used in the process may be valid. But there cannot be a patent for a philosophical principle only.

We should occupy too much space were we to elaborate this particular branch of the subject by referring to the numerous decided cases, and we will now proceed to another necessary condition to obtaining a patent. The applicant must be, in the words of the statute, the "first and true inventor." The inventor within the meaning of the patent laws has been described to be the man who discovers the mode of producing the substance or material in such a form, and to such an extent, as to make it useful to the public at large. He is not the inventor who merely suggests, unless, indeed, he suggest the actual process or machine. If the specific process is pointed out, the person to whom it is pointed out cannot afterwards be the inventor. In an action by a patentee for an infringement of a patent for a bleaching liquor, a chemist deposed that previously to the granting of the patent he had had frequent conversations with the patentee on the means of improving bleaching liquor, and that in one of them he had suggested to the patentee that he would probably obtain his end by keeping the lime-water constantly agitated; it appeared that this was indispensable in the process, and consequently Lord Ellenborough refused to recognise the patentee as the first and true inventor. Again, where a workman made an improvement, and his master patented it, the latter was held not entitled to sue for an infringement. But it is a question to be decided, upon consideration of the particular circumstances, whether the inventor by the nature of his employment, or by his contract, either assigns his invention to his employer, or at least divests himself of his property in it. If a person is employed for the express purpose of devising improvements, anything which he invents in the course of his employment is, it appears, the property of his employer.

A difficulty may suggest itself where there are simultaneous inventions by different persons. The case has arisen and been decided, and the decision is that he who first publishes his discovery by obtaining a patent for it will be the true and first inventor within the meaning of the statute, although he may not actually have been the first to make the discovery. Then again, is a person who obtains information abroad, and takes out a patent in this country, the first and true inventor? He is, and it is no objection that the patent is taken out in trust merely for the foreign inventor. But by a recent enactment it has been expressly provided that where letters patent are granted in the United Kingdom for any invention first invented in a foreign country, or by the subject of any foreign State, and a like privilege for the exclusive use or exercise of such invention in any foreign country is there obtained before the grant of such letters patent in the United Kingdom, all rights and privileges under such letters patent shall (notwithstanding any term in such letters patent limited) cease and be void immediately upon the expiration or other determination of the term of the like privilege obtained in such foreign country; or where more than one such like privilege is obtained abroad, immediately upon the expiration or determination of the term of such privileges which shall first expire or determine. And no letters patent granted for any invention, for which any patent or like privilege shall have been obtained in any foreign country, shall be of any validity if granted after the expiration of the term for which the foreign patent or privilege was in force (15 & 16 Vict., c. 83, s. 25).

Before proceeding, as we shall do in our next paper, to show how letters patent are obtained, we may mention generally that they are not by any means granted as a matter of right. The granting of letters patent is a prerogative of the Crown, and although a patent may now be always obtained for a new invention, yet the grant is still a matter of favour, and not of right, and all grants are clogged with certain conditions, to which we shall have to refer in some little detail. And when granted for the period allowed by the statute, the question of prolongation is one purely of discretion for the Privy Council. In a very recent case, the specification of a patent described it as an improvement in treating, deodorising, and disinfecting sewage and other offensive matter, and also for deodorising and disinfecting in general, and as being composed of two ordinary well-known chemical acids in combination, such acids being in common use for disinfecting purposes by the public before and after the letters patent. The invention was held not to be of such merit as to justify an extension, to the detriment of the public in the use of known sanitary agents. The Privy Council, however, has a fixed limit of fourteen years, beyond which it cannot grant a prolongation of a patent, and it may determine to grant an extension to any shorter period which the nature of the invention may suggest.

MAP AND PLAN DRAWING.—IV.

By C. C. King.

DELINEATION OF SMALLER AREAS.

In the previous papers we have very briefly examined the method on which surveys of large areas are conducted. Even when we have unlimited time and means at our disposal, so important is this branch of map-making, that great care and the most accurate instruments are required to efficiently carry out the operations. But in the delineation of smaller extents of country the chances of error are reduced; and in the construction of these plans less perfect means are employed, though, at the same time, care is equally necessary, and sufficiently correct

results can then be obtained for all practical purposes. It is not, however, advanced that the theodolite and level are unnecessary in this work, for whenever time or opportunity is afforded they may be used with advantage; but we shall endeavour to point out how, with very portable instruments, the survey of a small area is conducted, and how, with care, such may be both valuable and approximately true. We have, in defining the difference between a map and plan, described the latter as the representation of a less extensive tract than that to which the former applies; and plans, again, may be of two kinds—one of a comparatively large area, when it approaches the magnitude and nature of a small map, and when the method of construction will assimilate very nearly to that of a map, or the sketch of a very small space of ground, as, for example, a village or estate of a few acres, where triangulation would be perhaps difficult, through the want of prominent features, and in many cases unnecessary, as the distances could be accurately measured without going through the labour of ascertaining them by trigonometrical calculation. The second case, in fact, merely comprises the work done in the concluding portion of the first or larger plan—that is, in one instance the principal points or "bench marks" are determined by triangulation, and in the other by absolute measurement, if it appears to save time and trouble during the operations of "traversing," which will be explained later.

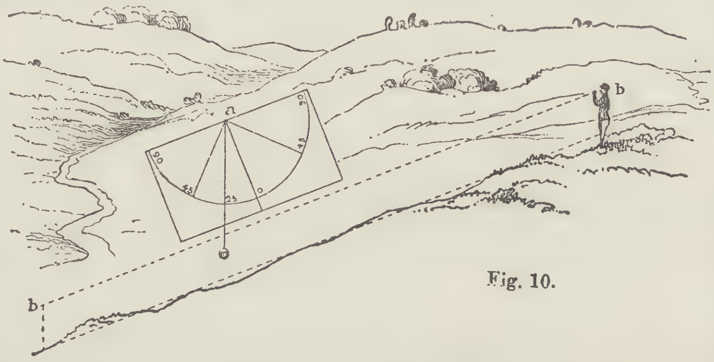

Fig. 10.

The instruments to be employed will necessarily have to perform the same kind of work as in more extended surveys—that is to say, a base has to be measured, triangles have to be constructed, heights have to be ascertained, and means of carrying out these requirements have to be provided. Those used in sketches of this sort are the prismatic compass, for reading angular bearings; the chain, or even a well-stretched line, and carefully-prepared line, if no chain be procurable, for measuring distances; the clinometer or orometer, for levelling and finding altitudes; and, lastly, a plotting-book and sketching-case.

In map making, that is, in extensive delineations, the "plotting" or note-book is alone used, as it would be impossible to transfer the work done in the field actually to paper, because of the size of the measurement; but in the present instance the plan, with any ordinary scale, is sufficiently small to come within the limits of a moderately-sized sketching-case; and though the note-book may be used to check the observations, it is advisable to transfer the work done, especially if time be an object, immediately to the field sketch, from which, if it be afterwards required, a copy can eventually be made. The plotting-book is a simple rectangular note-book, some few pages of which may be ruled to put down the series of angles in a triangulation, in the manner exhibited in the accompanying model;

STATION.	1st Observn.	2nd Observn.	REMARKS.
A	42° 15′	42° 15′ 30″	Bearing of windmill.
B	108 20	108 20 0	Bearing of St. Andrew's Church.

and the remainder ruled on each page, with two parallel lines which run along the centre of each page and divide it into three equal, narrow spaces, the use for which will be explained further on. The sketching-case may be of any form, but the most convenient kind is that which is provided with a slight metal frame for keeping the paper down in its place, on a pasteboard block, and which is further provided with a cover of some waterproof material, capable of being secured by elastic bands, over the sketch, and also with a leather strap at the back of the case, for the purpose of slinging it over the shoulder or round the neck, thus leaving the hands free for using instruments. The paper for prismatic compass work is ruled either in pencil or with pale-blue ink, with a series of parallel lines at irregular intervals. This is designed for the use of the prismatic compass and protractor, as will be seen in describing the method of depicting the work done. The protractor is a rectangular piece of ivory or wood, the edge of which is divided into 180°, and which has also a series of equidistant lines ruled on it, parallel to its shorter side. For convenience' sake a few scales, such as would be most generally useful in work of this nature, are marked on one side of the protractor.

The chain has been described in former papers, but any piece of well-stretched and carefully-dried cord can be used, and sufficient accuracy arrived at by repeated measurement. In many cases the pace of the surveyor is used for determining distances; and in military work this is invariably employed to a large extent; but care must be taken that the pacing is regular, and that allowance is made for irregularities of ground in ascending or descending hills or valleys.

The clinometer is a portable instrument for measuring inclinations of slopes, or even for tracing a horizontal contour line through the district; but as it is carried in the hand, and is therefore susceptible of any sudden irregular movement of the operator, and is also liable to be disturbed by wind, great care is required in its use, and the results arrived at by it are necessarily only approximately true. There are many varieties of clinometers, the simplest and most general form being a rectangular piece of wood or cardboard, three sides of which are graduated in degrees, on an arc of which the middle point of the upper long side is the centre; and to this point is attached a silken cord and plummet which, hanging vertically, aligns itself with one of the angular divisions and indicates the slope at which the upper edge is inclined. There are two methods of using it, either by making the upper edge parallel to the slope of a hill, seen as it were in profile (Fig. 10, *a*), when the flat side of the instrument is towards the observer; or by looking along the upper edge, either up or down hill (Fig. 10, *b*), and when its prolongation passes through a point the same height above the slope observed as the eye of the operator, reading the angle indicated by the plumb-line. It is evident, in the latter case, that practice is essential to ensure the upper edge being in a plane parallel to the slope of the hill. For contouring it is simply necessary to keep the plummet vertical through the zero point, which is immediately opposite to that whence the cord is suspended, and then notice where the prolongation of the top side of the rectangle, which is therefore horizontal, meets the sides of the hills or valleys (Fig. 11, *c*). These points should be marked temporarily by a stone or picket.

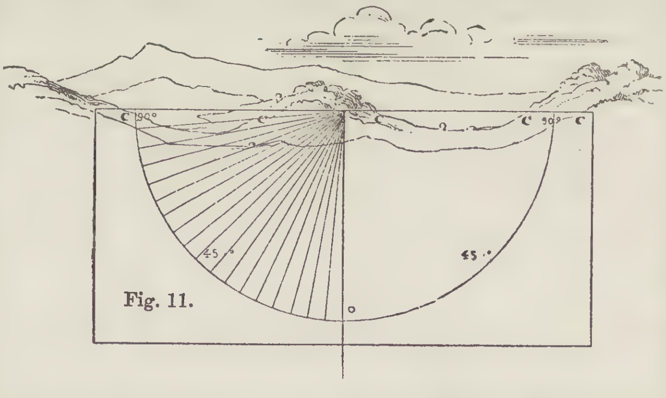

Fig. 11.

From the clinometer we will now pass on to describe the prismatic compass, which is, as its name denotes, an instrument for measuring angles with reference to the magnetic meridian. There is a great difference, therefore, between a series of angles taken by it and by the theodolite. With the latter the round of angles is taken with reference to the line on which the zero point of the instrument is directed. Thus, if the theodolite be placed at one extremity of a base, and the telescope be directed on the other extremity, the angles will be measured from that base, and will be those contained between it and the lines joining the several points observed with the station on which the instrument is placed. But in using the compass, the angles taken at any period have reference to the magnetic meridian, and are those contained between it and the lines uniting the observed points with the surveyor's position. It consists of a brass box, in which is a common compass-card, capable of free movement on a needle-point. The edge of the card is graduated in degrees from zero to 360°; and as these are read through a prismatic sight attached to one side of the box, the numbers are printed the reverse way. This prism is contained in a small brass case, working on a hinge, so as to admit of its being brought vertically over the edge of the compass-card, and has, when so placed, a notched "sight" on its upper surface. Immediately opposite this sight, and on the line, therefore, passing from it through the centre on which the card turns, is a small brass frame, which moves on a hinge, so as to bring it into a vertical position, and which contains a fine wire, carefully aligned by the maker, at right angles to the plane of the compass when held horizontally. Thus, if the eye be kept close to the notch of the prism, and the line of sight be directed, by means of the wire, on any given point, its bearing with reference to the meridian can be read on the card, through the prism, without removing the eye from the sight. The compass having free movement, is always seeking to point to the magnetic north, and to check its oscillation and cause it to remain stationary in that direction, a small spring, which can be pressed against the edge of the card by the finger of the operator, is attached to the front side of the box. For field-work a good pencil is an absolute necessity, and for all ordinary purposes, an F or a HHH, if good, are the best kinds, with perhaps a darker one, in case any of the hill shading is done in the field; and as a practical fact it is advisable that these, together with the india-rubber and penknife, should be attached by cords to the sketching-case, as the surveyor frequently works independently, and in moving over rough ground may suddenly find himself unable to continue his work, owing to the loss of his materials for noting down or transferring to paper the observations and results he has obtained.

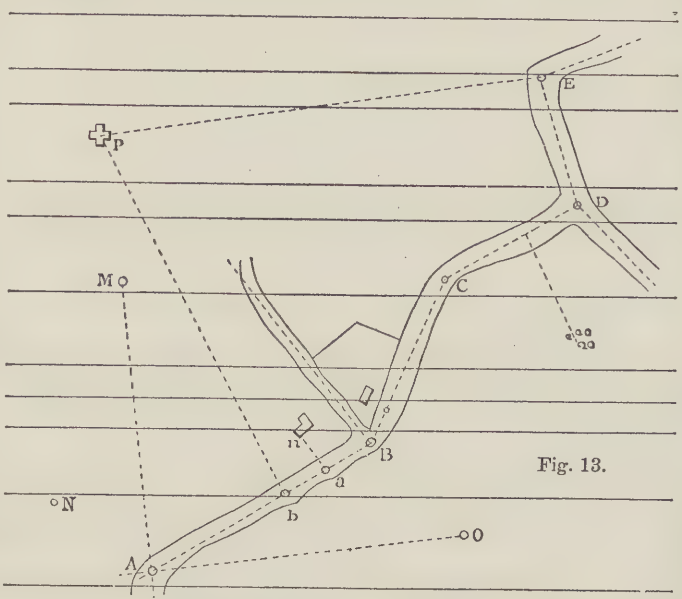

Fig. 13.

Let us assume, then, that the surveyor having walked over the area he intends to survey, so as to acquire a general knowledge of its features and of its extent, has finally selected a piece of tolerably level ground, conveniently situated in a somewhat central position, on which to measure his base. Choosing two points as far apart as possible (for on the length of the base much of the accuracy of his sketch will depend), and from which a tolerably numerous series of points can be seen, he marks them by pickets firmly planted in the ground, and proceeds to measure or pace the distance between them as often as may appear necessary. Should there be much difference of level between them, the angle of depression will be measured by the clinometer, and the base transferred to a horizontal plane by a simple trigonometrical calculation.* It is not absolutely requisite that the base should be so situated as to admit of all the prominent points in the neighbourhood being visible from its extremities. It may happen that the most convenient site for it is in a valley; but from it one or two points that afford a more extended view should be apparent, probably on nearly adjacent hill-tops, and these, when carefully determined by observation, will constitute, in some respects, a secondary base.

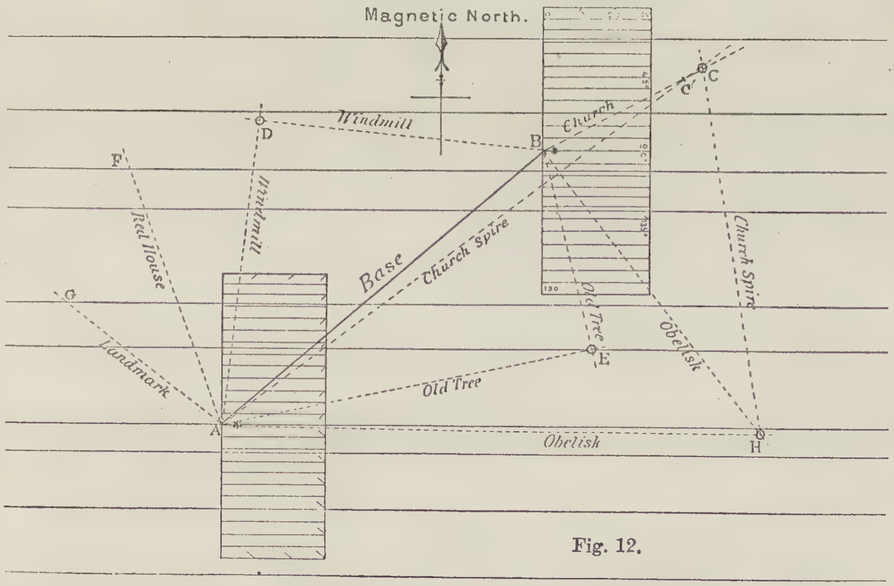

Fig. 12.

The magnetic bearing of the base is then observed, and according to the selected scale the base is transferred to paper.

* The required distance in this case is manifestly the base of the triangle, of which the actual measurement is the hypothenuse, and the angle at the base that ascertained by the clinometer.

The blue or pencil lines ruled on the prepared sheets are usually considered as magnetic east and west lines, and all lines at right angles to them are therefore magnetic north and south. Marking any convenient point on the paper to represent one extremity of the base, the protractor is placed with the zero mark at this point, and with *one* of the transverse lines marked on it coinciding with, or exactly parallel to, one of the ruled lines. Thus the edge of the protractor is north and south, and any angle measured will therefore represent the position of a point with the given bearing from the magnetic north. Thus, let the reading of the compass give 50°; then if the protractor be placed with the zero point at the point A (Fig. 12), and a mark be made opposite the given angle at B, the line A B will give the required direction of the base. Measure off the length of the base as ascertained according to scale in the direction of from A to B, and the first step in the work is completed.

From both ends of the base a series of angles may be taken at the most prominent points, and though as many as possible should be seen from both positions, as many others, which are only visible from perhaps one of the two extremities, should be observed and transferred to the paper. The process is similar to the previous one; but in marking off the various angles a pencil remark should be affixed to each, denoting the nature of the object referred to, so as to prevent confusion. As many points as are seen from both ends of the base will now be fixed by the intersection of the bearings. For example, the points C, D, and E have been determined, but not F or G, which are only seen from the point A (Fig. 12), and are therefore fixed by bearings from other points afterwards determined. In order to correct the work, and not be at a loss in case by accident any portion of the drawing should become erased, the angle should be noted in the note-book; and in this first series more than one set of observations should be taken.

POSITION.	1st Obsn.	2nd Obsn.	REMARKS.
Point B (east end of base)	230°	230°	Point A. West end of base.
	275	274	Windmill.
	62 30′	62	Church spire.
	196	196 30′	Old tree.
Point A (west end of base)	6 30′	6 30	Windmill.
	53 30	53 30	Church spire.
	79	79 30	Old tree.
	341	341	House.
	307 30	307 30	Landmark.

Leaving the pickets marking the base still in the ground, and distinguishing them by attaching to them a piece of paper or some conspicuous object, the surveyor then proceeds to one of the points already determined, and from it takes a series of angles embracing not merely those points already fixed, but such others as from their situation will give stations as nearly as possible equally distributed over the area. These are again transferred to paper and the note-book, and the most important places having been thus visited, a number of intersecting lines, bearings taken from different points, will give the relative positions of all the noticeable features, and enable them to be accurately laid down. It does not follow that all the bearings of any one feature will of necessity pass through the same point, as it is extremely difficult, if the lines cross at a very acute angle, to determine the exact point of intersection; but the mean of the observations should be taken, and the preference given to the points determined by lines that cross nearly at right angles.*

The next operation is that of tracing, or, as it is technically called, "traversing" any roads that may intersect the area, or if none be present, a line passing through that portion which contains the largest number of minor, natural, or artificial peculiarities. Any convenient place may be selected for the starting-point; and this, if it should not happen to be a station already fixed by bearings, may be readily marked on the plan by "interpolation." The bearings of two or three of the points previously determined are taken and noted down. These angles are then laid off from the points on the paper to which they refer, and the prolongations of these lines will give, by their intersection, the true place of the observer. Thus, in Fig. 13, if the road there traversed did not start from a known point (N), the situation of A would be ascertained by taking bearings of M and O, and measuring off the angles at these points: it will be seen that their intersection gives the required station. In commencing the work, the bearing of as much of the road as may chance to be nearly straight is taken and laid off on the paper, a definite point being selected on which the instrument is directed, and the distance to this point is then either measured or traced. On arriving at the termination of this measurement a second bearing is taken, and the same course pursued, and so on till the entire road is completed. In proceeding thus, however, many objects within a short distance of the road, or actually adjacent to it, are passed, and these are successively noted down, a halt being made in measuring when such a feature is reached; and if far off, a bearing is taken only; but if near, the actual distance in this direction is ascertained. If the objects be houses, or, in fact, anything that is very near the road, the halt may be made when it is, as nearly as can be guessed by the eye, at right angles to the line traversed. In Fig. 13, a halt is made at *a*, where a house is bordering on the road, and the distance *a n* measured or paced. Again, at *b*, the bearing of the church spire P is observed, but as it is somewhat remote from the path, its position is not determined by measurement, but by the intersection of this observation, and another taken at E further on. All details that can be examined in passing along the road should be measured and noted down, but if the operator is working alone, care must be taken that the point up to which his last measurement on the traverse was taken should be distinctly marked before he proceeds to the determination of the distances or dimensions, technically called "offsets," on either side.

In all this work, even if it is actually pencilled or "plotted" on the sketching paper, the note-book should be used, as much of the detail had better be drawn at a later period, to prevent the danger of the work being rubbed out.

The note-book, divided, as we have before indicated, into three equal parts, is opened, and the first entry made on the last page at the bottom, and the succeeding entries written up the page, reserving the right-hand side for those remarks which apply to that side of road, and the left for those in the other direction, while the bearings of the successive stations in the traverse are entered first.

	Station E.	
Church bears 262° 30′.	⊙	
	140 yds.	
	343° 30′	Road bears 133° 30′. Width, 20′. Banks and ditches.
	⊙	
	Station D.	
	160 yds.	
	100 yds.	Clump of trees. Bears 153° 30′. Distance 130 yards.
	61°	
	⊙	
	Station C.	
	190 yds.	
Brick wall.	110 yds.	
Corner of house. Wood, 60′+30′.	40 yds.	
	25°

	Station B.	
Corner of house. Brick.	260 yds.	
	210 yds.	
Church spire bears 330°.	165 yds.	
	59°	
	⊙	
	Station A.	

It will be noticed that the total measurements from the point whence the last traversed bearing was observed to each halting place, are written down, and *not* the intermediate distances; and the same plan should be adopted in transferring the work to paper, as it prevents errors in drawing. For example, in marking down the position of points *b*, *a*, B, in Fig. 13, the distances A *b*, A *a*, A B, are marked, and not the distances A *b*, *b a*, *a* B.

* Thus the point C (Fig. 12) is better determined by the bearings B C and H C than from B C and A C, which appear to intersect at C′. H is determined from A and B.

All the roads are thus gradually drawn on the sketch, and the greater portion of the information we are seeking to obtain has then been relatively traced on our plan, without reference, however, to the physical irregularities of the terrain. It remains, therefore, to complete the work by representing the character of the country, and by fixing the altitudes of the different features in it.

BIOGRAPHICAL SKETCHES OF EMINENT INVENTORS AND MANUFACTURERS.

XXXVII.—CHARLES VON LINNÉ OR LINNÆUS.

BY JAMES GRANT.

THIS distinguished naturalist was born on the 3rd of May, 1707, at Rashult, a village in the province of Smaland in Sweden, where his father, Nicholas Linné or Linnæus, was pastor. Charles he destined to be his successor in the pulpit, a hope which was never realised. The old man was a professed lover of flowers, and in the little garden attached to his parsonage he contrived to collect and to cultivate no less than 400 specimens of plants, most of which were of foreign growth; so this darling passion of the parent was reproduced in the son, who, for want of playmates, made the garden the circle of his juvenile diversions, save when he wandered into the woods and fields in search of plants and flowers to enrich it. His father, in his hours of leisure, taught him Latin, theology, and geography; and further, to qualify him for the pulpit, sent him to school at Wexio in Smaland, in 1717.

There the slowness of his progress induced the professors of the college to furnish him with such poor testimonials, that his father lost heart, and resolved to apprentice him to a cobbler, a result which was prevented by Johann Rothman, a physician of Wexio, who, having detected the bent of mind in young Linnæus, urged that he might be permitted to study physic and botany. On this new career he entered with ardour, and Rothman became his teacher, and Tournefort's "Institutiones Rei Herbariæ," which he found in the worthy doctor's library, became, as Stoever tells us, "the torch which illuminated the path of the youth, and opened new prospects to his eager views."

On completing his twentieth year, he resolved to attend a university, and the slenderness of his means compelled him to fix upon that of Lund, in the province of Scania, where Kilian Stobæus, who was then professor of physic and botany, became as an oracle to Linnæus, and perceiving that his circumstances were poor, he kindly took him as a free-boarder into his own family. After studying botany hard day and night at Lund, he took his departure for the greater university of Upsala, at Michaelmas, 1728. Scanty though his means, he pursued his studies there with ardour, but the end of the year saw him without the smallest means of subsistence. His father was too poor to aid him, but his kind-hearted Swedish fellow-students did. Among them he picked up a meal here and there, and was glad to accept their cast-off clothing, while necessity compelled him on more than on one occasion to cobble his own shoes; thus having recourse to the very trade with which the old pastor of Rashult had threatened him. On the arrival of the learned Olaus Celsius, professor of divinity, this state of poverty was ameliorated. He received Linnæus into his house, and obtained from him much valuable literary assistance in the compilation of his "Hierobotanicon."

It was about this time that Linnæus conceived his great idea of creating a new system of botany, and by attending closely to the position or connection of the stamens, or male organs in plants, he arranged all vegetables under one of twenty-four classes, and each class into two or more orders. He showed that the *stamina*, or dust-threads, were the male, and the *pistilla*, or dust-ways, the female parts of the plants. The sexes of plants now occupied his thoughts day and night, and this new system, of which he was the founder, began to attract the attention of the learned world.

"The system of Linnæus rests," says Figuier, "upon the consideration of the organs of fecundation—organs almost overlooked until then, but whose physiological functions have since been ably demonstrated. He introduced at the same time a salutary and much-wanted reform into botanical language and nomenclature, defining most rigorously the terms used to express the various modifications and characteristics of the organs, and reducing the name of each plant to two words, the first *substantive* designating the genus, the second *adjective* designating a species of the genus. Before his time, in fact, it was necessary to follow the name of the genus through a whole sentence in order to characterise the species, and in proportion as the numbers of the species increased, the sentences were lengthened, until it seemed as if they would never come to an end. It was like the confusion which would arise in society if, in place of using the family name and surname, we were to suppress the baptismal name, and substitute for it an enumeration of many qualities distinctive of the individual; as if, for example, in place of saying Pierre Durand or Louis Durand, we said Durand the great sportsman, or any other phraseology applicable to the qualities of the individual. Nevertheless, the Linnæan or binary nomenclature is one of the great titles to that glory which has been awarded to its immortal author. In the outline of the Linnæan system it has been found possible to describe all plants discovered since his time—an irrefragable proof of the great merits of this artificial classification of species." But although the new mode adopted by Linnæus did much to simplify the science of botany, there were defects in it which Linnæus himself soon detected by the force of his superior genius, but which even he himself was unable to rectify entirely.

In 1731, when the Academy of Sciences resolved to send a traveller to make discoveries in Lapland, Celsius recommended young Linnæus, who set out on horseback, and proceeded along the shores of the Gulf of Bothnia, till he reached the dreary district of Umea Lapmark. Through this province, so soon as the snow melted, he began his wanderings on foot, noting everything, the trees, herbs, animals, mountains, the dress and habits of the people, and sleeping wherever night found him, usually in the wretched cot of a Laplander. He next crossed the Norwegian Alps, a dreary journey, yet every mile of the way was full of allurements for the enthusiastic naturalist; but he was sinking with hardship, fatigue, and hunger, when on the 11th of August he reached Lulea in Sweden. He now visited Finland, Vasa, Abo, and other places, everywhere collecting plants and making notes; till, after travelling on foot and by horse more than 800 German leagues, he returned to Upsala in October, 1732, clad in a *Lapmud* of reindeer skin.

Ambitious to shine in the science he professed, and to secure the means of decent support, in the following year he began to lecture in public on botany, chemistry, and mineralogy, though he had not the right to do so, being without a degree. Information to this effect was lodged against him by a jealous rival, named Dr. Nicholas Rosen. He was forbidden to lecture, and thus deprived of all means for supporting himself. Full of rage, he lay in wait for Rosen, and as the latter left the Senate, he rushed upon him sword in hand, and would infallibly have run him through the body, had not the bystanders interfered. Rosen appealed now to higher authorities; Linnæus was threatened with proscription; yet for a time he still wandered about the streets, seeking for an opportunity of fighting Rosen, and killing him if he could; but after a time Linnæus also became a professor, and then his animosity to Rosen died away.

After another floral expedition through Dalecarlia, he began to lecture at Fahlun, where he fell in love with a beautiful girl named Sarah Moræus, daughter of a physician. He had a baron for his rival; but she preferred the young student, so did her father, who consented to their marriage, after a three years' engagement, and provided that Linnæus took his degree at some university. Here poverty was again a bar; but luckily at this juncture, a pension of sixty dollars yearly was assigned him by the University of Upsala; Sarah gave him one hundred dollars saved from her pocket-money, he left his native country to graduate in Holland, and took his degree at Harderwyk in Guelderland.

From thence he went to Leyden, where he found friends in the persons of Van Royen, the professor of botany; Lieberkuhn of Berlin, "besides Isaac Lawson, a Scotsman, whose loss (says Stoever), like that of the latter, the sciences had too early to mourn," Boerhaave, and Gronovius. At Amsterdam, in 1736, he published his "Fundamenta Botanica," in which the science of botany was reduced to 365 aphorisms. In 1751, the same work appeared under the title of "Philosophia Botanica." In his "Bibliotheca Botanica" he gave a system of botanical

researches divided into sixteen classes, extracted from upwards of a thousand books. In 1736 he was in London, with an introduction from Boerhaave to Sir Hans Sloane, the future founder of the British Museum. "He who shall see you both together," wrote old Boerhaave, "shall see two men, whose like will scarcely ever be found in the world." Sir Hans was displeased by this, and had no desire to see the old system of botanical science overturned by this new one, the sexes of plants and so forth. The chief object of the journey of Linnæus was to see the Botanical Garden at Chelsea, then kept by Philip Miller, F.R.S., who died in his eightieth year in 1771, and who, after some opposition to the new theory, finally arranged the garden on the Linnæan system. From London he went to Oxford, where the chief botanist then was Dillenius, a Hessian, who died in 1747. They conversed in Latin, as Linnæus was ignorant of English; Dillenius, whose age added to the pride of experience, utterly scouted the new system, though he highly esteemed the contriver of it.

After his return from England, the "Genera Plantarum" of Linnæus appeared at Leyden, illustrating the character of 8,000 plants. The same year a supplement to it with 60 more came out. Other brilliant works and translations of them followed; but still the great naturalist was in poverty, and the winter of 1738 found him in Stockholm, and for the sake of his daily bread he endeavoured, by the advice of his intended father-in-law, to practise medicine, but could nowhere find patients. However, on obtaining from the King the diploma of Physician to the Swedish Navy and Royal Botanist, the old doctor could no longer withhold his consent, and on the 26th of June, 1739, he married Sarah Moræus.

In 1741, to his joy, he received an appointment at Upsala. There he was to be professor of anatomy, while his old enemy Rosen was to teach botany; but the following year saw their chairs exchanged by order of the chancellor of the university. In 1745 he had the pleasure to see attached to it a botanical garden arranged under his own care, and on his own system. To profit by his lectures, students came from every country in Europe, and even from America; and during the Seven Years' War they numbered about 1,500. The Academy of Stockholm owes its existence partly to the zeal of Linnæus. He became member of the Academy of Montpellier, of the Society of Toulouse, of the Royal Academy of Berlin; at the instance of Tessin, he obtained the title of Archiater, or Dean to the College of Physicians, in 1747; and in the following year, he lost by death his father, who in his youth had resolved to make him a cobbler.

Under his auspices the royal museums were established in Sweden. In 1754 he discovered that plants were subject to a regular sleep at night like animals; and in order to surprise Nature in her wonders, he was wont to perambulate the garden and the hothouses, lantern in hand, that he might see the vegetable world in its dormant state, and there was scarcely any country in the world which he did not lay under contribution for his collections.

CHARLES VON LINNÉ OR LINNÆUS.

From the King of Sweden he received the order of the Polar Star, together with a diploma of hereditary nobility; and in 1754 he published proposals for cultivating and rendering profitable the wild and waste Alps of Lapland.

In 1772 he gave a fine proof of the vigour of his genius when, on resigning the rectorship of the university, he made a touching oration on "the Delights of Nature;" this was delivered in Latin, but was afterwards translated into Swedish; but two years later, when Lieut.-Colonel Dahlberg brought from Surinam eighty-six specimens of curious plants, Linnæus returned with ardour to his studies, and to the task of cataloguing them.

While lecturing in the Botanical Garden in May, 1774, he had a stroke of apoplexy, and was long insensible. He recovered, but a palsy affected his tongue, and at times he wrote in plaintive words in his diary:—"Linnæus limps, can hardly walk, speaks unintelligibly, and is scarcely able to write."

In the winter of 1776 his condition became more deplorable. Another stroke of apoplexy deprived him of power in his right side. Still he lingered, though his intellectual faculties were as much shattered as his frame, and his life became an intolerable burden, till his illness reached a climax of the most excruciating torture, occasioned by fever and stone. On the 10th of January, 1778, he fell into a gentle sleep, and never woke again.

He was interred in the ancient Cathedral of Upsala, where his remains lie beneath the organ, and in a side chapel in the north aisle is a fine mural tablet of red porphyry, with a bronze medallion portrait of him by Sergell. The inscription beneath denotes that this monument was erected to his memory by his friends and students in 1798, just twenty years after his death.

To the poor and needy foreign students who came to Upsala, remembering the hard days of his own youth, he left the whole of the perquisites which they must otherwise have paid him for lectures. One of the most distinguished attributes of Linnæus was his profound admiration for the divinity of God. In this he resembled Newton, Euler, and Locke. Like the last-named, he kept a diary, in which he recorded the principal events of his life. Besides this, he had began to write, in 1733, a little work, for his own warning, entitled "Nemesis Divina." Over the door of the hall in which he lectured were inscribed by his order the words, "Innocui vivite! Numen adest!" (Live guiltless! God observes you!)

His passions were strong and violent, as we have seen in his quarrel with Rosen; but his heart was open to every impression of joy and tenderness; and he loved jocularity, conviviality, and good living. His son, the younger Linnæus, who succeeded him as Professor at Upsala, was certainly not endowed with the same brilliant mental faculties; but the training he had undergone, and the ample notes and MSS. left by his father, enabled him to maintain with honour the post and the name that he inherited.

FISH CULTURE.—XI.

By Greville Fennell.

OYSTER CULTURE AT THE ÎLE D'OLÉRON, ST. BRIEUX, ARCACHON, AURAY, ETC.—PARCS AND COLLECTORS AT THE ÎLE DE RÉ.

At the Île d'Oléron, fifteen miles from the Île de Ré, slabs of stone from one foot to two feet high, by half a foot broad, are placed on the shore to collect the spat which is drifted to them from the natural beds. Unlike the process at Ré, no parent or breeding oysters are placed near the collectors, the spat being altogether derived from the natural oyster-grounds in deep water. From the fact that in no instance, so far as the Commissioners ascertained, have either foreshore cultivation or enclosed breeding ponds proved successful at any considerable distance from natural banks, or where such formerly existed, it would seem that their existence forms an important desideratum in successful culture. Instances are mentioned in the Report where, under supposed favourable conditions, cultivation has proved abortive, and where no apparent reason could be given beyond the fact that no oysters existed in the adjoining sea, or had ever been known to exist. It is reasonable to suppose that where oysters are absent naturally, and have always been so, some important conditions necessary for their development must be wanting in the water, soil, or temperature, etc.; and this would probably also militate against artificial culture. Considering the numerous oyster-banks which have existed, and still exist, the vast amount of spat annually voided, and the great distances to which it is carried by tides and currents, it is difficult to suppose that there is a square yard of our coasts that has not been visited by spawn; and it would therefore appear that in those places where oysters are not found, Nature protests, as it were, against them. In some places oysters are subject to exposure of more or less duration. In most parts of Ireland this would be attended with considerable risk from frost in winter, unless provision was made for having them submerged, as is the general practice in England.

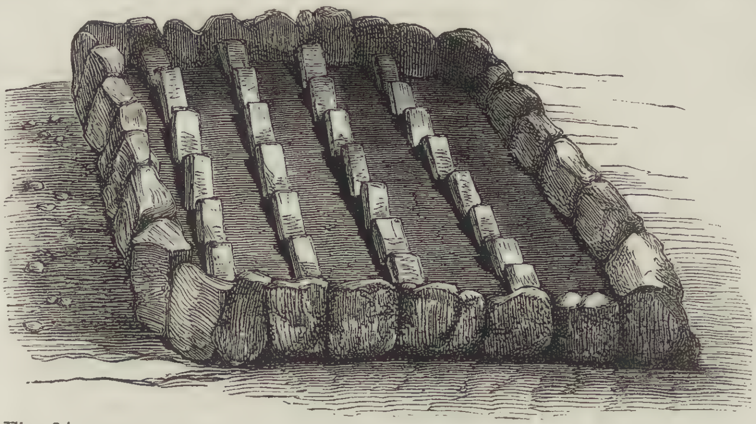

Fig. 24.—DIAGRAM SHOWING MODE OF CONSTRUCTING OYSTER PARCS AT THE ÎLE DE RÉ.

Fig. 25.—COLLECTOR OF ROUGH STONES IN OYSTER PARC AT THE ÎLE DE RÉ.

Although the cultivation is much less remunerative than it was formerly in France, still even in the depressed condition before the late war it paid better than any other industry pursued by the same class for the labour and capital expended upon it: it also possesses the advantage of interfering but little with other occupations, as the attention required to be bestowed on oysters could be given at times when labourers engaged in agriculture would be at leisure. The most encouraging instances of successful cultivation in France are to be found at L'Orient and Auray. At the former M. Charles has obtained remuneration for his capital, and at the latter M. Le Rouse has found as many as 300 oysters on one tile, and expects to profit at the rate of 20,000 francs per year. On the same river La Trinité, at Carnac, there are five other large proprietors; and seventy poor peasants, who have received assistance from the Government, have also commenced operations. All these rivers have a bottom of clay similar to that of the Essex rivers and other localities where oysters are most productive. At the Parc du Forêt, three leagues from Concarneau, the Government layings have proved successful.

The history of the origin of the Government enterprises at St. Brieux and Arcachon is of interest. In 1858, owing to the great scarcity of oysters which had prevailed for some time, M. Coste, a most distinguished member of the Institute of France, who had for some years devoted himself to the study and promotion of pisciculture, turned his attention, with most excellent results, to the promotion of oyster cultivation. By command of the Emperor, he entered into an inquiry on the subject, visited what may be called the parent source of oyster culture—Lake Fusaro, in Italy—and commenced operations in France. The result of his researches and efforts is to be found in his justly-celebrated work addressed to the Emperor, which should be read by all who desire to be conversant with the subject. It is much to be regretted that but a very brief notice of what that eminent man accomplished can be here given. One of his first undertakings was carried out at St. Brieux. This consisted in placing parent oysters, at certain distances, on the bottom of the bay, over an area of forty miles, and fascines or bundles of twigs were sunk, attached to large stones. The result exceeded all expectations, as many as 30,000 oysters being, in some instances, attached to the fascines—nearly all were plentifully covered.

Unfortunately, however, this most promising experiment was frustrated by severe storms, which covered the bottom of the bay with sand, so as completely to bury the fascines. M. Coste's next operation was at Arcachon, on the Bay of Biscay—a land-locked basin equal to about 30,000 English acres. Many years ago a very important oyster fishery had existed there, yielding annually nearly 80,000,000 oysters, valued at £10,000. As alleged, the fishery had become nearly destroyed from over-dredging. Under M. Coste's directions, in 1859, two Imperial parcs—Grand Ces and Crastorbe—were constructed. The first collectors used were wood, to which shells, etc., were attached by a resinous cement: these decayed rapidly, and were replaced by tiles, shells, and stone collectors. The first two years the proceeds were very considerable: subsequently there was a great falling off, but 1869 appears to have produced a very large crop. During six years the quantity removed from the Imperial parc was nearly sixteen millions of oysters; this was independent of the parcs of private proprietors, many of them concessions or allotments by Government, varying from one to eight acres.

A long, grass-like weed (*Zostera marina*), which grows in great quantities on the beds, proves very useful in protecting the oysters at low tide from the heat of the sun. Besides the area under cultivation, there are several natural beds in different parts of the basin, all subject to the Government regulations. The great bulk of the oysters bred at Arcachon are sent to Marennes, on the banks of the rivers Seudre and Tremblade, where the green tint so much esteemed in France is imparted to the beard of the oyster; but against which so unjust a prejudice exists in England as regards the Essex oysters, most of which are in consequence sent to France—the cause of the greenness being probably the same in both instances—the

presence of diatomaceæ, and not, as at Falmouth, owing to the presence of copper. Oysters impregnated with copper are always green in the body, whilst those of Marennes and Essex are green only in the beard or "fin."

The claires of Marennes furnish about fifty millions of green oysters per annum, and these are sold at very remunerative prices. (Bertram's "Harvest of the Sea.") The time required for fattening depends altogether on locality. At Marennes an oyster grows fat more rapidly than in the claires of the Île de Ré.

The only instance of importance of enclosed or tank cultivation in France which was visited by Mr. Francis Francis and his coadjutors was that of Madame Felix, at Regneville. Her experiments proved most successful. The enclosure is about ten acres in extent. In this 11,000 oysters were placed, and 11,000 tiles. The first year, 1864, the tiles were covered with spat, some of them having as many as 103 oysters, and the least of them about 20.

With respect to the natural oyster-beds of France, many of them became so denuded of oysters down to 1850 as to be hardly worth fishing; and some formerly of great importance—such as those of Cancale, Granville, etc.—have been all but destroyed. It was then that the French Government became alive to the urgent necessity of adopting stringent measures to prevent the threatened destruction of the comparatively few that remained on the natural banks, as well as to endeavour to replenish them where exhaustion had taken place. The laws for this object are very effective, and are fully given in the Report of 1870, but are much too long for quotation. Undoubtedly benefits accrued to the small cultivators of the soil near the sea from these grants of free shore, either for breeding or fattening purposes, and the Government encouraged such enterprises by affording facilities for obtaining stock from the Government reserves, and by occasionally making free grants both of oysters and tiles. Sailors, or the relatives and families of sailors, were allowed certain advantages over other applicants for such concessions.

Upon the causes of decline of production in France, the Commissioners state:—"The wonderful increase in the yield of the natural bed of Cancale from 400,000 in 1815 to 70,000,000 in 1847, and the subsequent equally rapid decrease, is a subject which, as it bears upon the restrictions necessary in our own country for deep sea-beds, deserves attention." Here we have, in the return, a long period of rest, and almost absolute cessation of dredging, and the fact of a vast accumulation of oysters taking place. Then follows the onset of a large fleet of boats, without restrictions, which produces, in a few years, the destruction of the bank. Comment is needless. Similar agreement in the main points is presented by the return of the public beds at Arcachon, the present regulations producing a steady improvement in the fisheries. It must be borne in mind that in certain conditions of soil, etc., the absence of dredging may be an evil instead of a benefit to the ground. Cases of this kind are those forming the subject of a Report by Mr. Cholmondely Pennell to the Board of Trade, in 1868. Mr. Pennell states that the Fish and Oyster Breeding Company have cleared 100 acres of the portion of the Blackwater estuary, and thirteen acres of ebb-dry foreshore. Of the state of this ground when it came into the Company's hands, Mr. Pennell remarks that it was, for all practical purposes, barren of oysters, and the "cultch" covered with mud and overrun with vermin and weeds. Fifty-six hauls of the dredge in 1867, before the Company was established, resulted in nine brood and spat, and nine oysters of larger growth. Recently writing in 1870, Mr. Pennell states that *two* successive gave—first, three brood, and sixty-eight spat; second haul, three brood and seventy-five spat (oysters of larger growth not counted), or an increase of 450 to 1 as compared with 1867. A stock of oysters, to the value of £11,631, had been laid upon the ground in 1868 and 1869.

The Roach River Company have reclaimed thirty acres of similar foreshore, and 270 acres of ordinary ground, and the result is equally satisfactory. In 1864, 150 hauls of the dredge gave a total of 38 oysters of all ages; and in 1869 one haul gave 100 brood and 153 spat, or an increase of brood and spat above 1,000 to 1 as compared with 1864.

That oysters cannot be dredged too much from the muddy rivers of the east coast, is the opinion of the oyster-culturist; while those who have ground in rapid and clear water, depose exactly the opposite—namely, that *rest is all* that exhausted grounds require.

The Commissioners are of opinion that all laws to be beneficial must consist of regulations adapted to the requirements of the locality, and not consist of a series of general rules arbitrarily adopted and enforced in despair of obtaining the truth when evidence so very conflicting is offered.

The foreshores at Auray, already mentioned as a success, run from the bridge to the sea a distance of twelve miles, the shores of the river being a scene of oyster culture such as it is hoped will in a few years be seen on many river-banks both in England and Ireland. The process is described as of the simplest kind. Each concession, duly bounded and marked by a numbered post or stone, contains nothing more complicated than rows of tiles, arranged so as to offer clean under-surfaces for the adhesion of the spat, which rises from the preserved banks in the river. To keep these clean, to remove all oysters of a year's growth, to lay them in claires to develop and grow, is all that is needful, and the result is entirely satisfactory. Upon the length of foreshore named no less than 88 parcs have been constructed. The number of oysters, at the time of the visit of the Commissioners, on some of the tiles was said to be 300.

We give in Figs. 24, 25 illustrations of the simple yet ingenious manner in which rude, cheap, and comparatively effective collectors were placed at the Île de Ré. These stones were procured by blasting the rocks, and they served likewise for the construction of the enclosing walls, both collectors and walls being arranged in parallel lines. The cost of a parc of 30 yards square thus constructed was stated at £12; and the number of such increased very considerably in a few years. It is now admitted by the proprietors themselves that the mud and dirt being allowed to collect upon and about these stones, and the improvidence of selling the parent oyster, and thus removing the source of the spat, were the combined causes of the present depopulated condition of the parcs.

SANITARY ENGINEERING.—XXV.

ON THE DISINFECTION OF SEWAGE ON A LARGE SCALE.

In a previous paper (No. XXI.) we have explained the *rationale* of one process adopted for this purpose, but only with reference to its limited application—viz., to house drainage. We now take up the same question upon a more extended scale—*i.e.*, with reference to large and complicated systems of sewerage, measuring perhaps many miles in length, and extending over many acres of ground. With the "products" of the sewage when "disinfected," and with their comparative commercial value as manure, we have for the moment nothing to do. The systems of sewage irrigation, where the matter is dealt with in its liquid form, are ably treated in other sections of The Technical Educator, and the details of one particular system, the A B C as it is called, have been explained at some length. Our present purpose is to describe the results of some of the most recent experiments upon a large scale, describing the various methods adopted, and giving the general result, but leaving the subject at the point of dealing with the sewage when disinfected, its commercial value, etc., which are treated by other authors under other headings. We commence by some extracts from a joint report by Dr. Letheby, the Medical Officer of Health, and W. Haywood, Esq., the Engineer to the Commissioners of Sewers, published in the year 1862, "Upon the Results of the Experiment applying Charcoal to the Sewer Ventilators." We quote from the report:—

"The district experimented upon is in the eastern portion of the City of London. It includes a space bounded by Bishopsgate Street on the west, from Cornhill to Widegate Street, by Middlesex Street and Somerset Street on the east, to the City boundary and by the Minories, and then by Leadenhall Street to Cornhill on the south—the whole of the main thoroughfares above-named being included in the area. It comprises a space of about 59 acres, with about 1,700 houses, and about 14,000 inhabitants.

"This district was selected for various reasons:—(1) Because the sewers have but a slight fall, and the currents in them are sluggish; (2) the area is densely populated, and has more than an average population of poor resident in it; (3) the thoroughfares are mostly narrow, and are therefore disagreeably affected

by the sewer gases from the ventilators; (4) the district afforded good means of isolation from other sewers.

"The total length of sewers in the district is 25,587 feet, of which 2,081 feet are pipes, and the remainder constructed of brick, varying from 3 feet high by 2 feet wide, to 5 feet high by 3 feet wide, internal dimensions.

"Wood charcoal was employed, broken into pieces about the size of a filbert. It was packed closely, but without compression, upon trays specially arranged for the purpose.

"The first air-filter ever put into action in the City was in Philpot Lane in 1859."

The report continues by saying that the deodorising power of the charcoal has been proved to be complete, and that it is patent to actual observation that the "odour of the sewer gases is not perceptible when they have traversed the charcoal."

But here we have to note one special point: the efficiency of the use of charcoal, and the length of time during which it may be safely employed, depend to a great extent upon the absence of damp. In some cases experimented upon twenty months have been allowed to elapse before removing the charcoal, and in others it has been changed at the end of a month. Local circumstances, and the completeness or otherwise of the mechanical appliances for its use, must to a great extent form the guide in practice upon this point.

The analysis of the charcoal when removed shows clearly an extensive absorption of organic matter of various descriptions; but attempts to trace the various constituents to their original source have hitherto met with very partial success.

The second branch of the inquiry has reference to the effect of the experiment upon the quantity of sewer gas admitted into houses during its continuance; but no detrimental results could be identified, and the report proceeds to recommend "charcoal respirators for workmen employed in sewers where any accumulation of noxious gases are to be apprehended." The question of cost was also reported on in full detail, which we will spare our readers, as having recorded the successful results of the experiment we may fairly pass on without further delay to other branches of the inquiry.

Having thus dealt with the disinfection of sewage gases, we now take up the question of the disinfection of sewage itself, and commence by quoting a letter conveying the suggestions and experience of H.R.H. the late Prince Consort, dated April 12, 1850.

"Leaving it to more competent judges to decide whether the sewage should be dealt with as liquid manure or solidified, upon which point His Royal Highness wishes to give no opinion himself, he has confined his attention to the latter mode of application from two causes:—

"(1) That in this shape it could be more easily transported; and (2) could be thus obtained at the least possible expense.

"The plan which His Royal Highness proposes is simply this: to form a tank with a perforated false bottom upon which a filtering medium should be laid, and to admit the sewage into the tank below the false bottom, when according to the principle of water finding its own level, the sewage will rise through the filters, and will run into the drain—if the filtering medium has been of sufficient thickness and of a proper nature—as clear as spring water.

"This medium will then have absorbed all extraneous matter, and consequently become the richest manure, which when the further supply of sewage matter is stopped, can be taken out by a common labourer with a shovel, and carted or shipped wherever desired. His Royal Highness tried the experiment on a small scale with apparent success. The medium which His Royal Highness has used is charcoal, gypsum, and burnt clay, substances in themselves highly useful as manures."

The process thus clearly foreshadowed has been adopted on a scale sufficient to test its efficiency at a large workhouse at Stoke-upon-Trent, containing about 650 inmates. The water-supply is abundant; there are water-closets and urinals, piggeries, stables, baths, etc.; and all the liquid refuse, with the rain-water of the premises, is conducted to one outfall. Previously, the whole of this sewage, about 10,000 gallons, was received into cesspools, the overflow being into the canal, which, however, produced such a nuisance, that as a consequence of certain legal proceedings, the process we are about to describe was adopted.

The sewage is first received into a depositing tank, where the heavier matter is allowed to subside, and then passes through a rough filter of coarse cinders and charcoal into a second tank, two-thirds filled with some filtering material, after leaving which it passes into a chamber in which is placed a cage filled with charcoal, which can be raised, renewed, and replaced when required. At this point the suspended matter is for the most part removed, and the sewage is then conducted through a second series of smaller filters, three in number, filled with finer charcoal and cinders, and the clear effluent water is allowed to escape into the drain. The various tanks are periodically emptied, and their contents thrown into the first tank, which is cleared out once in eight months, its contents mixed with ashes to secure dryness, and carted away to a manure factory at Newcastle-under-Lyme. The Birmingham Committee of Inquiry, who visited the works, report that they could detect no offensive odour.

It may perhaps be mentioned that the filters, though sufficient for 10,000 gallons daily, are unequal to meeting emergencies in times of heavy rainfall, when perhaps double the quantity, 20,000 gallons, have to be dealt with.

But this difficulty may be met either by enlarging the filters, or providing a reservoir large enough to contain the sewage arising from any possible flood, which might subsequently be passed through the filter by slow degrees.

At Bradford in Yorkshire works are now in progress, and nearly completed, by the Peat Engineering and Sewage Filtration Company, for dealing with the entire sewage of the town, about 5,000,000 gallons, upon this principle. The sewage will be conducted through several rows of filtering beds 700 feet long and 4 feet wide, and each particle of sewage will have to pass through 12 feet of charcoal.

The charcoal is manufactured from peat by the company above mentioned, at their works at Red Moss, under their patent, and there is practically no limit to the supply.

The charcoal when fully charged with sewage matter has considerable value as a manure, but this is beyond the scope of our present paper.

The attention of the engineers of the day, in this country and on the Continent, is now turning more in the direction of dealing with sewage in its solid form, and we recently saw some experiments in progress by which, with the convenience of a water-supply, a mechanical arrangement secured the retention of the solid matter, the surplus water being allowed to flow off by regular drainage channels, at the same time a powerful disinfectant was thrown on to the solid matter, which was subsequently removed as already described in our paper on Moule's Earth-closet System. The scheme was intended for a large Continental town, but the details are not sufficiently mature for us to do more than describe the general principle. Suffice it to say that these novel methods of treating sewage in the solid will never probably be desirable or applicable in large mercantile centres, such as London, Liverpool, or Manchester, as the immense additional organisation required would entail vast additional expense, while much of the existing drainage and other work would be rendered unavailable. If in the course of years the process becomes more extensively adopted, it would only be by the discovery of some method by which the product of the disinfected sewage would become sufficiently valuable to defray the cost of collection; but we have no hesitation in saying—and in this opinion we are supported by some of the best authorities of the day—that upon an extended scale this result has never been obtained in this country. We have read many curious particulars as to the way in which, in China, great results are obtained by the direct use of sewage matter for manuring purposes, which show clearly that under certain conditions the results are very remarkable; but the comparative states of their civilisation and our own are so widely different that no conclusion can be drawn from the facts as applicable to ourselves.

We conclude by alluding to one or two schemes for the chemical treatment of sewage, only remarking that hitherto we have no record of commercial and financial success upon a large scale.

One of these processes, as explained by Mr. David Forbes, F.R.S., "consists in treating the sewage with a solution of the native phosphate of alumina dissolved in sulphuric or hydrochloric acid. This solution is in itself a powerful antiseptic and disinfectant, completely arresting further putrefaction, and

depriving the most fetid sewage of its offensive smell; causing at the same time the supernatant water to be clear and colourless, even if tinctorial substances of great intensity be present in the liquid." This is commonly called the phosphate process. Another method employs lime, tar, and calcined chloride of magnesium, with other matters in certain proportions.

TECHNICAL DRAWING.—LXXX.

DRAWING FOR CABINET-MAKERS (*continued*).

FREEHAND DRAWING.

THE trade of a cabinet-maker is so dependent upon design, and stands in such close connection with wood-carving and other branches of ornamental art, that it will be almost unnecessary to point out the immense importance of this branch of study. Taste and refinement are called for in every article of furniture, and unless a man is satisfied to be a mere drudge —unless he would chain himself down for the whole of his life to the lowest class of work, and consequently to the lowest scale of wages—he must endeavour to improve his capabilities; he must, by self-culture and labour, fit himself for the great battle for superiority which is now going on between foreign nations and ourselves. The manual skill of our artisans is unquestioned, but they have until recent years wanted the art-culture which has been liberally bestowed on their class in other countries. Opportunities, however, are not now wanting; the noble Schools of Art and Science established throughout the kingdom are open to artisans at a charge easily within their means, and it is to be hoped that, in a few years' time, our English cabinet-makers will be able to assert, and boldly to maintain, that superiority in design and workmanship of which they have shown such great promise in the recent international exhibitions.

An important series of elementary lessons in freehand drawing is given in Lesson XLI. of "Technical Drawing" (Vol. II., page 265). To these and numerous other freehand examples given in the various courses of lessons, the student is referred, and he is urged to work the exercises carefully before attempting the following subjects.

Fig. 617.—This example presents part of the side with feet of a small work-table, which the student is advised to draw to a much larger scale, completing of course the right foot omitted in the figure.

In commencing, draw the ground-line and the central perpendicular, then the horizontal lines for the mouldings which separate the side from the feet.

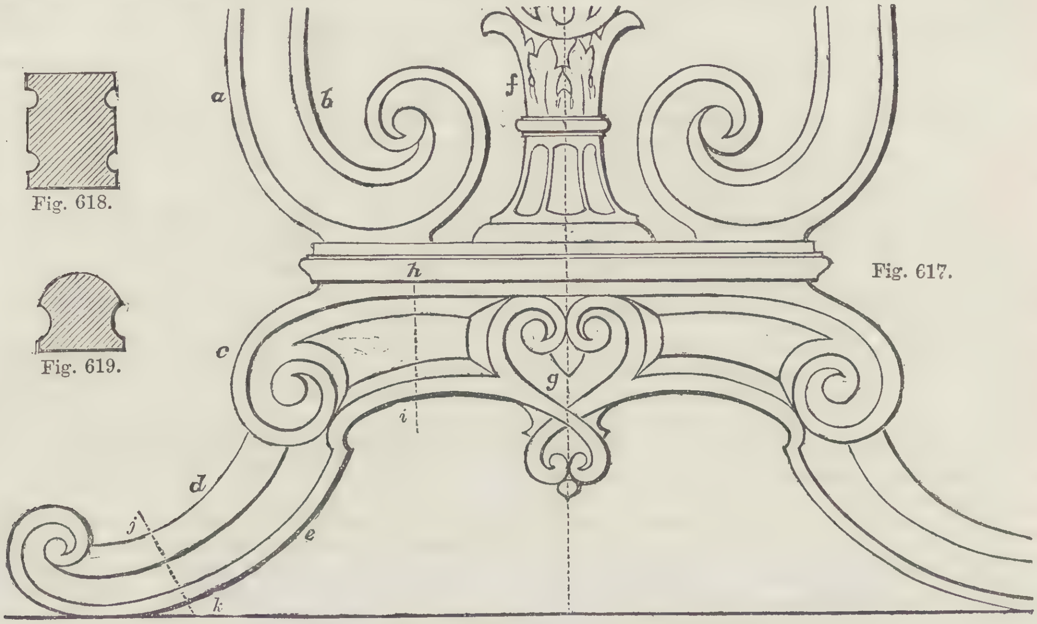

Fig. 618.

Fig. 619.

Fig. 617.

Now draw the scroll *a* on the left, and balance it by the corresponding curve on the right side; then draw the interior line *b*, but omit for the present the inner lines showing the edging. The drawing should, in fact, at this stage show the work as roughly cut out by the saw, before being handed over to the carver.

Draw the scroll *c*, and the curve *d*, for the outer line of the leg, repeating the same on the opposite side, and complete the general form of the legs by the interior outline *e*, which is to be carried round so as to form the scroll terminating the foot.

Next draw the middle part *f* of the upper portion of the subject, and the scrolls crossing each other in *g* beneath it. Having taken a careful survey of the whole, with the view of correcting the general form and proportion, the inner lines, showing the edging, etc., are to be drawn. Figs. 618 and 619 are sections on *h i* and *j k*, which will serve as guides in this portion of the work. The whole drawing will then be ready for "lining in."

Fig. 620.—This is a pattern for a running scroll, arranged so as to repeat; *a* will therefore join on at *b*, and thus the design may be continued.

It will be seen that, in order to equalise the spaces so as to carry out this arrangement, the whole is divided into squares, and the central flower is placed on the intersection of the diagonals.

In commencing this design, the general form is to be sketched of each scroll rising out of the previous one. At this stage no notice should be taken of the husks or foliage, *c*, *d*, etc., but the scrolls should be sketched as if consisting of the flowing stem only, and the husks should then be drawn outside the original form.

Great care must be exercised to ensure the smooth, spiral character of the curves. There must be no angular breaks, but the eye must be carried onward towards the centre of each scroll, and the husks must appear as *additions*, but not as *excrescences*. In order to test the correctness of the forms, turn the sketch upside down, place it vertically, or in any other direction, and if the design has been correctly sketched, the scrolls should be equally perfect in whatever position they may be viewed. This should be repeatedly done during the progress of the work, so that any part which may be too full or too flat may be improved before the husks, flowers, foliage, or other details are added.

Fig. 621.—The design shown in this example is a scroll such as might be used in ornamenting a console, etc. We shall give the description here with such hints and instruction as may be necessary to the learner, but the design itself will be found in our next lesson. (See Fig. 621, page 125.)

Draw the right angle in which the figure is to be contained, then sketch freely the spiral commencing at A, and continuing to B, following the direction of the stem only, regardless at the present stage of the foliage by which some portions of it are covered.

are then to be added. The separate portions of the leaves are next to be drawn within the forms already traced. The whole is then to be carefully corrected and lined in.

The student is urged to vary the studies herein given, to reverse them, and in every case to copy them of a different size.

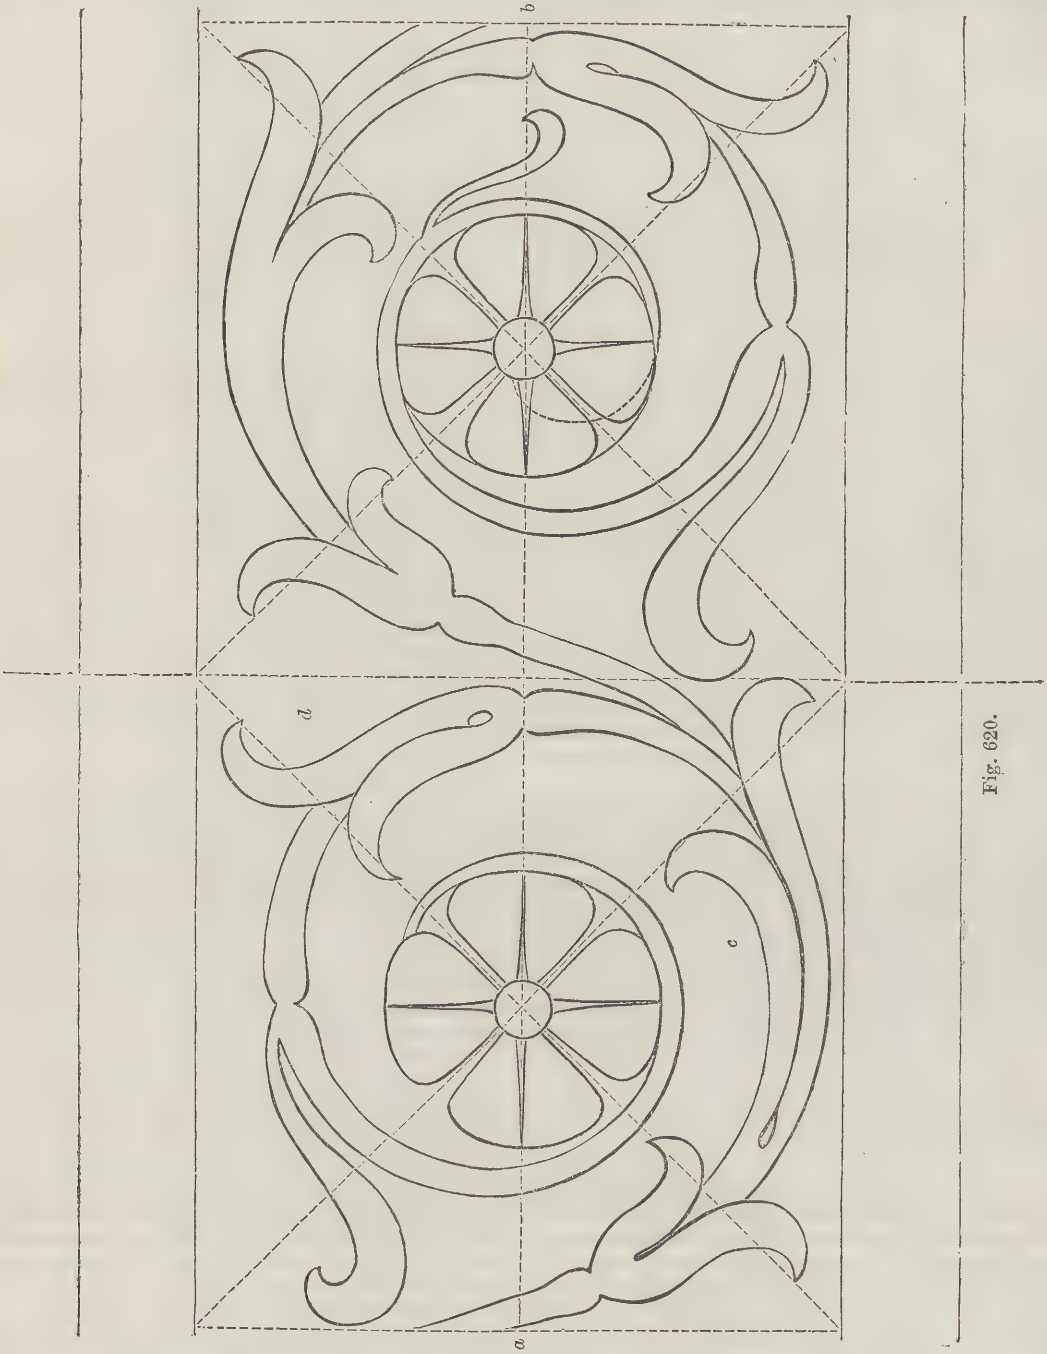

Fig. 620.

When this curve has been satisfactorily traced, draw the corresponding one, commencing at C, and following to D.

The foliage is next to be drawn, and in doing this the general form must be sketched first—the shape, as it were, of the block out of which it would be carved. This is shown in one portion, commencing at E. Thus from E draw the form extending to F, and thence to G. This will give the one lobe. Next proceed to H, and thence to I. In this way the whole of the foliage is to be sketched in, and the bud and minor parts Natural flowers and foliage afford the most excellent subjects for study, and thus the student who wishes to work need never stand still for want of examples.

We have said that the design to which the description just given applies is one which might be used in ornamenting a console or bracket. It will be a useful exercise for the student to attempt to make such a drawing as he may imagine to answer to our description, and then compare it with our design in Fig. 621 (page 125).

PATENTS AND PATENT LAW.—III.

By A Barrister.

HOW TO OBTAIN A PATENT AND HOW TO EXTEND IT.

We have seen what may be the subject of a patent, and who may obtain a grant of letters patent. The subject next requiring consideration is, how is the grant to be obtained? The principal matters requiring attention are the specification, the drawings, models, and specimens, the declaration of the inventor, the petition, the payment of the stamp duty, the letter patent, the examination of the letter by the Attorney-General, and his certificate.

First, then, as to the specification. The specification is either provisional or complete. The office and effect of the former is this. The Act of 1852 provides that any invention may be used and published for six months from the date of the application for letters patent for the invention, without prejudice to the letters patent, provided the provisional specification, which describes the nature of the invention, and is to accompany the petition for the letters patent, be allowed by the proper law officer (15 & 16 Vict., c. 83, s. 9). The same statute enacts that the applicant, instead of having a provisional specification, may, if he think fit, file a complete specification under his hand and seal, particularly describing and ascertaining the nature of his invention, and in what manner the same is to be performed, in which case the invention will be protected for six months from the date of the application, and may be used and published without prejudice to any letters patent to be granted for the same (sect. 9). A particular description of the invention is one of the conditions which we observed clog a patent. The specification must be clear and precise, in writing, under the hand and seal of the applicant, and it must be filed in the High Court of Chancery within a given period, generally six calendar months from the date. If a complete specification be filed along with the petition for the letters patent, then, in lieu of a condition for making void the letters patent in case the invention be not described and ascertained by a subsequent specification, the letters patent shall be conditioned to become void, if such complete specification does not particularly describe and ascertain the nature of the invention, and in what manner the same is to be performed.

The framing of the specification is a matter of great nicety. The description which it contains must correspond with the title of the invention contained in the letters patent; it must clearly describe the invention, but not go beyond the proper subject of the patent; nor must it omit anything necessary to make the description intelligible. The importance of being accurate will be plain when we state that whilst a patent has been held valid, the patentee has had its operation limited by reason of a defective specification. As an example, the title of a patent was "for the invention of certain improvements in the doors and sashes of carriages." The specification described the object of the patent in the following terms:—"I have shown my invention applies to railway carriage doors and window fittings, although the said several fittings are applicable to and may be applied to the doors and windows of any other description of carriage, or in any position where windows and doors are subject to jar or vibrate." It was decided that the words indicating that the invention might be applied to doors and windows other than those of carriages, did not amount to a claim that such additional applicability of the invention was comprised in the patent; for that the claim must be construed with reference to the title of the patent, and confined accordingly to the doors and windows of carriages.

Here we come upon one of the disadvantages under which patentees labour. Specifications are construed by the courts, and yet we have no court for the trial of patent causes. Mr. Justice Grove is the only judge on the bench who professes to understand patent law. Where novelty or infringement depends merely on the construction of the specification, it is a pure question of law for the judges; but where the consideration arises how far one machine, or a material part of one, imitates or resembles another in that which is the alleged invention, it generally becomes a mixed question of law and fact which must be left to the jury. The only aid which can be given to the court in construing a specification, is that obtainable by means of evidence admissible to explain terms of art or technical expressions known only to particular trades. There is a means, however, by which a grantee or assignee of any letters patent may abandon portions of the title or specification, and this process is called a disclaimer. This disclaimer must be entered with the clerk of the patents, after leave obtained, in the case of an English patent, of the Attorney-General or Solicitor-General, certified by his fiat and signature. The reason for the disclaimer must be stated. Or a memorandum may be entered, on leave being similarly obtained, setting forth any desired alteration in the title or specification —the disclaimer or alteration not being such as to extend the exclusive right granted by the letters patent—and such disclaimer or memorandum of alteration, being filed by the clerk of the patents, and enrolled with the specification, is to be deemed and taken to be part of such letters patent or specification in all courts whatever. The most obvious occasion for a disclaimer is where the Crown has been deceived, or if the specification is in any respect false or likely to mislead, so that the public cannot enjoy the benefit in the most ample manner. These are defects which must be cured. By the above process a patent originally bad may be made good from the time of the disclaimer or alteration.

We have mentioned the drawings and specimens. Where they are referred to in the specification they form part of it, and may help to make good a specification which would be otherwise defective. Next as to the declaration. The statute (5 & 6 Wm. IV., c. 62) says that whenever any person or persons shall seek to obtain any patent under the great seal for any discovery or invention, such person or persons shall make a declaration in the form of the old oath. The declaration states that the inventor has invented, and that he believes his invention will be of general benefit and advantage. Next we have to consider the petition which gives the title of the invention. This title must be very carefully framed, as will appear from a statement of two cases. Letters patent for a whole watch, the specification disclosing the invention of a particular movement only, were held void, on the ground of the title being more extensive than the invention. Letters patent were granted for an "improved method of lighting cities, towns, and villages," and the specification disclosed an improvement of the old street lamp, of parts known before, by a new combination. The letters patent were held void. But generality in the title, if not inconsistent with the invention as described in the specification, will not vitiate the letters patent. After the statement of the title in the petition, follows the averment, "which invention he believes will be of great public utility;" that he is the true and first inventor thereof, that the same is new in England, and that the same is not in use therein by any other person or persons, to the best of his knowledge and belief. The petition closes with a prayer that Her Majesty will be pleased to grant unto the inventor, his executors, administrators, and assigns, her royal letters patent under the great seal of Great Britain, for the sole use, benefit, and advantage of his said invention for the term of fourteen years.

This petition, with the declaration of the inventor, and provisional specification, must be left at the office of the Commissioners of Patents, who will refer them to the Attorney-General or Solicitor-General to consider. The law officer gives his certificate, and after some further forms and delays, the Lord Chancellor causes letters patent for the invention to be sealed with the great seal of the United Kingdom, granting to the applicant the exclusive right of using the invention within the United Kingdom, the Channel Islands, and the Isle of Man, and (if the warrant of the Patent Commissioners so direct) within the Colonies, for the full term of fourteen years. The letters patent always contain a proviso to the effect, that if the "complete specification" already filed does not particularly describe the nature of the invention, and in what way the same is to be used, or if none be filed, then if the applicant does not within a limited period file such a specification in the Court of Chancery, the grant in the letters patent contained shall be void.

A difficulty may arise in the course of these proceedings by the opposition of those interested in objecting to the grant of the letters patent. Any such persons are at liberty within a certain period to lodge particulars in writing of their objections. Similarly, objections may be made to applications to the Privy Council to prolong patents, a matter to which we will now

shortly advert, as being in effect a part of the grant. What the requirements of the Privy Council are, may best be explained by reference to the case of Hill's patent, a prolongation of which was opposed by a host of opponents. It was there said that in determining whether to recommend a prolongation of a patent or not, even where the claim to the first discovery and the beneficial nature of that discovery are both conceded, it will be still proper to consider both the degree of merit as inventor, and the amount of the benefit to the public flowing directly from the invention. These general observations, going really to the root of the principle upon which patents are granted, then follow:—A monopoly limited to a certain time is properly the reward which the law assigns to the patentee for the invention and disclosure to the public of his mode of proceeding. Whether that term shall be extended, in effect whether a second patent shall be granted for the same consideration, and the enjoyment by the public of its vested right be postponed, is to depend on the exercise of a discretion, judicial indeed, yet to be influenced by every such circumstance as would properly weigh on a sensible and considerate person in determining whether an extraordinary privilege not of strict right, but rather of equitable reward, should be conferred.

The prolongation of the patent in Hill's case—for an improved mode of compressing peat for making fuel or gas, and of manufacturing gas, or of obtaining certain substances applicable for purifying the same—was opposed on the several grounds of want of novelty, want of utility, and of the patentee having had sufficient remuneration. The Judicial Committee refused to entertain the objections going to the root of the validity of the patent—viz., want of novelty and want of utility—but proceeded to the question of want of merit in the inventor. The crucial test applied by this court was, has the individual patentee, under all the circumstances, received what in equity and good sense may be considered sufficient remuneration? To assist the court, a patentee on applying for a prolongation must furnish accounts, and it may be well that we should take from the judgment in Hill's case a description of the accounts required. "It must be remembered," are the words of the judgment, "that the accounts which a patentee renders in support of such a petition as the present are not such as might be proper between two several claimants on the returns of a mercantile firm, but such as show what profits made by a firm or individual are in a large sense attributable to the possession of the patent right—those which, without the patent, would not have existed at all; not, of course, excluding all just deductions for labour, capital, etc. If, but for the patent, there would have been no manufactory, then the net profits of the manufacturer are in that large sense attributable to the patent. . . . . Their lordships cannot satisfactorily discharge their duty unless they have the whole case before them. They must know the whole remuneration; different considerations may be applicable to different parts of it; but if to any extent the patentee has received his remuneration by the making and selling the patented article, the profits on that sale must be disclosed and taken into account." As to the deductions allowable, a patentee is not entitled to deduct from profits any loss by foolish or imprudent bargains, or hasty compromises of litigation; and where he manufactures his own invention, he is not entitled to deduct two-thirds as manufacturers' profits, and count only the other third as the profit alone attributable to the patent.

The prolongation of patents, we have before remarked, is entirely discretionary, and any reasonable conditions may be imposed. For example, in the case of Mallet's patent relating to the construction of fire-proof structures, licences had been granted by the patentee, and the Privy Council prolonged the term on condition that similar licences were granted to the public on the same terms.

It may be advisable to advert briefly to a case in which a patentee was held to have deprived himself of all right to a prolongation. This was the case of Trotman's patent for improvements in anchors, and in addition to the fact that his accounts were unsatisfactory, the Judicial Committee of the Privy Council considered that he had so dealt with his patent rights as to deprive himself of the power of showing the amount of profit derived from the working of the patent. This was the essential element, as the prolongation was asked for on the ground that the patentee had been insufficiently remunerated. This question of insufficient remuneration being an important one, we will quote the observations of Lord Chelmsford. There was, he pointed out, a peculiarity in this case—viz., the patentee, "instead of becoming himself a manufacturer of his patented anchors, has preferred to grant licences to ironsmiths to manufacture them on their own account, paying him a royalty. In all prior applications for the extension of the term of a patent, the patentee has himself made and sold the patented article, either exclusively or in common with other persons to whom he has granted licences, or he has assigned away his patent altogether, so as to substitute his assignee for himself in all questions respecting his patent rights. In these cases there is obviously no difficulty in ascertaining the profit which has been derived from the patent. It is supposed, however, that the unusual manner of working the patent in this case renders the application of a different principle necessary. This, however, is clearly a misapprehension. The question in all cases of this description is not what the patentee has received, but what has been made, or by proper judgment and application might have been made, by the patent. The petitioner might, if he pleased, have become the manufacturer of his patented anchor. If he had, it would have been necessary to ascertain what part of the profits of the manufacturing business ought to be ascribed to the patent. . . . But the petitioner was unwilling to incur a large expenditure in erecting the proper plant for carrying on the manufacture, and preferred to leave the expense of the new machinery necessary for forging his anchors to the licensees, being content to receive a royalty as his share of the profits of the patent business. Under these circumstances, if his royalty alone were to be regarded, it is evident that we should not arrive at a knowledge of the whole amount realised by the patent, but that the question would be changed from what the patent had produced to what it had yielded to the patentee." And on the general principle of prolongation it was said, "It must always be borne in mind that the extension of the term of a patent is matter of favour, not of right; and that it is essential to the favourable consideration of the patentee's application, that he should distinctly prove how much the public have had to pay, or, in other words, how much has been received on account of the patent. If, therefore, the patentee has dealt with his patent rights in such a manner that, when the time arrives for asking for a renewal of his term, he has put it out of his power to give the requisite evidence upon which his application must to a great extent have been founded, his petition must fail, because it wants the proof which is essential to its success." From this we deduce that a patentee who is his own manufacturer is in the best possible position for obtaining the renewal of his term.

Patents taken out in a foreign country may have an important bearing upon the question of prolonging English patents. The rules under the Act of 1852 seem to be these:—If an English patent is taken out before a foreign patent, the prolongation of the English patent will be granted, although the foreign patent has expired. Where a patent is taken out in a foreign country before a patent for the same invention in the United Kingdom, the latter patent must terminate at the same time as the foreign patent. And where the term of a foreign patent has expired, any grant of letters patent in the United Kingdom made after that period is of no validity. And where the two patents are taken out simultaneously, it would seem that a prolongation of the English patent may be granted.

Lastly, as incidental to obtaining a patent, we may refer to the payments to be made by the patentee. The statute 16 & 17 Vict., c. 5, s. 2, provides for the payment of the stamp duties set out in the schedule at the expiration of three and seven years from the granting of the patent. Unless these payments are made the letters patent will be void, and the powers and privileges thereby granted will cease. It may be interesting to our readers to know what these payments are. The schedule contains the following:—On petition for grant of letters patent, £5; on certificate of record of notice to proceed, £5; on warrant of law officer for letters patent, £5; on the sealing of letters patent, £5; on specification, £5; on the letters patent, or a duplicate thereof, before the expiration of the third year, £50; on the letters patent, or a duplicate thereof, before the expiration of the seventh year, £100. An application for a disclaimer costs £5.

INDIAN RUBBER.—I.

BY GEORGE GLADSTONE, F.C.S.

FIRST INTRODUCTION — SOUTH AMERICAN CAOUTCHOUC — INDIAN CAOUTCHOUC — SIPHONIA ELASTICA — MODE OF COLLECTION — FICUS ELASTICA — URCEOLA ELASTICA — CHEMICAL CONSTITUTION — PHYSICAL PROPERTIES.

It is only since the beginning of the last century that indian-rubber or caoutchouc has been known in this country; and when the first specimens arrived, speculations were rife as to whether it belonged to the vegetable or mineral kingdom. This may seem now to be very absurd; but there were stronger reasons for inferring a mineral origin than perhaps even those who held this view were aware of at the time; this will more particularly appear when we come to speak of its chemical composition. The question as to its vegetable origin was set at rest by a communication to the French Academy in 1736, in which it was stated to be the inspissated juice of a tree which grows in South America.

From that time till 1770 it appears to have been a mere curiosity. In that year it was introduced to the British public for the purpose to which it was long almost exclusively devoted, and from which it has derived its familiar name. In the preface to a book on perspective published in that year, the following singular passage occurs. "Since this work was printed off, I have seen a substance (no name is given to it) excellently adapted to the purpose of wiping from paper the marks of a black-lead pencil. It must, therefore, be of singular use to those who practise drawing. It is sold by Mr. Nairne, mathematical instrument maker, opposite the Royal Exchange. He sells a cubical piece of about half an inch for three shillings, and he says it will last for several years."

Just fifty years after that time experimenters, attracted by its singular and valuable properties, began to turn it to new and more important uses; and in 1823, Mr. Mackintosh, of Glasgow, succeeded in applying a solution of Indian rubber to cloths, by which he made the waterproof article which has since borne his name.

Up to that period the supply of the raw article was almost exclusively limited to South America, although some identical in its properties was known to be procurable in India, having been discovered by Dr. Roxburgh in Assam about fourteen years previously. Had it not been for the exertions of Dr. Forbes Royle, the East Indian caoutchouc might have remained much longer in obscurity; for when a gentleman up the country sent some to his agents in Calcutta, they simply wrote in reply that "the article being unknown in this market, we are sorry we can give you no idea of its value." This happened in 1828, when it was selling in London for 2s. per lb. By 1840 it had become a regular article of export, and by its competition had considerably reduced the price of the South American caoutchouc. From this time onward the sources of supply have been increasing as new modes of utilising it have arisen; and it is satisfactory to know that with proper care the produce of Indian rubber may be considered practically inexhaustible.

It is not a little curious that what is generally known as the Indian rubber tree, young plants of which are grown so largely in London rooms, is not the one which was first discovered, or which even now supplies the great bulk of the raw material. It is the Assam plant; whereas the South American one belongs to an altogether different family.

Fig. 1.—SIPHONIA ELASTICA.

The Euphorbiaceæ, or family of Spurgeworts, which are common in all the four quarters of the globe, all produce a milky juice, and it is this which in drying yields caoutchouc. *Siphonia elastica* is the tree from which it was originally derived. It grows in the low lands which form the basin of the great river Amazon. It is a true forest tree, growing up to a great height, generally 40 to 50 feet, before throwing off any branches; and sometimes reaching 80 to 100 feet in all. The trunk is usually 2 to 2½ feet in diameter. The crown is spreading and ornamented with a thick and glossy foliage, the character of which may be judged of by the accompanying drawing (Fig. 1). The milk may be collected at any period of the year, but it is considered best to do so in the dry season; and as the trees which have hitherto been tapped are those growing on the islands and in the swamps within the distance of 50 to 100 miles to the east of Para, there is an additional cause for choosing the dry season. This lasts from August to February. The trees, however, are not confined to this limited area; for Mr. Bates, on exploring the Amazon and its tributaries, found plenty of untapped trees in the wilds of the Tapajos, Madeira, Juruá, and Jauarí, as far inland as 1,800 miles from the coast.

The rubber—the original native name for which is *cahuchu*—

is collected in the following manner:—As soon as the dry season has set in, a party of Indians, men and women, proceed into the virgin forest to seek a clump of Siphonia trees, and when they have found a suitable sphere of operations, they cut paths through the wood to it. This is a work of no little difficulty, as, owing to the fertility of the soil and the tropical climate, the undergrowth forms a dense mass, and every step must be gained by the axe. Having effected a clearance, they make an incision in the trunk of each tree, about five or six feet above the ground, just below which they stick rude cups of clay to receive the milk as it flows out. Each morning they make a round of the trees to empty the cups of the milk, usually about a gill in quantity; and when the first incision ceases to yield, a second, and then in like manner a third and a fourth, is made. By this time the tree is exhausted, and it will not recover itself for a couple of years. The milk collected day by day is poured into larger vessels, and then the manufacturing of the rubber commences. For this purpose the natives gather together in heaps a quantity of Urucari or Inaja nuts, which, upon being set on fire, yield a thick oily smoke. Moulds of clay, in the shape of shoes, bottles, etc. etc., are prepared, which are dipped into the milk, and then held over the fire to dry. This is repeated day by day, until the articles have acquired sufficient thickness. The juice itself is yellowish, and of the consistence of thick cream, the dark colour of the manufactured article being due solely to the smoke in which it is dried. In some interior districts, where the nuts are not found, the rubber is sun-dried, and of a very light colour. For some little time after the smoking is finished the surface is rather sticky, and the several pieces would be liable to adhere together if they were allowed to touch; the shoes and other articles are therefore hung over horizontal poles to dry, and the natives usually bring their produce to market suspended in the same manner.

Several other kinds of Siphonia are to be found in tropical Brazil and Guiana, as well as other members of the family of Euphorbiaceæ, which also yield caoutchouc, but not in such quantity as the one above described.

The *Ficus elastica*—commonly known here as the Indian-rubber tree, from the diminutive specimens in rooms and greenhouses—belongs to the large family of Artocarpaceæ, which includes the Banyan, *Ficus Indica*—the largest of known trees—and the Breadfruit, which is the most prolific. The tree is found in great abundance in the forests of Assam and its neighbourhood; it is a true forest tree, of rapid growth, attaining 80 to 100 feet in height, with its branches extending to the distance of 75 feet in all directions from the parent stem. The larger branches throw out roots which descend to the earth, in the same way that the Banyan does. The incisions for the drawing off of the juice are made in the bark around the trunk, beginning at the base, or at the reflex roots, which generally lie exposed. The juice from the roots is found to be richest in caoutchouc. The oldest trees should be selected for the purpose of tapping, and the operation conducted in the cold season, as the juice then contains the largest proportion of solid, and the health of the tree is less affected than it would be were the sap withdrawn during the period of rapid growth. The bleeding may be repeated every fortnight; about 45 lbs. weight being obtained on each occasion. In India the rubber is sun-dried, so that it retains its light colour. The tree is generally to be found in the sheltered nooks of a rocky district; and as the region in which it is indigenous has as yet been only imperfectly explored, there are no precise data for estimating the probable supply from this tree. Sufficient, however, is known to assure an abundance of it for a long time to come. Other sorts of Ficus—the *Indica* and *religiosa*—also yield caoutchouc; and so does the Jack Tree, or *Artocarpus integrifolia*; but these are not usually tapped for the purpose.

Again, in the southern part of the Malay Peninsula, and in the great islands of Sumatra and Java, there is the *Urceola elastica*, belonging to the order Apocynaceæ, which yields the same product in great abundance. This plant, indeed, was the principal source of supply from the East prior to the introduction of that from the *Ficus elastica*. Its importance seems to have been discovered by accident, towards the close of the last century, the circumstance being recorded in the "Asiatic Researches" of 1798. It appears from the narrative, that in clearing a way through the jungle with cutlasses in the island of Penang, the juice which had collected on the blades turned on drying into a substance possessing all the characteristics of Indian rubber. The source of the juice was found to be a vine about as thick as a man's arm, which trailed along the ground for a great distance, sending out rootlets from each joint, and ultimately climbing to the top of the highest trees. Fig. 2 will show the character of its foliage.

Fig. 2.—URCEOLA ELASTICA.

These three plants which have been more particularly described are by far the most important that are yet known. But the families to which they belong are so widely spread, that there is every reason to expect that as the tropical regions both of the Old and New World are more thoroughly explored, many other districts will be added to the list of those which now produce this article. Its production seems to be greatly favoured by heat, as the milky juices of the Euphorbiaceæ which grow in temperate climates contain next to none of the solid matter; and it has been remarked by Humboldt that the proportion of it increases as the region from which they are derived is more essentially tropical.

The quantity of Indian rubber contained in the juice varies greatly, up to about 45 per cent. The rest consists almost exclusively of water, which is artificially expelled in South America, and by exposure to the heat of the sun in India. The

season of the year, the age of the tree, and other circumstances, all have their influence in increasing or decreasing the proportion of caoutchouc in the sap.

Caoutchouc is, in chemical language, a hydrocarbon; that is, a substance consisting of only the two elements, hydrogen and carbon. It would perhaps be more correct, however, to use the plural number, as it does not appear to consist necessarily of one, but rather of two or more hydrocarbons mingled together. The analysis by Faraday of a carefully selected sample gave the respective proportions at 87·2 per cent. of carbon, and 12·8 per cent. of hydrogen, which would indicate a composition of C_4H_7, or a multiple of those numbers. Other experimenters, however, have obtained results rather different from his, which points to the conclusion that it is not a strictly definite substance; and this is confirmed by experiment, for on dissolving it, one portion is often found to be more soluble than another, and the resulting solution cannot all be distilled over at a uniform boiling-point.

Under the microscope there is no evidence in Indian rubber of any structure, either fibrous or cellular, which would serve to identify it as of vegetable origin; and those who formerly declared it to belong to the mineral kingdom might have produced in support of their view an undoubtedly fossil hydrocarbon, also possessed in some measure of elasticity. Now-a-days, too, it is from the bowels of the earth that we derive the raw article from which by far the greater portion of our hydrocarbons are manufactured.

These, indeed, are common enough; but this one, prepared in Nature's laboratory, enjoys properties peculiar to itself, which render it specially interesting, and of the greatest importance in the arts. It will be as well to run over these cursorily at first, as they will call for fuller detail, when speaking of its manufacture and applications.

1. *Lightness.*—The specific gravity of the rubber made from the *Ficus elastica* is about 0·92, and of that from the Siphonia 0·94.

2. *Elasticity.*—In this respect it stands almost without a rival. After being softened by immersion in warm water, it can be drawn out to about eight times its natural length, to which it will return again on the tensile force being withdrawn. Its elasticity, moreover, can be suspended, and restored again at pleasure.

3. *Resistance to Pressure.*—This is the converse of the preceding. Whatever the compressive force that may be applied, the Indian rubber will recover its original bulk on the pressure being withdrawn.

4. *Insolubility in, and Imperviousness to Water.*—These qualities, coupled with the fact already mentioned of its being lighter than water, suggest at once a multitude of applications, if only the difficulties of manipulation are surmounted. How that is done will be seen presently.

5. *Resistance to the Action of Alcohols, Acids, and Alkalies.*—These qualities are of especial value to the experimental and manufacturing chemist.

6. *Resistance to Atmospheric Influences.*—The only important exception seems to be in respect to exposure to sunlight. In this case an oxidation of the substance takes place, which changes its character altogether; but the action only takes place if the rubber is kept perfectly dry.

7. *Non-conduction of Electricity.*—This is a circumstance of no little importance in connection with one of the most important developments of modern science, the submarine telegraph.

NOTABLE INVENTIONS AND INVENTORS.

XXXIII.—CHLOROFORM.

BY JOHN TIMBS.

THE employment of *anæsthetics*, or substances for producing temporary insensibility to pain, had been known and practised for ages before it was discovered that by the use of chloroform pain might be put completely under the dominion of the human will. *Anæsthesia*, as such agency is termed, was known 1,800 years ago, when the Greeks and Romans used the root of the mandrake "to cause insensibility to pain in those who are to be cut or cauterised; for, being thrown into a deep sleep, they do not perceive pain." Pliny tells us that the juice of mandragora had a narcotic effect as a remedy for injuries inflicted by serpents, and before incisions were made in the body, in order to ensure insensibility to pain. "Indeed," he adds, "for this last purpose, with some persons, the odour of it is quite sufficient to induce sleep." "Again, by drinking mandrakes with wine," says Apuleius, "a limb may be cut off without any sense of pain." All narcotic medicines will produce conditions of anæsthesia in which surgical operations may be performed without pain; and during the operation of alcohol on the nervous system in drunkenness, operations have been performed without the knowledge of the patient.

It has been discovered by M. Stanislaus Jullien that the Chinese, in the third century of our era, employed an anæsthetic agent, in the same manner as we use chloroform and ether, for producing insensibility during surgical operations. It is stated that Hoa-tho, who flourished between the years 220 and 230 of our era, gave to the sick a preparation of chanvre (*ma-yo*), when, in a few moments, the patient became as insensible as one plunged in drunkenness, or deprived of life; then, according to the case, he made incisions, amputations, etc. After a certain number of days the patient found himself re-established, without having experienced during the operation the slightest pain. This *chanvre* is prepared by boiling and distillation, and is set down as the Indian hemp, which is taken even now by the Arabs to produce agreeable intoxication. Theodoric, a surgeon in the latter half of the thirteenth century, in his work on surgery, mentions "a flavour for performing surgical operations," made of "opium, mulberry, henbane, hemlock, mandrake, wood-ivy, and lettuce, to be boiled until concentrated in a sponge, which, when wanted, was to be warmed, and applied to the nostrils of him who is to be operated on, until he has fallen asleep; and so let the surgery be performed." In 1579 Bulleyn described "the possibility of setting patients into an anæsthetic state during lithotomy, etc.," by the use of mandrake.

The narcotic and anæsthetic properties of Indian hemp were known to the Scythians, who inhaled the fumes of hemp-seed thrown upon red-hot stones; and Indian hemp has been set down as the *Nepenthes* of Homer, which was brought from Egyptian Thebes. Bang, which is prepared from Indian hemp grown in Africa, is taken by criminals who are condemned to suffer amputation; and Sir Joseph Banks testifies to this use of it. This hemp is smoked in Congo, Angola, and South Africa; its leaves, seeds, and flowers are pounded and mixed with a confection, a piece of which, the size of a walnut, when eaten, will deprive a man of reason, and is described as "the increaser of pleasure."

Towards the close of the last century, Lassard, a surgeon of Paris, recommended the employment of a narcotic previous to serious and painful operations; and in a work by Meissner, in 1782, it is stated that Augustus, King of Poland, was surreptitiously narcotised by his favourite surgeon, Weiss, while a part of his foot, which had mortified after being wounded, was cut off without pain or consciousness. Shakspeare, in "Cymbeline," describes the imagined effects of subtle distilled potions, producing, without danger, a prolonged state of death-like sleep or lethargy.

The history of the various anæsthetic agents is interesting; but it was only by the science of chemistry that the seekers after a perfect anæsthetic agent were guided in the true direction; and it was ascertained that by means of the inhalation of various kinds of gases many maladies would become amenable to the power of the physician. In 1799 Humphry Davy breathed nitrous oxide, which he found to lessen the pain of cutting a wisdom-tooth; and although he did not succeed in establishing nitrous oxide as a medicinal agent, in describing the effects of this gas he predicted that, "as nitrous oxide, in its extensive operation, seems capable of destroying physical pain, it may, probably, be used with advantage during surgical operations in which no great effusion of blood takes place." Nor was this an accidental conception of genius, but the result of ten months' experiments; so that Davy must be acknowledged as the originator of that prolific idea which has become one of the most glorious realities of the present century. Davy also foretold that pneumatic chemistry, in its application, was an art in its infancy; and had his prophecy and precepts then been heeded, "it is probable that pain would have been put into subjection to the intellect at the very beginning of the present century."

Forty-four years had, however, to elapse after Davy's

announcement that, "as nitrous oxide seems capable of destroying physical pain, it may probably be used with advantage during surgical operations," before this pregnant suggestion was acted on. In 1818, an article believed to have been written by Mr. Faraday, and published in the *Quarterly Journal of Science*, describes the great resemblance between the effects of the vapour of ether and those of nitrous oxide gas. In 1844, Horace Wells, a surgeon-dentist of Hartford, Connecticut, United States, having inhaled the gas, another dentist, Dr. Rigg, drew one of his teeth without pain, and Mr. Wells, after recovering from the inhalation, exclaimed, "A new era in tooth-drawing!" He then made other experiments, with various success; but a failure so annoyed him, that he became unsettled, came to England, returned to America, and at length died by his own hand, in January, 1848. Within three months Dr. Bigelow, of Boston, United States, removed a breast from a patient who had been rendered insensible by inhaling nitrous oxide. Next, Morton, Wells's pupil and partner, and Dr. Jackson, took up the idea, and having discovered that ether was much preferable for this purpose to nitrous oxide, they made known the important fact that under the influence of this agent insensibility might be produced under which persons might undergo the most severe operations without pain, and might be restored from this condition without injury to their health. On September 30, 1846, by the inhalation of ether Morton made himself unconscious during eight minutes; he also persuaded a patient to inhale ether from a handkerchief, and then extracted a bicuspid tooth, of which the patient knew nothing till he recovered his senses. The remedy was afterwards frequently used. Notwithstanding this success, the American medical journals condemned the discovery as a quackery, confirming the proverb, that "a prophet hath no honour in his own country;" the English journals, however, at once rightly appreciated it, though in November, 1846, the Paris surgeons received the announcement with all but indifference. Velpeau politely declined even to test its worth; yet, in January, 1847, the two great surgeons, Velpeau and Roux, averred, in the presence of the two Academies, that the discovery was "a glorious conquest for humanity."

In London the action of this new agent was extensively tried, and rightly appreciated. In January, 1847, the first experiment was made in England by employing the inhalation of sulphuric ether as a means of rendering surgical operations painless. The application had been communicated by Morton to Dr. Boott, of No. 24, Gower Street, who described it to Mr. Robertson, the surgeon-dentist, also of Gower Street. This gentleman, on the following day, operated upon a lady thrown into sleep by the inhalation, during which a molar tooth was extracted from her lower jaw. The inhalation occupied a minute and a half, and the patient's recovery from sleep another minute. Dr. Boott questioned her respecting the tooth, and she expressed her great surprise at finding that it was removed. She said that all she felt was merely a sensation of cold around the tooth, a sensation which was caused, perhaps, by the coldness of the extracting instrument. The apparatus employed consisted of the lower part of Nooth's apparatus, with a flexible appendage, to which was attached a ball-and-socket valve and mouth-piece, similar to those commonly employed for inhalation, together with a nasal spring. The full effect of the vapour was produced in from one to two, or three minutes generally, and as soon as it was perceived, the operation was performed.

Among the early cases recorded is that Mr. Liston, of University College Hospital, on December 21st, "amputated a thigh, and removed, *by evulsion, both sides* of the great toe-nail, without the patient being aware of what was doing, so far as regards pain;" he heard what was said, and was conscious, but felt neither the pain of the incisions, nor that of tying the vessels. Next, a patient in the Royal Infirmary, Edinburgh, was etherised, and had a limb amputated by Dr. Duncan, "without the infliction of any pain."

"Alas! that we must close this brief history of the discovery and application of the anæsthetic properties of ether, by stating that Morton shared the fate of almost every discoverer, viz., poverty, and the danger of being deprived of the honour of the discovery. The excitement of it injured his health. Having taken out a patent for it, and hoping, doubtless, that it would make his fortune, he neglected his business. Jackson, although he was content to get only a third share of the patent, claimed the whole merit of the discovery in a paper which he sent to the French Academy, and in which he suppressed Morton's name. Chloroform quickly superseded ether, and Morton found his patent valueless, his business destroyed, and even the bare honour of the invention wrested from him. But the pain with which we think of his misfortunes is greatly lessened by the knowledge of his attempt to keep his discovery a secret, and, under the name of 'Letheon,' to secure the possible profits of it exclusively for himself, by means of a patent, contrary to the usages of the profession." (Dr. Chapman, *Westminster Review*, 1859.)

A month after the first application of ether in England, Dr. Simpson, of Edinburgh, discovered that by its instrumentality the ordinary pains of maternity might be averted without danger. The remedy was used also, with a greater or less degree, in some of the most fearful and painful diseases; and by its aid many persons were rescued from certain death who must otherwise have undergone a difficult and most painful operation.

Ether, the first agent employed in this great revolution, is said to have been known to Raymond Lully and Basil Valentine the alchemists. In 1540 Valerius Cordus described the method of making it—the *oleum vitrioli dulce*, as he termed it. It consists of 4 atoms of carbon, 5 of hydrogen, and 1 of oxygen. It is usually procured by distilling common alcohol (the hydrated oxide of ethyle) with sulphuric acid; hence its usual name of sulphuric ether; its present chemical name is oxide of ethyle. "Ether," says Dr. Frobenius, "is certainly the most noble, efficacious, and merciful instrument in all chemistry and pharmacy, inasmuch as essences and essential oils are extracted by it immediately, without so much as the mediation of fire, from woods, barks, roots, herbs, flowers, berries, seeds, etc., from animals, and their parts, too."

The mixture, improperly called chloric ether, which is simply a solution of chloroform in alcohol, was, early in 1847, demonstrated by Mr. Jacob Bell to possess anæsthetic power. He exhibited its effects at St. Bartholomew's and Middlesex Hospitals. Mr. Waldie, of the Apothecaries' Hall of Liverpool, first acquainted Professor Simpson with the properties of chloric ether, which was mentioned during conversation, and Mr. Waldie being well acquainted with its composition, and with the volatility, agreeable flavour, and medicinal properties of chloroform, recommended the professor to try it. Acting on his advice, Dr. Simpson procured chloroform, undiluted, discovered the effects of its vapour, and thus bound his name indissolubly with one of the greatest boons ever conferred on man.

FARMING AND FARMING ECONOMY.

XVII.—FATTING CATTLE.

By Professor Wrightson, Royal Agricultural College, Cirencester.

Cattle may be fattened at any age. Calves, yearlings, and two-year-olds have all been made ready for the butcher, but the usual and best plan is to delay the process until the animal has arrived at something like maturity. This, owing to the improvement which has been effected by breeders of stock, takes place much sooner than was formerly the case, and at two-and-a-half years old steers commonly find their way into the fatting stalls.

In the management of fatting cattle care must be taken that the animals are quiet and comfortable, and that they are regularly supplied with sufficient quantities of suitable food and water. Each of these points is important, and we are therefore led to inquire, how cattle are best made comfortable? What is a sufficient supply of food? What foods are most suitable for fatting stock? and afterwards we shall discuss the questions of cost and return.

ACCOMMODATION FOR FATTING CATTLE.

Cattle are fed in fold-yards, boxes, and stalls, or byres. As we intend on a future occasion to devote a chapter to the subject of farm buildings, we defer the consideration of the structure and dimensions of these several kinds of accommodation. Small, well-shedded and spouted (troughed) fold-yards, protected from the north and east, give excellent shelter; but, owing to their being open and exposed to rain, they require a

large quantity of straw to be used as litter. The manure made in fold-yards suffers in quality from this reason.

The *box* system provides a separate apartment for each animal, and the boxes being arranged in a continuous series, the cattle have the advantages of society without any of its annoyances. Heifers, being apt to fight with each other, are the better for this restraint. Boxes, besides the above advantages, necessitate a smaller amount of straw as litter, and ensure a high quality of manure, owing to the protection they afford from rain.

The *byre* is almost universally employed for milch-cows, and is also used for fatting cattle. Tying up animals for long periods of time, as in the case of fatting cattle, is however unnatural, and unless the curry-comb and brush are freely used, they soon become dirty in the coat, the hair falls off in patches, and the skin becomes irritable. The hoofs of cattle so confined also grow to such an extent as to be impediments to the progress of the unfortunate animal, when at length he has to be driven to the shambles. These evils may with proper care be avoided, and this being granted, the byre possesses solid advantages. Where space is an object, no system of housing will accommodate so large a number of cattle in a given area, and it is the most economical method with regard to straw. The manure is, however, not well mixed, owing to the constrained position of the animals, and for this reason the litter ought to be daily removed, and spread evenly over a fold-yard, there to be further trodden down by young stock, and turned over by pigs. Whatever system is adopted, it is essential that the animal should have a comfortable bed, be protected from cold winds, supplied with water, and kept quiet.

FOOD AND FEEDING.

The selection of suitable foods and the best methods of giving them are the most important considerations in feeding cattle. We do not propose to study the chemistry of foods, but rather to adhere to a simple statement of the best agricultural practice. Accordingly, we find a few well-known vegetables and vegetable products employed for this purpose, among which we may name the following:—Turnips, swedes, mangel, hay, straw, grass, clover, vetches, and other root and forage crops; also linseed, cotton, rape, and poppy seed cakes; barley, bean, and pea meal; lentils, locust beans, Indian corn, buckwheat, millet, and many other similar substances which, from time to time, are brought before the attention of farmers. There are also artificially prepared cattle foods, such as Thorley's, Beache's, and Simpson's, which may be used with advantage as condiments in exceptional cases, but are too expensive for general purposes. Of these feeding materials, the first few mentioned are those most generally employed.

Cattle-feeding is carried out upon the most simple principles in the north of England and Scotland. There, an abundant crop of swedes may be generally obtained, and these of higher quality than the roots grown in the south. Comparing north and south country practice, we have in the former case heavy root-crops of superior quality, and in the latter case precarious and light root-crops of inferior quality. This alone must make a great difference in the practice of cattle-feeding, and hence we find that while in the north the staple foods are turnips and straw, supplemented at the later stages by comparatively small quantities of cake and meal, in the south of England the amount of roots is lessened, while that of the "artificial" or dry foods is very much increased. Appliances such as the chaff-cutter, the root-pulper, and apparatus for cooking food, have also found more favour in the south than in the north. Were we to describe cattle-feeding as carried on north of the Tyne, our task would be sufficiently simple. There, fresh or "forward" beasts are placed in folds or boxes, supplied with a liberal allowance of turnips and straw, and as they approach fatness, with from 3 to 7 lbs. of linseed cake or a "crowdy" of meal. In the summer of 1866, the writer visited some of the best farmers in Berwickshire and Lothian. At Edington Mains, Mr. Wilson's cooking apparatus had not been used for the last year or two, and a general impression seemed to exist that the old method of turnips and straw, supplemented with from 5 to 7 lbs. of cake or corn, was after all the most successful plan. One great object of cattle-feeding in Berwickshire is to crush down straw into manure; and to this end, it is extremely common in good homesteads to find the yards unspouted, so that the rain-water may do its part in turning the straw into manure. "Mr. Lyal's (Green Knowe, Gordon) method of feeding cattle is simply turnips and straw, both given whole, and supplemented by moderate quantities, 5 to 7 lbs., of oilcake. The fold-yards are also kept unspouted, so that the rain-water may help the crushing of the straw into manure." (*Agricultural Gazette*, Aug. 27, 1866.)

Mr. Wilson, of Edington Mains, tells us in his "British Farming," 1862, that "important changes have now been introduced," but the day is still distant when the pulper, the chaff-cutter, and other improvements will become general. The plan pursued in the south may be illustrated by the practice followed on the College Farm, Cirencester (1866), where the cattle are placed in boxes, and receive a liberal allowance of cake and corn, chopped straw, a little hay, and a very small allowance of roots. From 50 to 100 lbs. of roots may be reasonably given to a fatting bullock, but in the case just cited they generally only receive 20 lbs.—a smaller quantity than we have ever known given, except in cases in which cattle are fed without roots. The amount of food varies with the weight and condition of the bullock, and is gradually increased towards the end of the fatting period as follows:—The cattle commence in October with 5 lbs. of meal, 2 lbs. of cake, 20 lbs. of roots, chaff, and a little hay. In November the food is changed to 7 lbs. of meal, 2 lbs. of cake, and roots, chaff, and hay as before. In January the food is again changed to 9 lbs. of meal, 2 lbs. of cake, 1 lb. of "cattle food," roots, etc., as before. This is continued until the termination of the fatting process. The food should be given regularly, and often. Thus on the College Farm the cattle are fed seven times a day:—

At 5.30 to 6 a.m., meal, chaff, and a few turnips (just to moisten the chaff).
At 7.30 to 8 a.m., 20 lbs. of sliced roots.
„ 9.30 a.m., meal and chaff.
„ 12.0 a.m., oilcake and chaff.
„ 2.0 p.m., meal and chaff as before.
„ 4.30 p.m., ditto, ditto.
„ 6.0 p.m., 4 lbs. of hay.

The quantity of meal and cake will vary as above, but it is divided pretty equally—the 4.30 meal being, if anything, the heaviest.

In a prize essay contributed by Mr. Dobito to the sixth volume of the *Royal Agricultural Society's Journal*, a very good system of cattle-feeding is explained. Mr. Dobito commenced with tankard white turnips, and 7 lbs. of pollards per day. Early in November the following system was practised:—The first thing in the morning the cattle received 1 bushel of swedes, cut small in a Gardner's sheep turnip-cutter. When these were eaten, the troughs were cleaned out, and the animals then received 2 lbs. of oilcake, 3 lbs. of pollards, and a little hay chaff. While eating this the litter was removed, the floor made clean, and each bullock was brushed with a whalebone horse-brush. The cattle were then left to ruminate and rest. At midday each bullock received another bushel of swedes, and a repetition of the dry food with the addition of 3 lbs. of bean meal. According to this very liberal system of feeding, each bullock received 13 lbs. of cake and meal, hay, and 2 bushels of cut swedes. We conclude our account of cattle-feeding by abstracting a sentence or two from Mr. H. M. Jenkins's report upon the farm of the late Mr. Hudson, of Castle Acre, Norfolk (1869). From 100 to 140 beasts, steers (mostly shorthorns), are bought in every year at Peterborough Fair. These steers are placed in small well-shedded fold-yards, and receive 2 bushels of roots and from 10 to 12 lbs. of linseed cake each per diem, as well as a bushel of cut hay or cut straw after the hay is finished. They begin to go off fat in January, and ought all to be sold by May.

COST AND RETURN.

The cost of fatting a bullock has often been stated to be at the rate of from 6s. to 7s. per week. It is by no means easy to arrive at an absolute result, as much depends upon the price at which the green food, turnips, and other home produce, not usually marketed, are valued. Taking a liberal system such as that employed by the late Mr. Hudson, of Castle Acre, the linseed cake alone would, at £12 per ton, cost 1s. per day, and the hay, roots, and attendance might increase the amount by 6d., making in all 1s. 6d. per day, or 10s. 6d. per week. Mr. M'Combie, of Tillyfour, Aberdeenshire, considers his show bullocks cost him above 12s. per week, while another agricul-

turist has estimated the cost of ordinary fatting cattle as low as 6s. per week. The cost of feeding cattle of ordinary size may be thus calculated:—

	d.
6 lbs. of linseed cake per day, at £12 per ton	7·7
4 lbs. of barley-meal, at £8 per ton	3·2
56 lbs. of turnips, at 5s. per ton	1.5
5 lbs. of hay, at £4 per ton	2·1
Attendance at the rate of $\frac{1}{40}$ of the wages of one man, at 14s. per week	0·6
	15·1

According to this estimate, the cost would amount to 15d. per day, or 8s. 9d. per week.

The question of return is still more difficult to solve. Cattle pay for their food by the manure they leave, as well as by beef produced. The fact that cattle are looked upon by many agriculturists as mere manufacturers of manure, indicates that there is not much direct profit. In other words, if an animal pays for all that is expended upon it without leaving any profit, the farmer is still satisfied, because he has the manure for his land. If a bullock lays on 1 stone (14 lbs.) of beef per week he is doing well, and a glance at the foregoing estimates of cost clearly shows that, with beef at 8s. or even at 10s. per stone, there is no great room for profit, while at the same time neither interest nor risk is charged. We have heard of bullocks increasing at the rate of 3 lbs. per day, but this must be viewed as an extreme case, doubtless caused by an extra allowance of food. In spite of the recent high prices of butcher's meat, it is therefore evident that the winter feeding of bullocks is not highly remunerative, when the grazier purchases lean stock at an extravagant price. Either by very judicious and fortunate purchases, by taking advantage of favourable changes in the market, or better still, by bringing up calves, and thus avoiding the extreme prices now realised by lean stock, the fattening of cattle may be made a profitable occupation to the agriculturist.

SHIP-BUILDING.—XX.

BY W. H. WHITE,

Fellow of the Royal School of Naval Architecture, and Member of the Institution of Naval Architects.

WATER-TIGHT FLATS.

NEAR the extremities of ships, and below the lowest complete deck, partial decks or platforms are very often constructed, to form the floors of store-rooms, etc. These platforms are usually supported upon light beams, and in some cases are of considerable length. In addition to their usefulness in the particular just stated, they add to the strength of the structure, forming strong ties between opposite sides, and helping to support the bow in case of collision. This is true in all classes of ships, whether wood, iron, or composite; but in iron ships such platforms can, by means of light plating worked upon the beams, be also turned into horizontal water-tight partitions, adding much to the safety of the vessels. In fact, this method of water-tight subdivision is well adapted for use at those parts where the forms of ships necessarily become very fine, and is probably preferable to other methods of subdivision. As an example in point, we may refer to the iron-clad ships of the navy. Their double bottoms do not extend throughout the length, but only over, say, two-thirds of the length, leaving something like one-sixth of the length at the bow, and another one-sixth at the stern, without the protection of an inner skin. At or near the endings of the double bottom, transverse water-tight bulkheads are placed; and from these bulkheads to the extremities water-tight platforms, or flats, are built. The sizes of the compartments so enclosed are not large, because the form is very fine at these parts; and they are subdivided in nearly all cases by transverse bulkheads, as well as by the partitions built in the hold for special purposes—*e.g.*, for stowing the cables, provisions, and stores, for enclosing the shaft-passage, etc. By all these arrangements a comparatively minute water-tight subdivision is secured, without fitting an inner skin; and the advantage gained will be seen more clearly when it is considered that the section of the flat, at any cross-section of the ship near the extremities, corresponds roughly to the base of a triangle, of which the two sides would have to be plated over if an inner skin were fitted. In the *Great Eastern*, we believe, the inner skin is continued quite forward to the bow, but ended some distance from the stern. Mr. Scott Russell has, however, since expressed the opinion that it would have been better not to have followed this course; and from the foregoing considerations the reason will be obvious.

It need hardly be said that all openings or hatchways made in water-tight flats, for the purpose of gaining access to the spaces below them, must be supplied with water-tight covers of some kind. It very often happens that the spaces below the flats are not made use of, being very confined, and only visited for the purpose of inspecting and cleaning or painting the framing and plating. The openings, or man-holes, in the flat can then be closed by simple plate-covers, secured by nut-and-screw bolts, red-lead or some other material being used as a "stop-water" in the joints, and the covers being nearly always in place. Where use is made of the space below a flat for stowage—as is not uncommon in large ships—it is necessary to leave the hatchways open under ordinary circumstances, providing some form of scuttle or cover that can be quickly closed and secured in case of need. One of the simplest and best plans is to hinge the scuttle to one side of the framing round the opening in the flat; and then on any sudden alarm the scuttle can be turned down into the rabbet formed to receive it, its security being ensured by catches similar to those fitted to hinged water-tight doors. India-rubber beading is also commonly fitted in the rabbets of these scuttles to make the joints water-tight. Other plans of scuttles have been fitted, but we need not describe them, as they are only minor features of construction.

It will be remembered that the main objection to the use of closely-spaced transverse bulkheads in merchant ships is based upon the difficulty which ensues in stowing the cargo. Admitting the force of this objection, some persons have proposed to substitute horizontal flats for transverse vertical partitions, and so to leave *long* cargo spaces without rendering the individual water-tight compartments so large as to compromise the safety of the ship. One of the best schemes of this kind was patented by the late Mr. Lungley, who termed it a plan for constructing "unsinkable" iron ships. It may be briefly described as follows:—The cargo-hold is subdivided by several horizontal platforms, formed of water-tight plating. To each of the spaces thus enclosed, access is obtained by means of a water-tight "trunk" or "shaft," leading up to the height of a deck, situated considerably above the loadwater-line. Cargo would be introduced into the several spaces down through these trunks; and it will be obvious that if any one of the compartments were "bilged," the water which entered would be confined to it, and to the trunk connected therewith. The lowest water-tight flat really constitutes an inner skin, as it was intended by Mr. Lungley to place it so low down in the vessel that no cargo should be stowed below it. In steamships, the intention was to place the machinery in compartments constructed on the usual plan, with transverse bulkheads; and other transverse subdivision was to be introduced where it did not interfere with the stowage. Although favourably mentioned by several authorities, this plan has not found favour with ship-builders, nor does it seem likely to do so. It involves additional cost in construction, and moreover does not lend itself so readily as other plans to the efficient combination of structural strength with lightness and safety.

It may be interesting to refer in passing to other proposals that have been made again and again, especially in connection with ships of war, to render them practically unsinkable by means of minute water-tight subdivision. The matter is deserving of attention, because the progress made in the construction of powerful guns, the use of torpedoes, and the employment of steam-rams, has led many persons to believe that the use of armour-plating for the protection of war-ships will have to be discontinued, and "unsinkable" unarmoured ships built instead. Into this discussion it would be out of place to enter here; but it should be noticed that great practical difficulties would require to be overcome, before the subdivision could be made so minute as to give the desired degree of safety. Room must be had, for example, for the engines and boilers, and so some large compartments must be formed. Moreover, convenience of stowage in magazines, shell-rooms, store-rooms, etc., would have to be sacrificed, and all facilities for communication between different parts would be done away with. Improvements

in many respects, particularly in the construction of marine engines, may do much to remove these difficulties; but at present the preferable and most natural course appears to be that actually followed in our armoured ships—viz., to provide a good double bottom and numerous main transverse bulkheads; then utilise to the utmost possible extent the partitions erected primarily from considerations of stowage; and supplement this by such further water-tight subdivision as may be conveniently applicable.

PARTIAL BULKHEADS.

A description has already been given (Vol. III., page 182) of the partial bulkheads, or deep plate-frames, fitted in ships built on Mr. Scott Russell's longitudinal system. Strengthenings of a very similar character are sometimes fitted in ordinary iron vessels, with transverse framing, at parts where special transverse strength is required, or in cases where experience proves that the strength provided originally was insufficient. With numerous transverse bulkheads they are not, of course, needed; but when the cargo-holds are very long, and especially at parts adjacent to the main hatchways, where the decks are cut away considerably, such partial bulkheads are of considerable value. They consist simply of a deep plate-frame with single or double angle-irons on the edges. The plate-frame has often to be made in several lengths, which are well fitted and strapped at the butts, in which case the frames extend from gunwale to gunwale. In other cases the partial bulkheads are only extensions of the main transverse bulkheads, being fitted above the decks at which those bulkheads end. The latter arrangement has been adopted also in a few wood ships, which have transverse bulkheads in the hold and iron deck beams.

Under this head it will not be out of place to describe briefly the stern strengthenings fitted to the recent wood-built screw steam-ships of our navy. One of the great difficulties to be overcome in constructing such vessels, is to give to the overhanging stern that amount of strength which is needed to resist the severe local strains produced by the action of the screw propeller. The weakness at the stern displayed by many merchant steam-ships built of wood, had much to do with the rapid introduction of iron steamers; and in some of the finest unarmoured wood ships of the navy similar weaknesses were developed, the stern drooping and working considerably in spite of the precautions taken. Various means were tried to obviate this evil, one of the most common being the use of strong metal knees bolted under the ship's counter, and against the sides of the stern-post. Again and again, however, these knees were broken, until they were made of massive proportions, and even then the strains due to the propelling apparatus were not satisfactorily met in vessels with great steam power, until a simple but efficacious arrangement of internal iron strengthenings was devised, which has proved most successful in all cases. Its main features are as follow :—

The beams of the deck to which the upper ends of the stern-posts are connected are covered with strong iron plating, from the fore or body post to the stern. Between the two posts, and upon the inside of the counter, a strong iron-plate knee is fitted at the middle line, and connected with the posts and the counter by double angle-irons. In wake of each post, and between it and the ship's side, strong transverse bulkheads are fitted, their upper edges being riveted to the deck plating, and their other edges connected with the posts and the ship's sides by double angle-irons. The upper parts of the posts, within the ship, are covered with strong iron plates, in order to ensure a satisfactory connection between them and the iron strengthenings. It should be added that large holes are cut out of the central portions of the transverse bulkheads—thus turning them into "partial" bulkheads—and that stiffening angle-irons are fitted around the edges of these holes. These main strengthenings are supplemented by iron hooks and braces on the lower part of the stern before the body-post, by short iron flats on the lower-deck beams, and by external metal knees under the counter, all of which contribute to the rigidity of the stern.

Iron screw-steamers, even of the greatest power, can be made sufficiently strong at the stern without any of these supplementary strengthenings. In the extremely fine part of the run abaft the stuffing-box bulkhead, it is usual to form the lower portions of the transverse frames of lightened plates, with angle-irons on the edges, and in some cases horizontal frames, or flats, are combined with these transverse frames. No other features worthy of note on account of their speciality are generally adopted.

HOG-FRAMING, ETC.

Under this head, we desire to glance at some special forms of longitudinal strengthening used in American river steamers, and a few other vessels, but not common in sea-going ships.

It is well known that American river steamers have enormous superstructures built upon comparatively light and shallow hulls, being in fact floating hotels of two or three storeys in height. Moreover, their weights of engines, boilers, etc., are disposed in a very unusual manner, being often concentrated in very short spaces of the length; and this fact, taken in connection with the excessive fineness of form given to the hull, in order to attain high speed, renders the longitudinal bending strains brought upon the structure very great. The question arises, therefore, how is the necessary strength supplied, seeing that the superstructure is built almost exclusively with a view to accommodation, and helps the hull proper scarcely at all? And the answer is, by means of the hog-frame, or some similar plan. These hog-frames are really strong timber girders, capable of resisting either tensile or compressive strains, and are sometimes two or three times as deep as the hull proper. When so high they are built as follows :—Strong vertical struts of timber are erected, and strongly secured at the heels to some portion of the hull. Upon the heads of these struts a strong longitudinal scarfed beam is fitted, and forms the top of the girder. Diagonal struts are also fitted between this beam and the hull, in order to maintain the rigidity of the girder. Our meaning will perhaps be more clearly understood, if we say that these hog-frames may be fairly compared to the side-girders commonly fitted to timber bridges, and help the shallow hull just as those girders help to sustain the platforms of the bridges.

In cases where less strength is required, shallower hog-frames will suffice, and sometimes these are built in the hold, the vertical struts then being heeled on strong longitudinal keelsons, and made to extend up to longitudinal beams fitted under the lowest tier of deck-beams. It is interesting to remark that this latter arrangement, which is now extensively used in America on the western rivers, is identical in principle with a plan proposed by the great French writer Bouguer, more than a century ago. He was much impressed with the excessive hogging commonly occurring in the ships of that period, and to remedy it, proposed to construct what we should now call a hog-frame at the middle line, the keelson forming the lower flange of the girder, and a continuous carling or longitudinal beam being fitted under the lower deck beams. This plan is obviously applicable to sea-going ships, but the first-mentioned, where very deep hog-frames are employed, would scarcely be so. Of course, river steamers are not subjected to such severe strains as sea-going ships have to resist; but, on the other hand, the latter class in nearly all cases have the hull proper much deeper than that of river steamers, and (as was before shown) this increase in depth leads to a very great addition of strength in the hull itself, supplementary strengthenings not being so requisite, if at all required.

Before passing on, it may be interesting to add that the Americans generally end their hog-frames at fifty feet or so from the ends of the steamers, and that they support the extremities by means of what they term "masts and guys." This is a very simple but apparently effective device, and consists in erecting strong masts at parts of the ship where there are excesses of buoyancy, and then leading chains or "guys" from the tops of the masts down to parts, especially near the bow and stern, where there is an excess of weight. It will be obvious that, while this plan may answer very well in river steamers, where the strains at the bow and stern always tend to make those parts droop, it would not be applicable to sea-going ships, which when at sea may be subjected to sagging strains throughout the length. The guys are, of course, only efficient against tensile forces, and are only strained in that manner in the cases where they are employed; they are also subjected to no sudden and great variations of strain, like those experienced by the structure of a ship at sea. We mention these arrangements, therefore, rather as examples of simple plans adapted to particular uses, than as suited for general application, or as illustrating principles of construction.

In some iron and steel shallow-draught vessels, built for

service in the rivers of India and elsewhere, lattice-girders, serving the same purpose as hog-frames, have been fitted. With iron or steel, such girders can be made both stronger and lighter than when built of wood, and are also most simple in construction. It may be that hereafter girders of a somewhat similar character will be used as strengthenings in sea-going ships, if their dimensions be much increased as compared with our present ships, and a longitudinal system of framing be adopted. In bridge-construction the lattice principle is now very extensively employed; and, although not so well adapted to ship-building, it appears probable that the same principle may be applied to some extent with advantage.

In concluding these remarks on some of the principal special provisions for strength and safety, we would once more remind our readers that, within the limits of this series of articles, it is impossible to do more than sketch the main features of ship-construction; and we would refer such as may desire a fuller acquaintance with the subject, to the numerous published works giving detailed information.

SILVER.

ORES—ASSOCIATION WITH GALENA—GEOGRAPHICAL DISTRIBUTION—ASSAYING—SEPARATION OF SILVER FROM LEAD—PATTINSON'S PROCESS—ACTION OF ZINC.

STRICTLY speaking, it can hardly be said that we possess any silver ores in the British Isles, though, as has been stated in Article XXIV., the production of silver in this country is very considerable. It is true that specimens of native silver, as well as some of its ores, extracted from British mines, are to be found in mineralogical cabinets; and also that some of the Cornish mines have yielded native silver, and the sulphide and arsenide of silver to the value of some few thousand pounds sterling. In no case, however, have these mines been worked for the sake of this metal alone.

It is as an almost constant associate of lead that we look for our supply of British silver. Those ores of lead which occur in the older rocks, such as the lower Silurian and Devonian, generally contain the largest per-centage. Thus the lead ores of the Isle of Man yield fifty to sixty ounces of silver to the ton of lead, those of Cornwall and Devonshire about thirty ounces, those of Cardiganshire and Montgomeryshire fifteen to twenty-five ounces; while the great deposits of lead ore in the Carboniferous limestone often yield so little, as not to be worth the cost of separation. The annual yield from this source is steadily increasing; the average produce of the British mines for the ten years ending with 1868 was 666,804 ounces, while the two last of the decade contributed to this average 805,394 and 841,328 ounces respectively.

The principal European supplies are drawn from Spain, where genuine silver ores occur; from the Austrian Empire, in which the silver is for the most part associated with copper; and from Saxony and Prussia, where the ores consist principally of argentiferous lead.

More than three-fourths of the whole supply of silver comes from the New World. Mexico, until within the last few years, has always headed the list by far; but the great discoveries of late in some of the most recent acquisitions of the United States have caused even Mexico to be outdone by its modern rival. The whole of the mountain chain which may be considered the backbone of America, extending from the southern Andes in Chili to the Rocky Mountains in the north, is more or less argentiferous; and the produce throughout the whole length of this region would be very much greater than it is at present, were there a larger working population, and greater facilities of communication.

The assaying of silver ores, so far as concerns Englishmen, will principally have reference to the argentiferous lead; but something should be said as to how to treat silver ores proper, as they are always liable to be met with, especially in mining for copper. If they contain much earthy matter, they may generally be most conveniently treated by fusing them in an earthen crucible with some carbonate of soda and borax, and more litharge than is necessary to take up the silver in the ore, so as to yield an alloy which shall be moderately rich in the precious metal. The mixture is melted in an ordinary assay-furnace, until the slag has become quite liquid; it is then poured out into an iron mould, and on cooling, the button of alloy will be found at the bottom. This has then to be cupelled in order to separate the silver from the lead. The cupel, upon which this operation is conducted, is made of bone-ash ground up with water, pressed into a mould, and hollowed out in the centre. The cupel, which must first be perfectly dried, is placed in the muffle of an air-furnace, and gradually raised to a bright red heat. The button of alloy is then placed in the hollow of the cupel, where it soon melts; and the air passing through the muffle over the surface of the metal, oxidises the lead in the alloy, and converts it into litharge. This is absorbed by the bone-ash of the cupel as fast as it is formed, and so the silver is ultimately left behind in a state of purity. When cold, the bead of silver is taken out and weighed; from the weight has to be deducted the quantity of silver that may have been present in the litharge, and the result will be the quantity of silver in the ore. This correction for the silver introduced through the litharge is necessary in all exact determinations, but it occasions little trouble in practice, as one testing of the litharge will suffice for a whole parcel; the litharge itself is tested by cupellation, and if necessary, can be done simultaneously with the other.

If the silver ore contains a large proportion of the sulphides of other metals, it may be conveniently assayed by the scorification process. In this case, the pounded ore is put into an open earthen dish, with an excess of granulated lead, and some borax. This is heated to a bright red heat in the muffle of an assay-furnace. A portion of the lead being soon converted into litharge, enters into combination with the metallic sulphides, forming with them, the earthy portions of the ore, and the borax, a fusible slag; the excess of lead is thus protected from the action of the air, and remains in the metallic condition, uniting with whatever silver there may be in the ore. A button of silver lead is the result, which has then to be cupelled as before, and a proper allowance made for the silver originally contained in the lead.

The assay of silver lead ores has been partially described when treating of the inferior metal. For the purposes of sale, the ore must be assayed first to ascertain the quantity of argentiferous lead, and then the relative proportion of silver and lead in the product must be determined. From these two data, the value to the smelter can be calculated. The former part of the process has been detailed in Article XXIV.; and the latter will now need no further description than to say that it is done by cupellation, exactly as the button of alloy produced in the assay of silver ores is treated.

We must now turn to the separation of silver from its other associates on the large scale. The chief of them is lead. In former times it used to be separated from this metal by cupellation alone, a plan which is still adopted at many Continental works, but which has been almost entirely superseded in England by a more convenient one, known by the name of the inventor, the late Mr. Pattinson of Newcastle.

Pattinson's process is dependent for its action upon a curious property of the ordinary alloys of silver and lead—viz., that they melt at a lower temperature than pure lead does. This rule applies to any compound of the two metals in which the proportion of silver does not exceed $2\frac{1}{4}$ per cent.; but as this per-centage is equivalent to a yield of 735 ounces to the ton, it will be seen that the limit vastly exceeds in richness the produce of the most valuable ores. The consequence of the alloy melting at a low temperature is, that on slightly cooling the molten mass, a redistribution of the particles takes place, and a portion of the lead tends to crystallise out. By removing the crystals before the rest of the metal solidifies around them, and repeating this operation several times, the crystallised lead becomes almost entirely freed from silver, and the remaining alloy becomes gradually enriched with the precious metal, until it nearly reaches the limit above stated. The desilvered lead rarely contains more than one-half to three-quarters of an ounce to the ton, or about 0·002 per cent., beyond which point it is not found profitable to carry the operation.

The plan by which this process is carried out is as follows:—From eight to ten or more iron pots are placed in a row, and sunk into a platform of brickwork, beneath each of which is a

separate furnace, with a wheel flue passing below the whole of the under surface of the respective pots before passing away into the common chimney. Fig. 1 shows a cross section of the row of pots from back to front. A represents the pot sunk into the brickwork, B; C the furnace, with the ash-pit, D, below; E E E show the arrangement of the flue encircling the under side of the pot, before passing into the general flue F. The platforms G and H, for the men who attend to the pots, extend the whole length of the row. Each crystallising or Pattinson pot, as these are often called, is hemispherical in shape and about five feet in interior diameter. The outside pot on the left hand is rather smaller than the rest, and is distinguished by the name of the "market pot." Each of the crystallising pots will conveniently hold about $6\frac{1}{2}$ tons of melted lead.

Suppose a series of ten pots are used, and that the crystallising pots are numbered consecutively 1 to 9, No. 1 being next the market pot. In all of them, with the exception of the market pot, there will be a quantity of lead more or less rich in silver remaining over from the last shift. The fires are got up, attention being first given to pot No. 5, the central one of the series, in which the process of separating the silver will be commenced. This pot is filled up with the lead to be desilverised, and the fire below it is kept up till the whole is thoroughly melted. As soon as this point is reached, the lead is skimmed, to remove all the oxide that has formed on the surface during the melting; the fire is withdrawn, and the lead is left to cool, cold water being generally thrown upon the metal to hasten the cooling. As soon as the lead begins to crystallise on the surface, and round the edges of the pot, one of the workmen detaches the adhering crystals by means of a long iron bar shaped at the end like a chisel, called a slice, and stirs them up among the still liquid portion. Another man then takes a perforated iron ladle, and dips it to the bottom of the pot, bringing up in it a quantity of lead crystals; with a slight jerking motion, they are pretty thoroughly freed from the liquid portion which runs through the perforations in the ladle, and the crystals are then turned over into pot No. 4, the next in order on the left hand of the workman. The ladling is thus continued till rather more than two-thirds of the contents of pot No. 5 have thus been transferred to No. 4, when the remainder, consisting of enriched lead, is removed by ordinary ladles into pot No. 6 on the right. The same process is now applied to pots 4 and 6, the crystals from these being ladled into Nos. 3 and 5 respectively, and the enriched lead into Nos. 5 and 7 respectively, and so on until the market pot is reached at the one end, and No. 9 at the other end, of the series.

Thus, if we suppose a lead to be operated upon which contains twelve ounces of silver to the ton, that will represent the richness of No. 5; but as the crystals will only carry away with them a small proportion of silver, the remainder (from one-third to one-fourth part of the whole) will generally be at least double as rich as it was before the separation, and No. 6 will, therefore, be worth about twenty-six to twenty-seven ounces to the ton. By this process of addition, as the mixed metals travel to the right from pot to pot, and of subtraction as they travel to the left, it will result that at the one extreme the lead will be found to contain some 250 ounces to the ton, while that in the market pot at the other will be practically desilverised, containing only about three-fourths of an ounce to the ton. The enriching of the lead can be carried higher if desired, but that is found to be about a convenient limit, as the crystals become each time more difficult to separate, and an alloy of such richness is well suited for the next step of the process, the cupellation.

The perforated ladles above mentioned are about sixteen inches in diameter across the bowl; and including the handle, weigh about 130 lbs.; at each lift the workman takes up about 250 lbs. weight of crystals. The handle rests, when the ladle is full, upon a block at the side of the pot which serves as a fulcrum, the long arm of the lever being in the hands of the workman; but, nevertheless, the work is rather heavy. In some establishments, therefore, cranes are used as a substitute for manual labour, a crane being fixed between each two successive pots; and then ladles which will hold double the quantity of crystals can be employed, pots which will hold about ten tons of metal being generally adopted in such case.

As the perforations in the ladles are apt at times to get clogged with the cooling metal, it is usual to have small pots, called temper or wash-pots, placed between every second crystallising pot, containing hot lead of the same richness as that in the pot from which the ladle has been taken. In some works, however, these are dispensed with, and the ladle is reheated by being dipped for a while in the hot lead contained in the pot to which the crystals are being transferred.

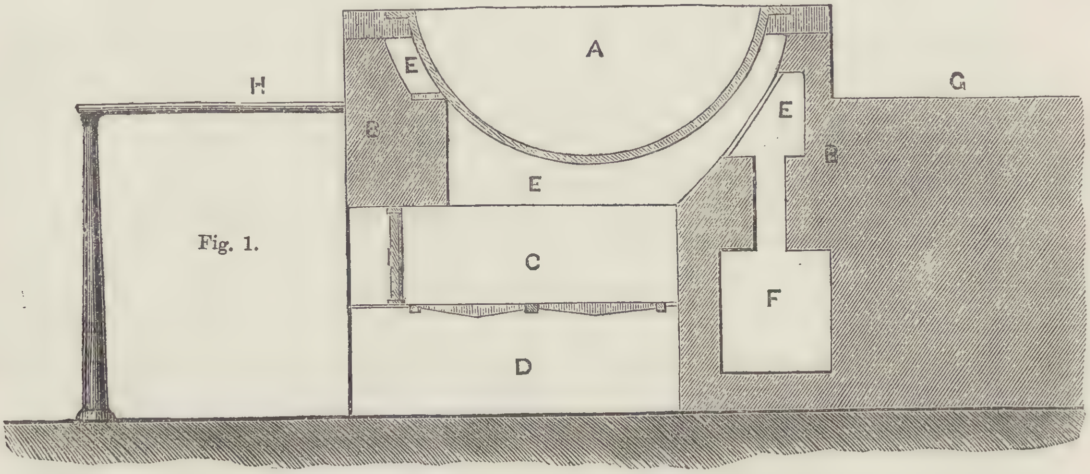

Fig. 1.

The loss of metal in skimmings, when a series of ten pots is used, will amount to nearly one-fourth of the whole quantity; but the skimmings are utilised by re-conversion into metallic lead, so that the ultimate loss is very small.

Silver may be separated from lead by other processes besides cupellation, and that of Mr. Pattinson; one of the most convenient of these, though it has not held its ground in competition with the others, is due to the action of zinc. It is found that if about 5 per cent. of zinc be added to any given quantity of argentiferous lead, and the metals be mixed together in a liquid state, the silver will separate itself from the lead and combine with the zinc; and as the latter has a higher melting-point than the former, the zinc on cooling will crystallise out first along with the silver, and form a layer on the surface of the lead, which can be separated with readiness. It will be remembered that in Article XXIII. zinc was spoken of as being highly volatile, and as silver is only very slightly so, the inferior metal can be removed by distillation in retorts made upon the Belgian principle; or it can be separated from the silver by dissolving it in weak sulphuric or hydrochloric acid. This principle, with certain modifications rendered necessary by the peculiar character of the ores from which the lead is made, has been adopted with greater success at some of the smelting-works on the Continent.

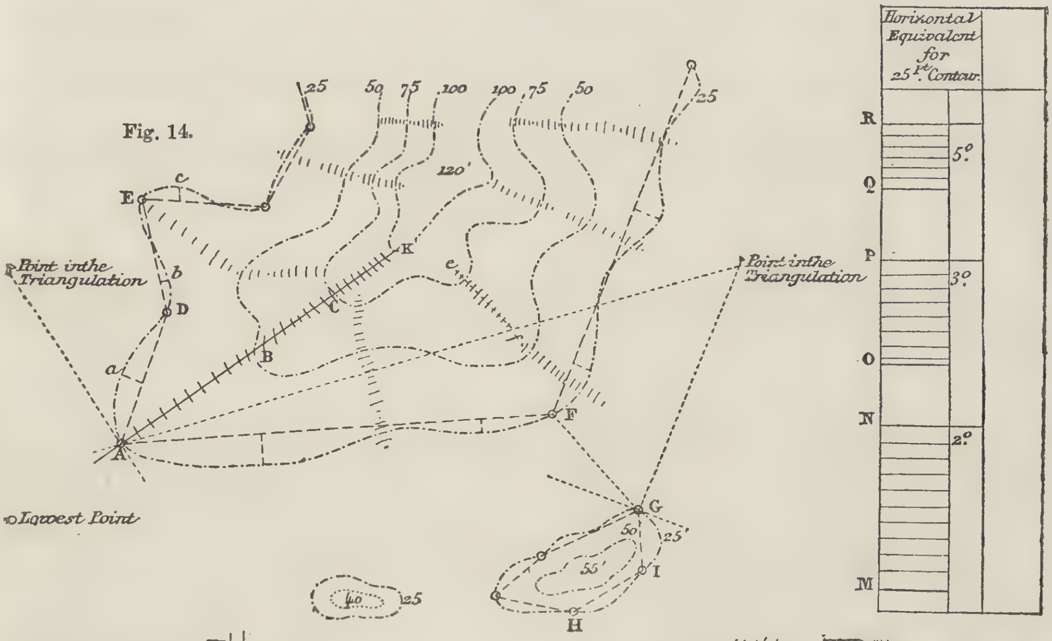
MAP AND PLAN DRAWING.—V.

By C. C. King.

METHOD OF CONTOURING.

It is not always absolutely necessary to run a system of contours or levels through an area, though whenever time is afforded it is advisable to do so, not only because of the greater accuracy of the relative heights of different points, but because it enables the draughtsman to obtain a much better appreciation of the sketch. When the exact altitude of the lowest point above the surface of the sea is known, the contour lines at any chosen distance apart, say 25 feet, will be enumerated from its exact height; thus if it be 200 feet above the sea, the contours will number 225, 250, 275, and so on. But where this cannot be ascertained, the lowest point is marked zero, and the contours and altitudes will only refer relatively to that point, and will be 25, 50, etc. It may be remarked that the intervals between the contours depend somewhat on the scale of the drawing.

Fig. 14.



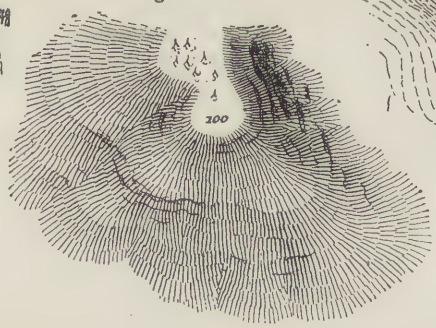


Fig. 15.

Fig. 17.

intricacies of the country, and hence much facilitates his sketching those features. Where the extent of ground is not large, where the differences in level are very slight, or where again they are not numerous, as would be the case if a small solitary hill alone broke the general flatness of the surface, it would scarcely be worth while to trace regular contour lines; but as this would rarely occur, it will be well to treat contouring as a step in the work which can be omitted if the nature of the country does not demand its being carried out.

We have before defined what contouring is. It means simply describing level lines at stated regular intervals of altitude which intersect the area and follow the windings of the hills and valleys. It is evident, therefore, that some point must be selected to start from, and this is termed the datum level of the Thus with one inch to a mile they are usually 50 feet apart; from this to six inches to the mile the interval is 25 feet, and with larger scales 10 feet. In either case it is best to select one of the highest hills, and ascertain its height as carefully as possible, marking by pickets the points through which the contours will pass—that is, at 25 feet intervals above the lowest point in the sketch. This can be done with sufficient accuracy by the small clinometer before described. The observer, holding it horizontally, will note where the prolongation of the upper surface cuts the front of the hill before him, and knowing the height of his eye above the ground, he will, on walking to the point he has observed, have ascended that height above his starting-point. By repeating the operation he will gradually ascend the slope, and the position of the contour lines will be

marked as he rises successively 25 feet above the datum level. Starting from any one of these points, he will direct the clinometer on all the prominent or re-entering features of the hill or range of heights, and notice such points as may appear to be on the same level, and taking the bearing of the nearest with the compass, he will measure or pace the distance to it. From this point a second level and a second bearing are observed, and the interval measured, the process being continued until the entire hill is traced. Outlying isolated hills may be on the same level as the starting-point, but being separated by valleys from the hill on which it is situated, the contour line passing through it will not, of course, be continuous with that indicating the form of the hill itself. In this instance a point on a level with one of the contours, and situated on the "outlier," is carefully observed; and then, with this as a fresh starting-point, the contour is traced around the hill by bearing and measurement, and marked with the same number as that on whose level it is. Thus, in Fig. 14, A, B, C are the starting-points of contours at 25 feet vertical interval, and their position is traced on the paper by finding the true place of A by interpolation, taking the bearing of the line A C, and measuring off on it the distance measured between the pickets A, B, C; or if the slope be very steep, tracing these measurements reduced to a horizontal plane. The picket A has been selected for the first starting-point, and thence the points D, E have been successively observed, and the intervals A D, D E measured and transferred to paper. But near F lies the hill G, and when the surveyor reached this point he noted that the tree or other object at G was on the same level; proceeding to this point, and fixing it by interpolation or by bearing and distance from F, he then completed the small continuous contour G H I, etc.

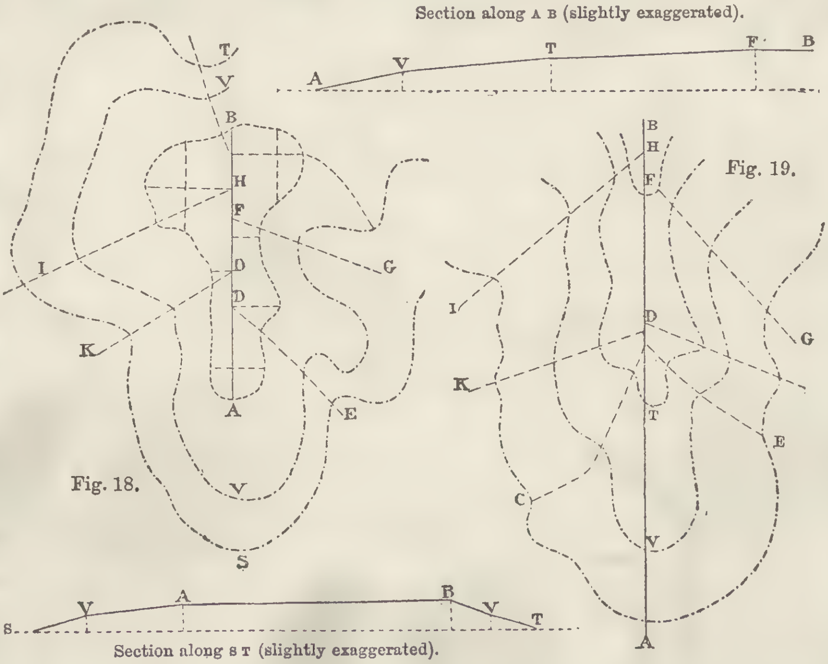
These are then numbered according to their elevation, and are traced usually in colours, either blue or red, with a dotted line. It will be noticed that when the curve is short it is considered sufficient to take bearings across the arcs, and either sketch them in by hand or pace to the distance of the farthest point of the curve from the bearing, as shown at *a b c* (Fig. 14). These levels will evidently determine the relative height of nearly all the features; but where, as at H, the hill-top lies between the contours—that is, about 55 feet high—its altitude is ascertained from any known point on the contour by levelling up by repeated operations until the summit is reached. In many cases the heights may be approximately measured by eye, and in others the angle of elevation above the lowest point may be taken by the clinometer, and the height of the hill above this be found by calculation from a table generally printed on it.*

* This table is one of natural sines, and contains two columns, one of angles from 1° to 60°, the other the decimal numbers representing the natural sines of these angles. Thus, suppose the distance of the hill-top from a known point A was either actually chained or else taken by scale from the map, and found to be 400 yards, and at the point A the angle taken by directing the top edge of the clinometer on the summit of the hill was observed to be 3°, we should look in the table for 3°, and multiply the number ·0523 opposite it by 400, which would give us 62 feet nearly as the height of the hill.

In conducting this portion of the work, as well as in traversing the roads, it is advisable to correct the position of the observer at various convenient points by taking the bearings of any of the prominent features of the triangulation and interpolating the result. This will frequently show an error in "place," especially if the line traversed or contoured be intricate, and where the time at the disposal of the surveyor is short, a large amount of useful and approximately accurate work can be done by simply fixing a series of points in this manner, and, without measuring their distance apart, sketching by eye the intermediate portions. This necessarily requires practice, but the results obtained are, when experience is gained by repeated attempts, singularly trustworthy, and, by showing the nature of the ground, are of very material assistance in filling in rapidly the shading of the hills.

The contouring glass, a simple and very portable instrument, giving very good results, may also be used for ascertaining the position of the contours. It is a small brass tube provided with a spirit-level, and a reflecting glass is so arranged that on looking through the tube the bubble of the spirit-level is seen when the tube is held horizontally. Crossed wires intersecting in the axis of the tube are fitted in the object-glass, and when the bubble is visible in the reflector, the intersection of the wires, and a point on the hill-side in the prolongation of the line of sight, are on the same level.

Section along A B (slightly exaggerated).



Section along S T (slightly exaggerated).

Altitudes may again be determined with considerable accuracy and with great saving of time in mountainous districts, where the differences in level are more marked, by means of the pocket aneroid. It resembles a watch in size and appearance, being, therefore, extremely portable, and is graduated in feet. An error of 10 or 12 feet in 100 should rarely be exceeded, as it is but little affected by change of temperature, and if returned to the same pocket after each observation the results will be more correct.

Before describing the finishing steps of the work, it will be well to examine briefly the principles on which hill-shading is based. There are many different ways of representing the physical features of the earth's surface. In France, carefully traced contour lines at near intervals are described over the area, and these depict the character of the ground with great distinctness to a practised eye, while at the same time the map is not encumbered with drawing; but it cannot convey so much information to unskilled readers as the more minute and laborious methods which depend on effects of light and shade.

There are two principal modes of expressing the nature of hill and valleys on a plan. One, the vertical, which is largely employed in France and Prussia, and also in England, when the scale is very small and the maps are to be engraved; and in this method it is assumed that the lines represent the course which the rills of water would take in descending from the water-sheds to the lower levels. It may be used simply for expression of the ground when the relative thickness or distance of the lines apart have no especial meaning beyond depicting the folds and irregularities of the ground; or the lines and distances may be constructed according to a scale of shade, as in

German military maps, where their relative thickness denotes the *angle* of the slope as well as its form. Thus Lehman's scale of shade commences with fine lines at 5°, and proceeds in increasing thicknesses of line every 5° up to 45°, which being practically impassable is represented as composed of very thick black lines, extremely close to one another. Figs. 15 and 16 show the difference in the appearance of the two methods. Contour lines are equally useful in this as in the other kinds of drawing, but the lines or *hachures* between any two contours should not exactly coincide or be in continuation of those above or below, as too much regularity detracts from the beauty of the sketch. The work should be commenced from the crest of the hill, and in the steeper portions the lines are closer and blacker than in the plains or valleys, where the hachures become lighter and more divergent.

The advantages of this style are, that in very hilly districts, where the roads run rather across the slopes, and are of a zigzag form, they are clearly shown as they cut the hachures at an angle; and in mountainous countries, such as the Pyrenees, where the spurs and ridges are very steep and uniform, vertical lines may, perhaps, express their nature better. Again, names are printed more clearly across than between a series of lines, especially if the latter be dark. The great disadvantage is, that it does not show the relative differences of level so readily as the horizontal style.

The horizontal method (Fig. 17) may be considered as but an extension of the principle of contouring, as the space between the chief contours is filled in with horizontal lines, preserving a rough parallelism to them. These hachures are not, however, continuous, as this would tend to make the drawing too smooth and even, and destroy the irregularity of work produced by drawing them in sets or groups of various lengths, which, moreover, tends to produce a nearer resemblance to the roughness of the actual surface. The pencil should be firmly held, so as to produce an even stroke, and each set should be somewhat of a diamond pattern, the axis of which is the direction of an imaginary water-course or rivulet. Thus, in Fig. 14, the line *e f*, perpendicular to the general direction of the hachure, is the axis. As in the vertical method, the hachure may either be used to express the ground, or may give accuracy as well as expression by the use of a scale of shade. The former plan produces, perhaps, neater drawing, and admits of the display of more artistic skill, but it has the great disadvantage of want of uniformity between the work of different draughtsmen, and hence a hasty survey of a large area, subdivided between a number of surveyors conjointly, becomes an impossibility, as it cannot be put together.

The scale of shade in use in England, by military men more particularly, is that of Colonel Scott, and in this system the distance between the hachures, as well as the intensity of the line, varies with the slope, the variations occurring at 2°, 3°, 5°, 10°, 15°, 20°, 25°, 35°, beyond which the slopes are practically impassable for military movements, and the delineation is left to the skill of the draughtsman. One column in the printed "scale" is devoted to giving the number of lines which for any given slope will lie between contours 25′ apart vertically, on a scale of 6 inches to the mile; thus at 2° the horizontal equivalent for each contour—that is, the base of the triangle, of which the slope is the hypothenuse—admits of the drawing of eleven fine lines $\frac{1}{12}$th of an inch apart; at 15° four rather dark lines, $\frac{1}{30}$th of an inch apart, fill the horizontal space between two contours at that slope, and so on. This arrangement is advantageous in two ways. It admits of drawing, generally accurate save in minute irregularities that may exist between contours, being executed by the aid of contour lines only; for if the spaces in the column of horizontal equivalents are applied to the plan it is evident that the space which coincides with the distance between the contours at any point gives the number of horizontal hachures of a certain thickness and interval necessary for that angle, and hence describes the slope that lies between the contour lines. Thus, in Fig. 14, if the distances A B, B C, C K, be measured and found to agree with the spaces M N, O P, Q R, on the scale of shade, a portion of which is shown, it will only be necessary to fill in the intervals with lines of the same character as those shown in M N, O P, etc. Again, we are able to ascertain the height of any point approximately by measuring the number of lines due to a certain slope by the intervals in the column of horizontal equivalents; for if there be eleven lines of the character which expresses a slope of 2°, the difference in level between the first and last hachure will be 25 feet, since that number of lines occupies a space which is the horizontal equivalent of the slope on a scale of 6 inches to the mile; if twenty-two lines, the difference in height would be 50 feet, and so on. The disadvantage of this scale of shade is, that it is weak in the description of undulating or only slightly rising ground, and a sketch completed by it is wanting in the richness which distinguishes work executed with more attention to expression than accuracy.

Lastly, the character of the ground may be represented by washes of Indian ink, neutral tint, or sepia; but this, though excellent for rough sketches, and capable of expressing very distinctly the hills and valleys, is not susceptible of accuracy, and depends too much on the individual artistic skill of the draughtsman. In shading by "brush work" contour lines may still be used, and the only care necessary in executing it is that the washes should be laid on lightly, carefully shaded off, and the effect produced rather by repeated application of the brush than by at once endeavouring to give expression to bold features by a heavy wash of colour. The early washes should be entirely of neutral tint, and when the country is faintly marked out in this colour, Indian ink should be used for finishing the sketch, the steepest slopes being the darkest.

Whatever method be employed, it is necessary to construct some framework which shall guide the drawing. If the surface of the earth were seen from a point of view some distance above it, we should notice that the level portions would appear lightest; and since the summits of the hills are usually more or less level, and, moreover, form portions of the local water-shed of the district, it is usual to begin by describing accurately, as far as possible, the hill-crests. When the area is such that no plateau or true summit is apparent, as would be the case when the survey was conducted over a large regular spur sloping definitely in one direction, the first thing traced is the main line through it, which forms the local water-shed, and which is determined by bearings and transferred to the plan. Thus, in Fig. 19, the line A B is first marked and traversed, and from it the bearings of all the main water-course lines are determined, and set off as D C, D E, etc.; and when the ground is intricate, or when prominent spurs and ridges diverge from it, these should be further marked, and will serve as guiding lines for the hachures showing their shape.

When a plateau forms the crest of the hill, a line will be taken right through it, from a point fixed by interpolation, and its form traced by offsets (Fig. 18), and the water-course and guiding lines are delineated as before.

Having thus formed the groundwork on which the hachures can be accurately drawn, and which, from having all the main features indicated by lines, will only admit of inaccuracy in the minor irregularities of the detail, the examination of the slopes themselves must be carried on.

It would be impossible, and practically unnecessary, to test the angle of slope of every portion of the area, and it is found in practice sufficiently accurate to mark carefully down the alterations in the inclination of all the principal spurs or ridges from the summit or water-shed to the base, and leave the intermediate spaces to be filled in by eye-sketching. Thus the angles of the different portions of the spurs in Fig. 14 are carefully noted down in the following way. Commencing at the summit of the hill, the angle of the slope is taken by means of the clinometer as far as it continues uniform, and the distance to the point where the alteration occurs is paced on the guiding line. This is marked on the paper, and the space filled with small hachure lines, of the nature due to the slope, according to the scale of shade. From this point a second observation of the slope is made, the result noted down, and the distance paced as before. All the small outlying features, such as hillocks or ridges, which are not united to and form part of the main ridges and their projecting spurs, are visited in the same manner, and the details of these "under-features" sketched in.

It is advisable to make a short halt after any two adjacent spurs have been traversed, and from the one which gives the clearest view to fill in the ground lying between them: this assists the workman to complete a large section of the main features entirely before turning to the under-features, which are near it. The actual manipulation of the pencil is a matter that depends entirely on natural aptitude, and even more on constant

practice. In cases where the country is so intricate as to make it difficult to indicate whether the slopes are running up or down—as, for example, in sketching a perfectly symmetrical cone, and a perfectly symmetrical hollow of a similar shape—it is usual to denote the water-courses by a small arrow pointing towards the lower level.

In reading the work it must be remembered that the summits of the hills are left blank under ordinary circumstances, and to distinguish them from a cup-like hollow the altitudes are marked in figures on them. A blank space would also be left in drawing a saddle between two hills, and would be distinguished from the hill-top solely by the nature of the surrounding drawing.

Thus we finally have the drawing of the area completed, and it simply remains to fill in any details of houses, farm enclosures, hedge-rows, or woods, by actual traversing them with a compass and a chain. Starting-points can always be found by interpolation, and thence a series of traverses taken in different directions will provide a number of intersecting bearings which will determine the minor details. In finishing up the work much can be done by mere eye-sketching, and a number of conventional signs, altered to suit the scale of the plan, are adopted to facilitate the expression of the ground. Any particular way of delineating certain unusual characteristics that may occur can be employed so long as a reference is made to it in a column of remarks.

Nothing more remains to be done, except to draw the scale, add the names of all the places, and the direction of all the main roads—that is, whence they come, with the distance from the nearest town, and whither they lead, with the distance to the next place of importance. The directing lines which were made for the use of the prismatic compass and protractor, will give us the position of magnetic east and west, and in a convenient corner the magnetic north is indicated by an arrow, while the true north is also denoted by an arrow, inclined at an angle to it, dependent on the variation of the compass.

This may be ascertained by previously taking the magnetic bearing of a point known to be due north of the observer's position, or, if none exist, by taking the bearing of the centre of the sun as it crosses the meridian. For this it is necessary to have the instrument fitted with coloured glasses, capable of being moved over the prismatic sight, and a mirror attached to the sight-vane in which the vertical wire is fixed; but it is essential in making the observation that the compass should be horizontal, and it had better be placed on some level surface.

The time when the sun is crossing the meridian is known by referring to the Nautical Almanack on the given date, and subtracting from the known local time the difference between the sun time and mean time given in the tables.* This will give the moment, according to the local time, when the sun is on the meridian. It is evident that in northern latitudes the bearing observed will have to be subtracted from 180° to give the variation as the sun is to the south of the observer. The bearing of the pole-star may also be taken, but this is not an easy matter, on account of the difficulty of reading the compass bearing when the star is in its right position. It adds much to the value of the plan in many instances if a section of the survey on any given alignment be given. This is produced by drawing a line across the plan, as A B (Fig. 19), and measuring off on it from one end, A, the positions of the points through which the contours pass, or where any undulating alterations of level occur. A horizontal line is then traced, and these distances transferred to it, and from the points thus marked a series of vertical lines are drawn, on which are measured respectively the heights of the several points, which may be ascertained from the plan itself.

GREAT MANUFACTURES OF LITTLE THINGS.—X.

SCREWS.

BY CHARLES HIBBS.

In tracing the progress of man from savagery to civilisation, we are generally oppressed with the idea that it has been a slow, painful, and laborious journey. But here and there we come upon the record of some happy invention or discovery, which has enabled him to make a sudden start forward, and clear a great space at a bound. Such was the invention of printing, and such the successful application of the power of steam. It would seem, however, with all the boasted rapid advance of modern times, that antiquity was vastly richer in those sorts of discoveries which begin epochs, and give a new and tremendous impetus to human progress. The old discoveries seem to be of far larger importance than the new, and to have had far more influence upon the destinies of mankind. How insignificant, for instance, is the invention of printing, compared with that of written language itself—the representation by inscribed characters of the sounds of the human voice, and their reduction to an alphabet! How profitless would have been the discovery of the expansive force of steam if there had not previously been made the far greater discovery of the mechanical powers which it sets in motion—the lever, the wheel, and the screw! We might speculate curiously as to who made the first screw. The saw was reckoned so wonderful an implement that its inventor was ranked among the gods. Was the same honour awarded to the inventor of the screw? If it could have been foreseen how important and various were the offices it would be made to serve, how immensely human effort would be aided by it, there would have been no question in those days about assigning to it a superhuman origin.

The screw, as the mechanical student is of course well aware, is simply a modification of the inclined plane. A winding road round a hill, or a winding stair by which the summit of a tower is reached, will be familiar illustrations of this fact. A common wood screw enters a piece of wood in the manner of a wedge, or movable inclined plane, with the difference that it acts in a circular instead of in a direct line. When a lever is connected with the shaft of the screw, as in an ordinary vice-pin, there is a combination of two powers; and when weights are affixed, as in the loaded arms of a fly-press, there is the addition of momentum, which together produce an almost irresistible force. These considerations belong rather to the abstract science of mechanics than to the subject of these papers, which treat principally of manufactures; but may be usefully alluded to here as illustrating the principles which should guide production.

If a strip of paper be wound round a shaft of wood—say a lead pencil—at an angle, it will be found that its edges fall into a position resembling the threads of a screw. This was, indeed, the method formerly used for originating the large screws used in machinery. A piece of paper was cut into the shape of an inclined plane, *i.e.*, a right-angled triangle, the height of which corresponded to the length of the shaft of the intended screw, and the hypothenuse to the inclination or pitch of its threads. This was wrapped round tightly and pasted to the shaft, and a nick made with a file along the spiral line formed by its edge, the indentation being afterwards deepened until from the incipient worm a nut could be formed, which served as a holder or guide for the cutters that were to complete it. After the pattern screw was made any number of copies could be produced from it, by processes we have yet to describe; but it was often a matter of importance to get a true thread of a new size or pattern, and many were the contrivances adopted for the purpose. A workman at Soho employed the following modification of the paper method:—He first of all turned his cylindrical shaft perfectly true, and then cut a strip of paper of the same length, whose width would just encircle the shaft when pasted round it, the edges coming together accurately. Before pasting it on he had marked it with a series of diagonal lines, drawing them from points made by compasses along the sides at intervals equal to the distance which one thread of the screw was intended to traverse. When it was cemented to the shaft, these lines ran into each other and formed a continuous thread, along which he made a series of indentations in the metal by means of a centre punch and a hammer, afterwards connecting them with a file. We may readily conceive that this method would admit of greater nicety of manipulation than the last, because there would be only one thickness of paper to cut through before reaching the iron. When he had produced a roughly-formed thread, he suspended the shaft in a box properly contrived, and cast round a portion of it a block of lead, the impressions in which served as cutter guides. A ruder method was to wind a piece of iron wire obliquely round the shaft, and form a mould from it by compression, with the same object of getting a guide for the cutters. A more

scientifically elaborate, though still primitive, method of originating screws is described in the *Philosophical Transactions.* Two straight edges are fixed parallel to each other upon a table, the distance between them being exactly equal to the length of the screw-shaft. Their own length must be equal to as many circumferences of the shaft as the thread is intended to traverse it, which depends, of course, upon whether the screw is intended to have a slow or a quick pitch. Thus, if the screw is to advance one inch in a complete revolution, and the shaft be ten inches long, the length of the parallel straight edges must be ten circumferences of the shaft. A third straight edge is now fixed diagonally between the other two from end to end, and its angle in that position is precisely that of the thread proposed to be made. In the upper edge of this cross-piece a groove has been cut, and a strip of Bristol board inserted, which is smeared with printers' ink. The smooth shaft is now made to roll evenly between the parallel uprights, over the diagonal, which prints upon it a regular spiral line, which the workman can follow with his tools. As the mechanical arts advanced it became easy to cut a correct thread in a lathe, without any guides or previous marking, the only requirements being that the cutter should be fixed at the proper angle, and that its rectilinear motion along the shaft should bear the same relation to its revolution as the pitch of the thread does to its circumference. Beautiful screw-cutting lathes are now constructed, in which, by the substitution of wheels of different radii, these relative motions can be so adjusted as to cut threads of any pitch upon shafts of almost any size.

From screws of moderate dimensions plates or dies can be formed, which will in turn cut other screws, and so on, *ad infinitum.* The way in which an interior screw can be made is by converting the original screw into a tap, which may be effected in various ways. It may be done by filing down the point of the screw into a taper square, leaving just a small portion of the thread upon the corners. This leaves obtuse angles, which are not of much use for cutting, but which serve well enough for some kinds of work. If it is filed of a triangular shape, the angles will have more cutting power; but they are still too obtuse to take out the substance of the metal. Or the tap may be filed away to a half-circle, in which case a radial angle is obtained, the sharpest that is ordinarily consistent with safety. Generally, taps are in succession used consisting of all these various forms, or with the addition of others nicked across the thread, the first having the threads blunted or left shallow, and the later ones coming up gradually to a sharp and perfect worm. The metal to be operated upon is held firmly in a vice or other machine, and the taps, fixed in a wrench of some kind, are worked backwards and forwards until the interior screw is a reverse fac-simile of the exterior one, plenty of oil being used to facilitate the process. If the whole substance of the metal were cut out from the hollows of the thread of the interior screw, the hole made to receive the tap in the first instance should be exactly the diameter of the inferior shaft, *i.e.*, the external screw stripped of its thread; but as part of the worm has to be formed by compression, and as some portion of the solid metal will be forced into the hollows of the tap, the hole must be made a trifle larger to allow of it. It is from neglect of these precautions that workmen get what is called a "slip-screw," viz., one in which the threads do not bite, and the screw turns round in its receptacle; if the hole has been bored too small the tap will not enter readily, or progress in proportion to its work, and blurs or strips the thread as it makes it; while if it be bored too large the thread made is too shallow, and is mainly formed by the burr of the metal, which will have no holding power. Pins with external screws are made with screw-plates, or dies, in the reverse manner to that just described, a portion of the thread being cut away to form a cutting or compressing surface, and a series, gradually deepening, being generally used. Dies are in two, three, or more pieces, being fixed in stocks, and tightened up with screws as the work advances. It need scarcely be remarked that the cutting instrument, whichever it may be, is hard, and the metal to be operated upon is soft. Innumerable are the uses for metal screws, from the minute pins, scarcely visible to the naked eye, which are used in watch-making, to the massive bolts which hold together the parts of our largest men-of-war.

Wood screws, by which are meant iron screws to screw into wood, are made in immense quantities, and are daily coming into more general use as a substitute for nails. In some parts of Scotland they are called "screw-nails," and it is worthy of remark that the screwed pins used in military small-arms are still, in the antiquated phraseology of the War Office, called "nails." Wood screws used to be made by a process which was primitive enough. The blanks were forged by the nail-makers, and resembled that species of nail called "counter-clout," with a blunt end. The transverse nick, or slit, was cut by a hand-saw in a vice, and the worm was filed laboriously out by hand. Later on they were wormed by means of a simple hand machine constructed as follows:—A spindle, with a "chuck" to hold the screw, worked in a frame fixed upon a bench, the back part being fitted with a winch. In front were a pair of cutting dies, upper and lower, the lower one being a fixture, and the other lying upon it heavily weighted. By means of a lever pressed down by the foot, the workman raised the upper die a little to allow the point of the screw to enter, and then, releasing the weight, turned his winch backwards and forwards until the thread was cut deep enough. The work, though very hard, was frequently performed by women, who bore the contemptuous designation of "screw-girders."

About the year 1849 machinery for making screws began to be extensively worked by steam power. It was the invention of a German, named Colbert, a clock-maker, and, compared with the clumsy methods formerly in use, must have been regarded as a remarkable step in advance. The screw-blanks were now made from iron wire, drawn of the required thickness, and cut off from the coil by a machine, which at the same time punched up the end to form the head. The half-formed screws were then turned one by one in a lathe, and cutters of the required form finished off the heads neatly. The next process was to nick the heads, which was also done by a machine. There were many different forms of nicking machines in use at various manufactories; but in principle they did not differ greatly, and the following description may serve to convey an idea of their generic type:—A small iron barrel or cylinder revolved slowly, overhung by a series of fine-cut circular saws, which revolved very rapidly, the motion of the saws and the barrel being in opposite directions. The surface of the barrel was pierced with a number of small holes, in lines running round the circumference immediately under the saws. The screw-blanks were fed into the holes, either by hand or by a self-acting feeding machine; and as they were carried round by the cylinder each head came under a saw, and was nicked across the centre, the blanks falling out afterwards by their own weight. They were then taken to the worming machine, which was thus constructed:—In front were a pair of holding clamps, which could be opened by the touch of a lever, and which gripped the head of the screw tightly, being assisted thereto by a small interior chisel which entered the slit. The driving-band being now slipped from the loose pulley to the tight one, the screw-shaft began to revolve, and at the same instant two other actions of the machine were brought into play. The spindle which carried the blank was furnished at its hinder end with a regulating screw the size and pitch of the one intended to be cut, and a nut being engaged with this carried the spindle forward at the same time it was revolving. Simultaneously, a cutting instrument came into contact with the shaft of the screw, and cut upon it a worm identical with that on the regulating screw behind. The machine having a reversible motion, this process was continued backwards and forwards, until the thread was perfect.

The screws made by this machinery were immensely superior to those formed in the old-fashioned compressing dies, which could not make a thread of sufficient depth, and a little force would suffice to "draw" them if the wood were at all soft. Still, the new screws were defective, inasmuch as they were not pointed or gimlet-ended, and, consequently, would not enter readily; and there was a burr left at the hinder end of the thread which "ragged" the wood. A beautiful screw was introduced and patented by Mr. Nettlefold, in which all these defects were avoided, and many new advantages secured. The shaft was tapering and pointed at the end; the thread was deep and bold, the under side having as great an inclination as could be given to it, while the upper side was almost flat. This enabled the screw to penetrate the wood easily, and at the same time to resist almost any force tending to draw it out.

The screw-making plant just described has been altogether

superseded by machinery introduced into this country from the United States about twenty years ago. In the "Patent Records" of that time we find the following description in a specification lodged by a firm of manufacturers from Rhode Island:—"This invention consists of a peculiar arrangement or combination of parts into a machine for cutting wood screws, for which purpose a series of holders or revolving spindles, suitable for holding revolving screw-blanks, are used. These spindles or holders are placed and revolve at a tangent to the periphery of a circulating rotating tool, which carries numerous cutters, and by reason of there being a cam or guiding track for the cutters, they are engaged as they come opposite a screw-blank, to be moved outwards, and to make a cut across the revolving screw-blank. Each cutter, after making its cut, is moved back out of action till it comes to the next screw-blank; it is then moved outwards to make its cut, and so on continually; the succeeding cutter being protruded further out than the preceding one, cuts more and more deeply into the screw-blank. The cutting point or edge of each of the succeeding cutters is wider than the preceding one, and therefore cuts wider and wider as well as deeper and deeper into the screw-blank carried by the holders. It will be evident that by thus using several cutters in the same rotating tool, several revolving holders may be used, each carrying a screw-blank in the presence of the rotating tool, and have the separate cutters act in succession on each screw-blank."

Here for the present we must leave this interesting subject, but in a future paper we shall describe the effect which the introduction of the American machinery had on the screw trade, and give additional particulars respecting this important manufacture.

NOTABLE INVENTIONS AND INVENTORS.

XXXIV.—CHLOROFORM (*continued*).

BY JOHN TIMBS.

The action of ether, and the best mode of administering its vapour, was investigated by Dr. John Snow, who in September, 1849, published a work on "The Inhalation of the Vapour of Ether." This subject was investigated with great success in Edinburgh, and led to the discovery by Dr. Simpson, of that city, of chloroform, a terchloride of formyle, which acted more speedily and effectively. From this time chloroform became more generally employed for the production of artificial anæsthesia. The general effects of chloroform resemble closely those of ether. It is a more potent remedy, and produces anæsthesia more rapidly and certainly than ether.

Chloroform was first discovered and described at nearly the same time by Soubeiran, 1831, and Liebig, 1832; its composition was first accurately ascertained by the distinguished French chemist Dumas, in 1835. It had previously been used by some practitioners internally. Guillot prescribed it as an anti-spasmodic in asthma, in small doses, and diluted 100 times. But no person, Dr. Simpson believes, had used it by inhalation, or discovered its remarkable anæsthetic properties, till the date of his own experiments. It is a dense, limpid, colourless liquid, readily evaporating, and possessing an agreeable, fragrant, fruit-like odour, and a saccharine, pleasant taste.

In March, 1847, M. Flourens caused animals to inhale pure chloroform, which rendered them insensible; but, believing it to be a dangerous agent, he did not think of commending it for the prevention of human pain. Dr. Chapman says, "Anæsthetic agents should only be administered by those who possess knowledge and experience of their properties. The very essence of anæsthesia consists of a partial arrest of the vital processes, and is, in fact, a stage on the way from life to death; only those agents which are capable of leading us along this solemn path, and which having done so for a certain distance, will allow us to retrace our steps, are really endued with the power of saving us from pain."

As an inhaled anæsthetic agent, chloroform possesses over sulphuric ether the following advantages:—1. A greatly less quantity of chloroform than of ether is requisite to produce the anæsthetic effect. 2. Its action is much more rapid and complete, and generally more persistent. 3. The inhalation and influence of chloroform are far more agreeable and pleasant than those of ether. 4. The use of chloroform is less expensive than that of ether. 5. Its perfume is not unpleasant, nor does it exhale in a disagreeable form from the lungs of the patient, as generally happens with sulphuric ether. 6. Being required in much less quantity, it is much more portable and transmissible than sulphuric ether. 7. No special kind of inhaler or instrument is necessary for its exhibition. A little of the liquid diffused upon the interior of a hollow-shaped sponge, or on a pocket-handkerchief, or a piece of linen or paper, or held over the mouth and nostrils, so as to be fully inhaled, generally suffices, in about a minute or two, to produce the desired effect.

"The following is the chemical constitution of chloroform:—Formyle is the hypothetical radical of formic acid, first discovered in the red ant (*Formica rufa*), and hence named. It is now obtained from starch, sugar, and, indeed, from most other vegetable substances. A series of chlorides of formyle are produced when the hypochlorites are brought to act on the chloride, oxide, and hydrated oxide of methyle (pyrolixic or wood spirit). In the same way, as formic acid may be artificially procured from substances which do not contain formyle ready formed, so also are the chlorides of this radical capable of being procured from substances which do not originally contain it.

"Chloroform, chloroformyle, or the perchloride of formyle, may be made and obtained artificially by various processes—as by making milk of lime, or an aqueous solution of caustic alkali act upon chloral—by distilling alcohol, pyroxylic spirit, or acetone, with chloride of lime—by leading a stream of chlorine gas into a solution of caustic potass in spirits of wine, etc. The resulting perchloride of formyle consists of two atoms of carbon, one of hydrogen, and three of chlorine.

"It is now well ascertained that three compound chemical bodies possess, when inhaled into the lungs, the power of superinducing a state of anæsthesia, or insensibility to pain in surgical operations, etc.—namely, nitrous oxide, sulphuric ether, and perchloride of formyle. These agents are entirely different from each other in their chemical constitution; hence their elementary composition affords no apparent clue to the explanation of their anæsthetic properties." (Dr., afterwards Sir James Simpson.)

Dumas, in his examination of chloroform, showed that if for the three equivalents of oxygen three equivalents of chlorine were substituted, the product would be a *terchloride of formyle*. Such being Dumas's ingenious view of the constitution of this important substance, he very properly named it *chloroform*.

This substance is prepared, according to the Pharmacopeia of the London College of Physicians, as follows:—"Take of chlorinated lime, 4lb.; rectified spirit, 0ss.; water, 0x.; chloride of calcium, broken into pieces, ℥j. Put the chlorinated lime, first mixed with water, into a retort, and then add the spirit, so that the mixture may fill only a third part of the retort. It is then heated in a sand-bath, and as soon as ebullition begins, the heat is withdrawn. The liquid is then distilled into a glass receiver. A quart of water is then added to the distilled liquid, and well shaken. The heavier portion, which subsides, is then separated, and the chloride of calcium added to it, and frequently shaken for an hour. The liquid, which is the chloroform, is again distilled from a glass retort into a glass receiver. It is a transparent, colourless liquid, having a specific gravity of 1·48. It has a fragrant, apple-like smell, and a slightly acid and sweet taste. It is soluble in alcohol and ether, but requires 2,000 parts of water for its solution. It dissolves camphor, Indian rubber, wax, and resins. It is not inflamable. This substance is sometimes given internally, in doses of from five to ten minims, and acts as a stimulant, sedative, and anti-spasmodic and anæsthetic."

Sir James Simpson's special application of the new remedy in child-birth must next be noticed. In early days it was believed that the period of insensibility could not be prolonged with safety. This erroneous belief was speedily dispelled by Simpson, whose most profound compassion had been excited by the sufferings of women in child-birth. These sufferings he determined, if it were possible, to relieve, and on the 19th of January, 1847, he, for the first time, employed ether for this purpose, and with complete success, in a case of unusual difficulty and severity. Others of like kind followed, and in March he published his first memoirs on the subject. From this time his use of ether in natural labour commenced, and in November, 1847, he announced that he had employed it, "with few and rare exceptions," for every patient he had attended.

"And I have no doubt whatever," he adds, "that some years hence the practice will be general. Obstetricians may oppose it, but I believe our patients themselves will force the use of it on the profession. I have never had the pleasure of watching over a series of better and more rapid recoveries, nor once witnessed any disagreeable result follow to mother or child, while I have now seen an immense amount of maternal pain and agony saved by its employment. And I most conscientiously believe that the proud mission of the physician is distinctly twofold—namely, to alleviate human suffering as well as to preserve human life."

"While announcing these successes, Simpson had, nevertheless, been struck by certain inconveniences connected with the use of ether, and by the idea that its anæsthetic properties were probably common to many substances of a similar kind, some of which might offer still greater advantages. He made inquiry among his chemical friends with regard to such agents, and selected several for experiments, in which he was zealously seconded by his assistants, Dr. Keith and Dr. Duncan. In such experiments it was Simpson's custom first to test the safety of a new vapour by inhaling it himself, and then to observe its effects by administering it to his assistants. Mr. Waldie had suggested that the perchloride of formyle might be worthy of a trial; and in the application of this agent, soon and since universally known as chloroform, Dr. Simpson made the great discovery of his life. His work was very materially promoted by the highest personage in the land, who, having sent for him and heard his opinions, and the results of his experience, retained Dr. Snow to officiate as chloroformist at her then pending accouchement. One Edinburgh damsel, when the example set by Her Majesty became known, is said to have expressed much surprise that the new pain-destroyer 'should hae gotten sae far sooth as London;' but the example, nevertheless, had great weight, and every fresh convert served to spread conviction in ever-widening circles. For many years the use of chloroform has been as customary with the accoucheur as with the surgeon, and it would now be more remarkable that it should be withheld than it should be administered." (Review of Sir James Y. Simpson's Work, *Times*, May, 1872.)

The physiological effects of the vapours of ether and chloroform are classified by Professor Brande in five definite and progressive stages. 1. In the first stage, which is transient, the patient is exhilarated, but conscious of what is passing before him, able to direct the motions of his limbs, and sensitive to pain. 2. In the second stage, mental functions as well as voluntary movements are performed, but irregularly. The patient knows not where he is, and is generally, but not always, ready to do what he is directed. This, according to Dr. Snow, who has investigated the whole subject with great accuracy, is the stage of dreams. 3. It is in the third stage that the mental functions and voluntary movements become dormant, although external impressions may here produce involuntary action. Any pain inflicted in this stage might call forth a groan, but it would be expressed by articulate words. 4. In the fourth stage there is no movement besides that occasioned by the snoring of the patient, which indicates him to be in a condition of absolute insensibility. 5. In the fifth stage, which has been witnessed only in the inferior animals, the breathing becomes laboured and irregular, involuntary and voluntary muscles are alike powerless, respiration and circulation successively cease, and death ensues.

The fatal effects of chloroform depend not upon peculiarities in individual constitution, but upon faults in the mode of administration.

Dr. Phipson states of the action of chloroform: "In the human body exist different systems of nerves, and the art of producing anæsthesia consists in allowing one system to work as usual, while the other systems are under the influence of sleep. The nerves of motion and sensibility are made to sleep, while the nerves of organic life continue their functions. We are now enabled to appreciate these wonderful discoveries, and to admire the marvellous arrangement of the nervous system. The problem of depriving man of sensibility and motion without impeding respiration, circulation, digestion, or, in other terms, of depriving him of the means of his faculty of moving and of feeling pain without depriving him of life, has been solved. During anæsthesia (the sleep of chloroform) man lives like a plant: his animal functions are taken from him for a time."

Dr. Chapman considers that we have no expectation that any agent of anæsthesia will ever be discovered which may be used by ignorant, inexperienced, or incautious persons. We may again repeat that "the very essence of anæsthesia consists of a partial arrest of the vital processes, and is, in fact, a stage on the way from life to death; and only those agents which are capable of leading us along this solemn path, and which having done so for a certain distance, will allow us to retrace our steps, are really endued with the power of saving us from pain." This consideration should teach us that these beneficial agents, like that of fire, cannot be recklessly used with impunity, and that only those who possess knowledge and experience of their properties and modes of action are justified in administering them.

Lastly, chloroform has been extensively used in every hospital in Europe. It was the greatest boon to our poor wounded in the Crimea and India. The exhaustion of the stock of chloroform in Lucknow was one of the greatest calamities in that fearful siege. No fatal case occurred from its frequent use in the Crimea. Dr. Snow could ascertain but fifty fatal cases throughout the world which could fairly be attributed to chloroform during ten years. For several years before his death he made about £1,000 a year for administering chloroform in private practice. He met with but one fatal case among the many thousands to whom he administered chloroform. The fatal effect is by paralysing the heart; but the chance of this result, with due care, is very small; indeed, it has been compared with the chance of a fatal railway accident.

WEAPONS OF WAR.—XIV.

BY AN OFFICER OF THE ROYAL ARTILLERY.

RIFLED PROJECTILES.

In immediate connection with the preceding chapter (Vol. II. page 391), is the subject of rifled projectiles. The subject is not only a very important but a very wide one—so wide, indeed, that we despair of doing justice to it within the limits which must necessarily be observed in a series of papers of this description. As to its importance, that must be evident to the most superficial observer. A gun, after all, is only the means of application of its projectile. It is the motive power of the machine, not the machine itself—it is the projectile which strikes and does the work. Therefore, upon the suitability of the projectile for the end for which it is designed, depends ultimately the value of the gun. Even the "Woolwich infant" firing snowballs, or discharging cast-iron shot against an armour-plated vessel, would accomplish nothing. And so the ultimate virtue—the effective value—of the gun resides in the projectile, by which the destruction to life or material is wrought.

To attempt even to enumerate within a single chapter the varieties of rifled projectiles in the service would be vain. In the case of smooth-bore projectiles, where the sphere is the only practicable form,* and where there are no changes to be rung on modes of rifling, the classification is comparatively easy. But with rifled projectiles, we have not only the shot or the shell, each with its varieties, but we have of each the breech-loading and the muzzle-loading type, as well as infinite varieties of form and proportion.

Breech-loading projectiles, although they exist in great numbers in our service, are gradually disappearing before the more simple, less expensive, but not less efficient, muzzle-loading projectiles. As has been already explained in preceding chapters, the breech-loading projectiles in use in the English service are of a construction suggested by Sir William Armstrong—viz., an iron projectile covered with a leaden coating, slightly larger than the bore, which on the explosion of the charge becomes forced into the shallow grooves of the rifling, thus communicating the required rotatory motion to the shot. It should be clearly understood that the lead coating is merely a means of spinning the projectile. It is not an essential or integral part of the projectile—that is to say, breech-loading projectiles can be spun by other means than a lead coating, although this lead coating may, and does in fact, cover an infinite variety of constructions of projectile. Some of the salient advantages and disadvantages of this *système forcé* have already been

* Except in the case of such exceptional projectiles as the smoke ball and Manby's shot.

mentioned in a former chapter. To discuss this branch of the question as it merits is impossible here. Suffice it to say that a series of experiments, carried out almost without intermission, and by all sorts of committees, since 1858, has ultimately resulted in the decided preference of studded to lead-coated projectiles for our service. Gradually projectiles of the latter type will disappear; and although other nations, such as the Germans, appear to cling to them, it is not improbable that fuller experimental inquiry will tend to the same conclusions as those at which we have arrived. The normal type of rifled projectile in our service is now a muzzle-loader, the spin being given to the projectile by means of studs, set on so as to suit either a uniform or an "increasing" spiral, according to the rifling of the gun. The material of the studs, their size and strength, are proportioned to the strain which they will have to bear. They are made either of copper or of gun metal (copper and tin), and are attached to the projectiles by means of "undercutting."

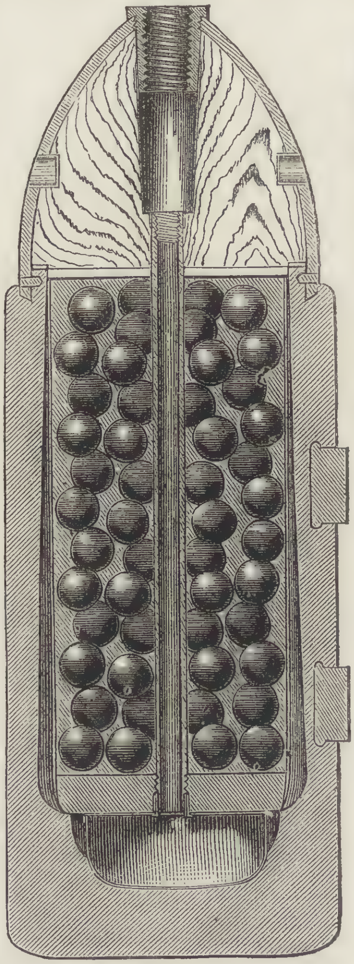

Fig. 1.—RIFLED SHRAPNEL SHELL (SECTION).

Passing from the means of spinning the projectile to the projectile itself, we find several varieties, according to the nature of the work required to be accomplished. The simplest form of rifled projectile is the shot. Of this there are two or three principal types — the ordinary solid shot, the case-shot, and the Palliser shot. The ordinary solid shot, which is an elongated cylindro-conoidal projectile of cast iron, about $2\frac{1}{2}$ calibres in length, is comparatively little used now. It is of no use against an armour-plated vessel, while against a wooden vessel, or against inflammable material of any description, a shell is much more effective. Therefore ordinary solid shot are used chiefly for practice, as being the cheapest form of rifled projectile available for the purpose. The case-shot differ from those used with smooth-bore guns only in detail. They are provided with segmental zinc linings, to prevent the crushing up of the case into the grooves of the rifling. Some patterns have coal dust between the balls, others sand and clay, to prevent the agglomeration of the balls, or their loss of form on discharge. For short ranges against the *personnel* of an enemy a case-shot is the most effective projectile known to artillerists. But this effect, on account of the lightness of the balls, and their rapid dispersion, is soon lost, and then the shrapnel shell comes into play. Of the smooth-bore shrapnel we have already spoken; of the rifled shrapnel we shall speak directly.

A more important projectile for the larger rifled guns is the Palliser shot. This may be considered the projectile *par excellence* of our heavier or plate-piercing guns. The Palliser shot is called after its inventor, Major William Palliser. This distinguished officer, who, though not an artilleryman, has done much to improve our artillery material, has the merit of having, in his shot, as in other of his inventions, struck out an original line of his own. At the time when Major Palliser introduced his shot efforts were being made to find some material suitable for piercing iron plates. The choice seemed to lie between a tough steel and a hard wrought iron. It was generally thought at that time that toughness was one of the elements necessary to success. And this combination of hardness and toughness was exceedingly difficult to obtain, at anything like a reasonable cost and with uniformity. Major Palliser may lay claim to originating the idea that toughness was not necessary at all. All that was wanted, he said, was hardness—hardness intense and unvarying; and this he found, allied with cheapness, in ordinary "chilled" iron—in iron, that is to say, which had been cast in an iron mould or "chill"* instead of in sand. Great care was necessary in the selection of the iron, and innumerable experiments were made on this point in the Royal Laboratory. Indeed, even Major Palliser's genius would have availed little without the indefatigable and zealous co-operation of the able manager of that department, Mr. Davidson, who, under Colonel Boxer, laboured for years at this important subject. At last a suitable iron was found, and the appliances for casting these shot were brought, under Mr. Davidson's guidance, to great perfection. It must not be supposed, however, that hardness is the only feature in Major Palliser's projectiles. On the contrary, that hardness had to be associated with a particular form of shot to produce any useful results. A flat-headed or an obtuse-headed chilled shot shivers to pieces like so much glass on the side of an iron plate. Major Palliser had got the hardness, but with it he had got brittleness. How was this brittleness to be neutralised or eliminated? Up to that time it had been supposed that it could be got rid of only by introducing some toughening element. But, as we have stated, Major Palliser chose another course. He argued that if he could make his shot of such a form that it would convert the shock of impact into a gradually increasing pressure, he would neutralise the brittleness. He applied this principle by adopting an ogival head, with a radius of from $1\frac{1}{4}$ to $1\frac{1}{2}$.

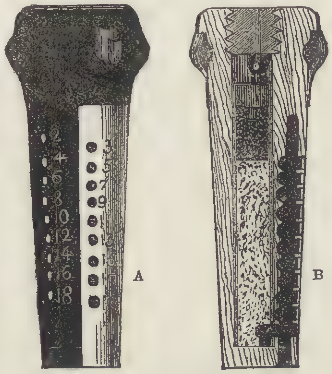

Fig. 2.—BOXER'S NINE SECONDS' TIME FUSE.
A, fuse; B, section of fuse.

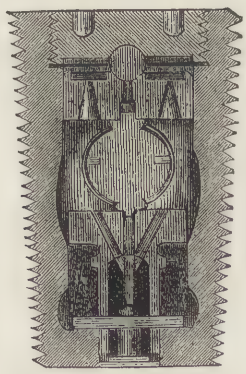

Fig. 3.—PETTMAN'S PERCUSSION FUSE.

Thus the Palliser projectile is not merely a chilled iron projectile—for that would constitute in itself no novelty, although chilled iron had never before been applied to the penetration of armour plates—nor is it merely a sharp-pointed ogival-headed projectile. It is a combination of material and form, and in this combination the virtue of the discovery resides. Indeed, we believe that Major Palliser lays no particular stress on the chilling, except as a convenient and inexpensive means to an end. Any hard, white metal shot, made

* At one time *all* shot were cast in this way.

with a Palliser head, would answer the purpose; in fact, some successful experiments have been made with white iron shot of the Palliser form, the shot having been cast in sand and not in chill. A few words should here be said as to the meaning and effect of chilling. The meaning of chilling is casting iron in an iron mould instead of in sand. The result of such casting is that the metal, instead of being slowly cooled, is quickly cooled, or "chilled," by being brought into contact with a material of high conducting power. In proportion as the cooling is slowly or quickly effected so does the separation of the carbon from the iron proceed more or less completely, quick cooling being unfavourable to such separation. In proportion as the separation is complete, so will the iron assume a greyer or darker tint, in consequence of the mechanical diffusion through it of the particles of carbon in the form of graphite; while, conversely, in proportion as the separation is incomplete—in other words, in proportion as the cooling is rapid—so will the iron assume a more or less brilliantly white appearance, the carbon being held in chemical combination with the iron. White iron, as compared with grey iron, is intensely hard and brittle; and Major Palliser's process consists in converting into this hard and brittle material iron which is primarily neither one nor the other—viz., grey or mottled iron. The result, when cast into ogival-headed projectiles, is extraordinarily effective. At comparatively small cost a shot is obtained with which no steel projectile has yet been able to compete, and the effect of these shots breaking up after they have penetrated, and entering the vessel in a shower of splinters, is equal to that of a shell or of a case. At first Palliser projectiles were cast entirely in chill, but it was subsequently found desirable to cast the bodies in sand (so as to avoid exposing too brittle a portion to the shock of discharge), and the head only in chill (so as to obtain the necessary penetrative results). Palliser shell differ from Palliser shot only in having a powder-chamber for the bursting charge in the centre. For manufacturing reasons, which need not be here entered into, the shot are now cast with a small cylindrical hollow or "core" in the centre, but the shells have a much larger hollow, and contain from 2 to 15 lb. of powder, according to their size. The explosion of the powder is effected by the breaking up of the shell on impact on iron plates, no fuse being required. This effects a considerable simplification in the use of these projectiles. The Palliser shell is shown in Fig. 5.

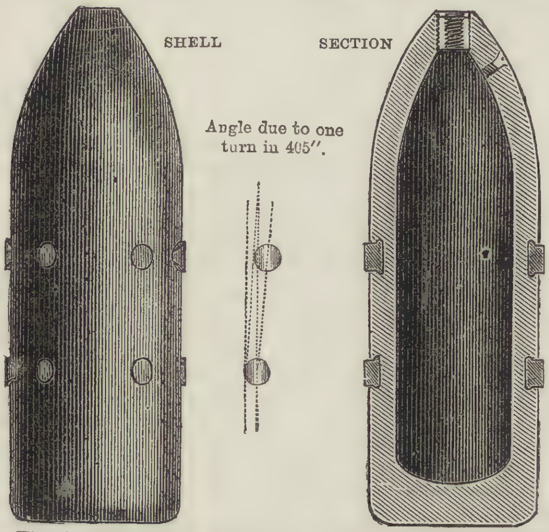

Fig. 4.—NINE-INCH MUZZLE-LOADING COMMON RIFLED SHELL.

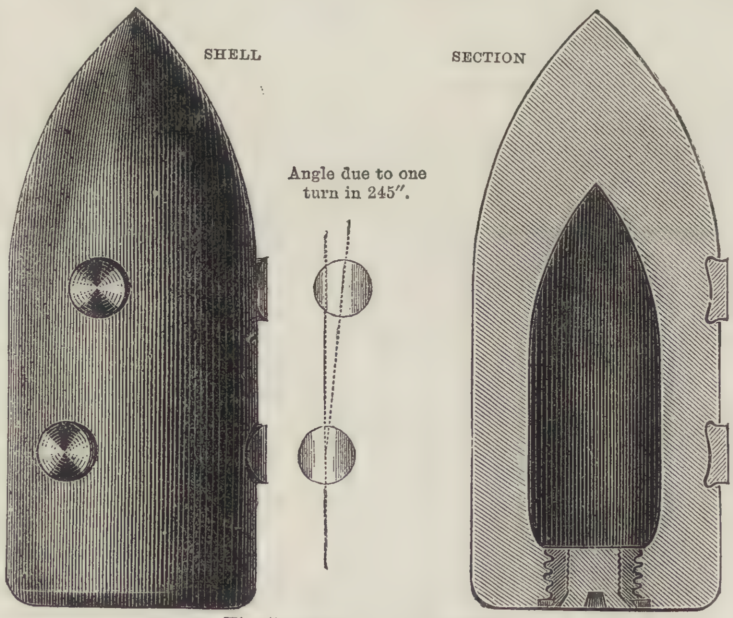

Fig. 5.—THE PALLISER SHELL.

In addition to Palliser shell and shot, our rifled guns fire common and shrapnel shell, and some of the smaller natures fire segment shell, which latter, however, are gradually giving place to shrapnel. A few remarks must now be made on each of these projectiles. The common rifled shell (Fig. 4) is a cylindro-conoidal projectile of cast iron, which is exploded by means of a fuse (either "time" or "percussion") fitted into its apex. The length of the 12-inch shell is about 30 inches, that of the 7-inch about 22 inches, or, roughly, from $2\frac{1}{2}$ to $2\frac{3}{4}$ times their calibre. In the case of the 10-inch shell the proportion is greater, that projectile being 32 inches (or over three times its diameter) in length. The capacity of some of the larger shells is enormous. Thus, the 12-inch shell takes no less than 35 lb. of powder, the 10-inch shell takes 26 lb., the 9-inch 18 lb., the 8-inch 13 lb., and the 7-inch 8 lb. For use at short ranges the 7-inch gun is also provided with a "double" shell—*i.e.*, a longer projectile of increased capacity. This shell contains nearly 13 lb. of powder. It is instructive, as conveying an idea of the enormous increase of shell power due to the use of elongated projectiles, to compare the above-mentioned bursting charges with those of the old smooth-bore spherical shell. Thus—

	Rifled.	*Smooth.*
13-inch,	32 lb.	10 lb.
10-inch,	26 lb.	5 lb.
8-inch,	13 lb.	$2\frac{3}{4}$ lb.

For use against wooden ships one rifled shell would be as powerful as many smooth-bore shells; and when the greater range and accuracy of the former are taken into consideration, it will be evident that the importance of the introduction of rifled projectiles as a means of destruction can hardly be overrated. They deal destruction at greater distances, in a larger degree, and with increased certainty. Against iron-plated vessels common shells have comparatively little value, on account of their low penetrative power. But if the ship is only very lightly plated, or not plated at all, one rifled common shell may cause her destruction. The moral effect of the explosion of from 20 to 30 lb. of powder inside a vessel is incalculable. We believe that it is a fact that the defeat of the *Alabama* by the *Kearsage* was practically completed by a single shell. In the smaller guns common shells are very useful against an enemy's earthworks, houses, and material generally. By some nations (as the Germans) they are largely, almost exclusively, used against his *personnel*. But such a use seems hardly suitable for common shell; at any rate, greater destruction can be effected in an enemy's ranks by means of shrapnel and segment, and the Germans have, since the late war, taken

steps to introduce shells of the shrapnel—or, as we should say, *man-killing*—type.

Before speaking of the rifled shrapnel shell, it may be well to explain the construction of the segment shell. This projectile, which is now gradually dying out of our service, was the invention of Sir William Armstrong. It consists of a thin cast-iron shell, inside which are built up a number of rows of segmental pieces of iron, like stones in the arch of a bridge, a cylindrical cavity being left up the centre for the bursting charge. This construction gives the projectile very great strength to resist external pressure, whether from the shock of discharge or the shock of impact, or otherwise, while it enables the shell to be opened by a small bursting charge. The internal strength is to the external as the internal strength of an arch is to its external strength. Then, when the shell is opened by the bursting charge, the segments form so many separate missiles, of a formidable and destructive character. In the course of the trials at Dartmoor, in 1869, no less than 1,194 hits of all sorts were obtained with 15 rounds of 12-pounder segments fired against a column of six rows of infantry targets. This is, we believe, the greatest effect ever obtained with shells of this class, and to this extent it is exceptional; but on many other occasions the segment shell has greatly distinguished itself. Long series of experiments have, however, gone to show that such distinction is likely to be achieved only when the conditions of the practice are peculiarly or accidentally favourable. Thus, with a known range, at a column of troops, with plenty of time, with ground especially favourable for percussion fuses, and with good men to lay the gun, excellent results may be obtained. But such a combination of favouring circumstances is rare, and what is wanted is a shell which will give good average effects under the ordinary conditions of service. This the segment does not do, and cannot do, for two very good reasons:—(1) the bursting powder being in the centre of the shell, it necessarily causes great lateral dispersion of the segments in opening the bullets; (2) the segments being made of iron, which, as compared with lead, has a low specific gravity, and being of an irregular form, are not favourable to sustained flight and velocity. These two conditions result in the effect of the segment shell being exceedingly local. A good shell bursting at the foot of a body of men will produce tremendous effects; but let the point of rupture be twenty or thirty yards from the column, and the effect will be at once enormously reduced.

These defects have been remedied in Colonel Boxer's rifled shrapnel shell, which is an application to the rifled projectile of the construction adopted by him in the diaphragm shrapnel. The accompanying section (Fig. 1) of the rifled shrapnel explains itself. It will be observed that the powder is situated *behind* the missile matter, with which the shell is filled, and which consists of spherical bullets. The size, weight, and number of these bullets varies, of course, with the calibre of the shell. Thus, the 7-inch shrapnel contains 227 8 oz. balls; the 8-inch contains 376 10 oz. balls; and the 9-inch, 564 12 oz. balls. The 16-pounder shell contains 63 large bullets and 56 small ones; the 12-pounder breech-loading shrapnel contains 42 bullets, 18 to the pound; and the 9-pounder, 21 of the same bullets. From time to time, as the patterns of the shell alter, these numbers are slightly varied. The above figures are, therefore, given only as exhibiting approximately the capacity of shells of this class. As *man-killing* projectiles, the effect of the rifled shrapnel shell is tremendous. It is intended to be opened at a certain distance in front of the object to be fired at, when the bursting charge, ripping up the sides of the shell, liberates the bullets, which proceed onward in a curved cone, the apex of which is at the point of explosion. On one occasion, at Dartmoor, the 12-pounder shrapnel, firing nine effective rounds, gave 652 hits of all sorts, of which 374 were "throughs." In the recent trials against the German gun at Shoeburyness, the shrapnel shell more than once greatly distinguished itself. For example, out of 5 rounds fired at 800 yards with percussion fuses, the effects were on one occasion no less than 103 hits per round, against 33 hits with the German common shell. At 1,500 or 2,000 yards the shrapnel gave from 30 to 40 hits per round. In the course of the 16-pounder trials, the following results have been obtained. At 1,000 yards, against two rows of targets, 67 hits per round; at 1,500 yards, 82 hits per round; at 2,000 yards, 70 hits per round. These are prodigious effects, particularly when it is considered that to produce them it is not necessary to make a good shot every time—that is to say, the shell may be burst from 50 to 150 yards short of the object with excellent effect, thus giving a large margin of permissible error in the laying of the gun, and in the preparing and burning of the fuse. And the great advantage of the shrapnel over the segment is, that it can be used with excellent effect with a "time" fuse, as well as with a "percussion" fuse—in other words, it is independent of the character of the ground over which it may be fired; whereas the segment, requiring an accuracy of action not to be obtained in the field with time fuses, can be effectively used only with percussion fuses, and is thus useless over boggy, or very broken, or very soft ground. To discuss the subject of shrapnel *versus* segment as it deserves, would occupy far more space than can here be allotted to it. What we have said as to the relative merits and performances of the two, will show that both shells possess considerable merit, the shrapnel having the advantage in general utility and effect.

With these remarks we conclude our hurried and imperfect sketch of rifled projectiles. But before closing this chapter, we should wish to make a few remarks upon the subject of fuses for shells. In the case of Palliser shells no fuse is required, the heat generated on impact being sufficient to fire the powder. But with other shells a fuse is necessary. There are two great classes of fuses, time and percussion (or concussion). The time-fuse is a contrivance for igniting the bursting charge of a shell (whether common, shrapnel, rifled, or smooth-bore) at any particular *time* after the shell leaves the muzzle of the gun. Various sorts of time fuses have been proposed, and of these varieties several have found a temporary footing in our service. The typical time-fuse, however, is the Boxer (Fig. 2), in which a cylindrical column of fuse composition (which burns at the rate of 1 inch in 5 seconds) is disposed vertically in a truncated wooden cone. By means of horizontal side holes, placed one-tenth of an inch apart measuring vertically, the wood can be easily pierced at any required point, opening a vent for the burning composition, which instantaneously flashes down the vertical powder-channel. For example, supposing that the shell is required to burst $2\frac{1}{2}$ seconds after it leaves the muzzle, the side hole marked $\frac{5}{10}$ ($= \frac{1}{2}$ inch $=$ 5 half-seconds $= 2\frac{1}{2}$ seconds) would be bored through into the composition; the flame would come through when the composition had burnt down to that point, and would proceed by a flash down the powder-channel to the bursting charge of the shell. Breech-loading time-fuses are made on the same principle, with the addition of a detonating arrangement in the head for igniting them, this being necessary because the fuse cannot, as in the case of the muzzle-loader, be ignited by the flash of discharge.

Percussion fuses are of infinite variety, and great has been the expenditure, often fruitless, upon their production. They are intended to explode the shell on its striking an object, and without reference to its time of flight. One of these fuses, the Pettman, may be taken as a type (Fig. 3). In this fuse a small brass ball, coated with detonating composition, is enclosed between two supports, one of which rests upon a wire (and a lead cup), which is broken (and the cup is crushed) by the shock of discharge. The ball is thus liberated, and on impact is thrown violently against some part of the interior of the fuse and exploded. The flash passes at once to the bursting charge of the shell. By an ingenious arrangement in the head of the fuse, which our space does not permit us to describe, this fuse may be used for either rifled or smooth-bore projectiles, the conditions of which are different.

MUSEUMS: THEIR CONSTRUCTION, ARRANGEMENT, AND MANAGEMENT.

BY SAMUEL HIGHLEY, F.G.S.

XIV.—SYSTEMATIC COLLECTIONS, ETC.

Details of Systematic Collection.—Practically, the "displayed" specimens in the public galleries and the "store specimens" in the adjoining studies would form one series. In 1862, Dr. J. E. Gray reported that he exhibited in zoological galleries 140,000 specimens, and that he had in store for the use of students (including under that term "experts" in zoology) 489,000 specimens, making a total of 629,000 specimens for the national illustration of zoology. This number included varieties and duplicates, but in the new museum "all specimens that are

*absolute duplicates** should be disposed of, as Thomas Bell very properly pointed out to the committee on the British Museum, and to that end should be kept in a separate department in the basement, for the purpose of exchange with dealers or private naturalists, or for replacing damaged specimens. Of late years, however, the question of the origin of species has made us regard duplicate specimens with an entirely different eye to what we did before, for many "varieties" which formerly would have been looked upon as mere duplicates have now become as important as "species." But a few years back the Museum was sadly deficient in specimens that were needed to prove or disprove Darwin's theories. On Professor Owen being applied to by a celebrated naturalist, in 1860, to assist him in procuring the specimens illustrative of the species and varieties of pigeons, he could not find more than twelve varieties of the most common domesticated pigeons, and three skeletons. The collection possessed specimens of the "tumbler," but not one of the common "pouter" pigeon, for at that time the series promised by Dr. Darwin to illustrate his work had not reached the Museum; and Professor Owen was forced to state, "As to showing you the varieties of species or any of the phenomena which would aid in getting at that mystery of mysteries, the origin of species, I am obliged with shame to say, I can show you none of them." But surely our country ought to possess specimens of everything that is known to naturalists, and expect in our national museum to find (at least in the future) all that is attainable.

Another point of the utmost importance connected with the systematic collection is that the skins, skeletons, spirit and histological preparations, models, eggs, nests, nidamental structures, and fossil species, at present widely scattered over the British Museum, should be amalgamated into one series. In regard to the amalgamation of the fossil with the recent species, very decided opinions have been expressed by Drs. Sclater, Wallace, and other eminent naturalists, including Professor Flower, who thus conveys the general feeling on this important question:—"If the construction of the new museum tends to perpetuate the present artificial distinction between extinct and recent species of animals, it will hinder instead of promote the progress of any general conception of the organic world as a whole, and will also impose unnecessary difficulties in working out the minute comparisons by which the affinities and gradations between the various units of which that world is composed are recognised."†

Professor Flower, in the same article, thus fully justifies the prevailing opinions I have advocated in these articles:—"We are only beginning to form any idea of the enormous numbers of specimens actually required to enable us to rest our generalisations relating to most zoological problems upon a firm basis, and of the importance of keeping these specimens in such a condition, and so placed, that they can be examined and compared with the greatest facility. Provision should, therefore, be made in the new museum for the great bulk of the collection being thus treated. It would be quite a mistake to suppose that they would then be shut up and put away, and that the public have no further concern in them, and ought not to be expected to pay for their accommodation. They would be in exactly the same circumstances as the books in a well-arranged library, and ought to be equally accessible under suitable regulations; and *there are thousands of people who will read with interest the conclusions that scientific men will draw from their study of them, who would never care to see, or if they did, never learn anything from, the specimens themselves.*"

Much greater care should be given to "setting up" the stuffed animals and mounted skeletons in an artistic manner than has hitherto been thought necessary in this country, though the educational importance is fully appreciated by the curators of the Stuttgart Museum, which Mr. Alexander Agassiz, after visiting all the great collections, regards as the most instructive museum in Europe. To this end the most artistic taxidermists should be secured—men who should be artists in the true sense of the word, and who could render the characteristic aspect and motion of the animals represented. Think of the common cat as a familiar illustration of the "characteristic motion" of animals: see how upright she stands on her paws, head erect, tail moving in graceful undulations, whiskers bristling, eyes looking straight forward; suddenly they flash with a brilliant phosphorescent emerald-green light, the fore part of the body is simultaneously depressed, the limbs from the paws to the elbows nearly touch the ground, the hind quarters are raised and the limbs thrown backwards, while the tail lashes from side to side with vicious fury; then how stealthily, with undulating back, she creeps forward, and with noiseless bound springs upon her prey, with talons till now sheathed, and with white, sharp, dagger-like teeth, crushes her victim in the dust, anon flings it in the air, plays with it, pats it tenderly with her cushioned but ruthless paws, till it suits her pleasure to give the *coup de grâce*. What taxidermist, unless deeply imbued with an artistic appreciation of his subject, could, with plastic touch, imbue the dead skin with any of the characteristic aspects here described; yet there are, or have been, such men who could blend artistic feeling with scientific truth, as Waterton of our own country, Verreaux of Paris, and the Stuttgart staff.*

The "deadly-lively" stuffed beasts that are yet too prevalent in our existing museums, do more harm than good among the class for whom they are chiefly intended—viz., the uninitiated in natural history. In our national museum, at least, they should be rendered as life-like as the taxidermist's skill will admit of; and we know what Waterton's fingers could effect, guided by a naturalist's appreciative feeling. Far more must also be done in rendering by wax modelling the soft parts of mollusks, tube-bearing worms, coral-forming animals, etc., in connection with their shells and hard parts; while many other groups, such as Hydrozoa, Actinea, Polyzoa, the Ascidians, Nudibranchiata, Vermes, Starfishes, etc., the flowers and fruit of plants, etc., could only be rendered with lifelike aspect by means of carefully-executed wax models. The embryological and anatomical character must often be represented by the same means; while the bones of unique specimens, whether of recent or fossil species, such as the Dodo, Mylodon, etc., might be rendered in counterpart by means of plaster models, that would be undistinguishable from the original specimens. Though, as a rule, wall-cases and floor-cases are best suited for the display of the vertebrate classes, and table-cases for the invertebrates, minerals, etc., no fixed rule should be laid down, but that sort of case should be selected which is best suited for the particular group to be arranged for public inspection. It may here be noted that Schlegel, the director of the extensive Netherlands National Zoological Museum, at Leyden, arranges each "family" in a separate case; and by the position and arrangement of the several links of the chain of Nature in natural sequence, imparts knowledge by that method of silent information which may be made of such educational value in any museum. The "life history groups" should include illustrations of the habits and mimetic† characters of animals.

The botanical collections allow of but limited display, as they mainly consist of specimens of plants and parts of plants, mounted on separate sheets of paper, which are laid upon each other like the leaves of an unbound book, and kept in the trays of small cabinets, which allow of their being arranged or rearranged in blocks, that form series which illustrate the systematic geographical or historical aspects of botany. Such portions are known as herbaria, and being from their nature unfitted for public display, are consequently kept in the studies for the use of working botanists. It is only the hard parts, such as the seeds, fruit, leaves, wood, or sections of woods, fossil species, models of plants, etc., that are suited for public inspection, which is the reason the botanical department makes so little display at the existing museum, though the herbaria is one of the finest and most extensive in the world. Still much more might be effected than has yet been attempted by the use

* It may here be noted that in rendering fossil forms, many specimens may, from their damaged condition, be required, to show by a group all the characters of one species. Such duplicates could not, for instance, be regarded as "absolute duplicates."

† *Nature*, May 26th, 1870.

* The members of this staff have published a work that should be better known to the curators of this country, viz., "Die Praxis der Naturgeschichte, Dermoplastik und Museologie, oder der Modelliren der Thiere und das Aufstellen und Erhalten von Naturaliensammlungen." Edited by Herr Martin, and published by Voigt, of Weimar.

† See Fig. 7, page 329, Vol. III., of THE TECHNICAL EDUCATOR for an example of this phenomenon.

of such *multum in parvo* screens as are shown in Fig. 26 (page 64), and by models of botanical type forms, when the natural object would lose its characteristic aspect and colours, if exposed to light, etc.

The public galleries should be devoted to the illustration of structural botany to the fullest extent practicable; the studies to the specific character of plants. Both Sir Charles Lyell and Professor John Phillips attest to the value of recent specimens for the studies of the palæophytologist, and that, without the aid of the national botanical collections, they could not have identified certain fossil species described in their geological works. The late Robert Brown made it a proviso in his will that his collection of fossil woods should only be given over to the trustees of the British Museum on the condition that it should "form part of the botanical *exhibition*, under charge of the Keeper of Botany;" and should they decline to accept it on this condition, it was to be handed over to the Edinburgh Museum! The mineralogical collection, besides the series of meteorites at present displayed, should include such a series of rock specimens as is described in Cotta's "Gesteinslehre," and a complete suite of crystal models, for both of which there is existing material at the British Museum, though not displayed for want of space. The geological collection should be arranged in stratagraphical order, with restorations of extinct forms such as Unger* and Waterhouse Hawkins have suggested, the latter as to individual forms, the former as to entire landscapes; including both plants and animals, and such accessories as would best convey to the popular mind the creative phases of our earth, while not forgetting the practical requirements of the working geologist.

The wall-space above the cases in the galleries should be utilised with diagrams, the subdivisions of classifications, and maps showing the geographical range of the species displayed on the shelves beneath; while in the stratagraphical gallery, geological should be combined with geographical mapping of the distribution of animal or vegetable life.

TECHNICAL DRAWING.—LXXXI.

DRAWING FOR CABINET-MAKERS.

OBJECT DRAWING.

The student is at this stage advised to work through the course of lessons on Object Drawing, commencing at page 3, Vol. II., of The Technical Educator. The examples there given will show him the application of the Perspective lessons, and he will thus be prepared to benefit by the following studies.

Fig. 622 is a sketch of a drawing-room chair, placed so that its sides are at different angles to the plane of the picture. In commencing this subject, sketch the general ground-plan on the principle shown in the drawing of the kitchen chair, observing that in this case the plan is not a square, the chair being wider in front than at the back.

The uprights of the back are, as in the perspective study alluded to, continuations of the back legs. The light is supposed to come from a point in front of the object and in the left side, and above it; thus, the left angle of the seat and the left-hand front leg receive the strongest light. The side which is in full shade is not visible in the present view; the seat, which is slightly rounded, receives in consequence a slight shade towards its distant edge. The student is advised to draw several chairs placed in different positions in relation to his eye and to the light.

Fig. 623.—This sketch represents a "Davenport," or small writing-desk, supported on a pedestal containing drawers, and by two spiral legs in the front.

In commencing this subject, draw the entire cubical block out of which the whole mass could be carved, regardless of legs or recess—drawing, in fact, the mere packing-case in which the object could be contained. When this has been done, draw the line giving the bottom of the desk on each of the two visible sides; and as of course these lines are in the object horizontal, forming as they do two of the edges of the bottom of the desk, and as they are parallel to the bottom line of the side, and to that which would connect the two legs in the front, they would converge to the same vanishing points as the two last mentioned.

Next sketch the front edge of the desk, which will also converge to the left-hand vanishing point, to which the line joining the two legs has been drawn, the rule being borne in mind that all lines which in the object are parallel to each other vanish in the same point. The two short perpendiculars for the ends of the front of the desk having been drawn, raise the distant perpendicular for the back of the desk, and draw a line to the left-hand vanishing point, this line, too, being of course parallel to the front edge. Now complete the desk by drawing the slanting edges, etc.

Draw the perpendicular indicating the width of the pedestal containing the drawers, and also the corresponding one in the distance, connecting these at the bottom by a line parallel to the front of the desk, and thus converging to the same point. The framing at the bottom is now to be drawn, the lines converging to the left-hand vanishing point.

The spiral legs must now occupy attention. For each of these a central perpendicular should be drawn, and a line on each side of it, between which the whole pillar is to be contained, observing that the distant one must be rendered slightly narrower than that in the immediate foreground. The oblique and curved lines giving the twisted appearance will be easily followed from the example.

The light is supposed to come from a point in front of the object, above it in height, and on the left side; the front therefore receives the light, the brightest being at the angle, and on the slanting surface of the desk. The whole of the distant side is covered with a shade, whilst a shadow is cast by the desk on to the front of the pedestal. The right side of the pillars too are shaded, a reflected light being seen at the edge. The cast-shadow on the pedestal, as well as that on the ground, must, it will be remembered, be darker than the shades.

Fig. 624.—This sketch represents a loo-table. The spectator is in this case supposed to be *sitting* nearly in front of the object. The method of drawing circles in perspective has been explained elsewhere, and it will therefore be understood that if the spectator were supposed to be *standing*, the point of sight would be higher, and the width of the ellipse representing the circle would consequently be greater, and that as the point of sight were lowered the breadth would decrease, until it became lost altogether; thus a circular disc, when placed immediately on a level with the eye, is seen only as a straight line.

In commencing this figure, draw a perpendicular line for the centre of the pillar, and a horizontal crossing it for the long diameter of the ellipse representing the top of the table, which should now be sketched, as well as the double line representing the edge and the framing around it. The pillar should next be drawn, and then the base. This is an equilateral triangle in perspective, its angles being cut off, and its sides curved inward. Care must be taken in drawing the distant side of this triangle, which should in the first instance be sketched as one continuous curve, although afterwards interrupted by the pillar which crosses it. The thickness of the base, and the feet on which it rests, should now be drawn.

The light comes from a point in front, but slightly towards the left of the object. It will be seen that as the curved surface presents no sharp edge to the light, there is no definite point at which the shade commences. The brightest light is at the part of the circular edge and frame nearest the light, and from this it gradually tones down into the darkest shade, slightly lightened at the distant portion by reflected light.

The cylindrical pillar is shaded in a similar manner, but over a great portion of this the shadow of the top of the table is cast, and falling from above on a cylindrical surface, its outline is a curve tending obliquely downwards. It must be impressed on the student, however, that unless a shade is bounded by the absolute lines of a surface on which it falls, it must have no definite outline—its edge must be slightly softened off. Observation will show the student that the extremes of a shadow are always more or less toned down into the tint of the surface on which it falls.

The right-hand side of the triangular base is next to be shaded, and then the shades on the feet. The cast-shadow on the ground, and that cast by the projecting edge of the top on the framing beneath it, will complete the drawing.

SEATS OF INDUSTRY.—XXXIII.

MARSEILLES.

BY WILLIAM WATT WEBSTER.

ONE of the oldest commercial towns in Europe, Marseilles, or properly Marseille, is the chief mart, and, in respect of population, the third largest city in France. About six centuries before the Christian era, a colony of Greeks from Phocæa, in the Ionian Confederation, obtained a grant of the site from Naunus, the king of a Ligurian tribe, and built a town there which they called *Massalia*, a name that was afterwards changed into *Massilia* by the Romans. For a long period the Greek settlers were assailed by the natives of the place, but they successfully defended themselves, and gradually extended their territory, planting several colonies along the adjacent coast, at Antipolis, Nicæa, Emporiæ, and elsewhere. The Massaliotes devoted themselves chiefly to commerce, and the republic they founded was from an early period celebrated for the wisdom of its laws and institutions. Under the domination of the Romans, Massilia continued for a long time to rival Alexandria and Constantinople in the extent of its trade. On the outbreak of the Punic war in 218 B.C., it was of sufficient importance to be received into the alliance of Rome, and the Massaliotes were useful and faithful allies of Cæsar during all his Gallic campaigns. In the great contest for supremacy between Pompey and Cæsar, the town espoused the cause of the former, and was besieged and captured, after a protracted and stubborn resistance, by the latter, who carried off all the ships, military equipments, and public money, and deprived the Massaliotes of their peculiar privileges. After this event the commerce of Massilia declined, but subsequently the town acquired a new importance as the school where the neighbouring Gauls learned philosophy and rhetoric. Cicero speaks of it as the Athens of Gaul. In the reigns of Augustus and Tiberius it was the principal seat of learning in the West, and many Roman youths received their education there, among whom may be mentioned Agricola, the conqueror of Britain. Between the time of Cæsar and the downfall of the Roman empire no remarkable event occurred in the history of Massilia, but its inhabitants acquired a high character for virtue, temperance, and simplicity of life.

On the downfall of the Roman power, Marseilles fell alternately into possession of the Visigoths, Ostrogoths, and Franks; and in the early part of the eighth century the larger and older part of the city was sacked by the Saracens, who destroyed the remains of the ancient monuments that previous barbarians had spared. The upper portion of the city, however, successfully resisted assault, and held out till Charles Martel and his brother Childebrand brought a strong force to its relief, and expelled the Saracens. During the latter half of the eighth century, and especially during the reign of Louis le Debonnaire, in the beginning of the ninth, Marseilles suffered severely from pirates. The republican government of the city, which was aristocratic in its character, and consisted of six hundred dignitaries called Timachi, from whom an administrative committee of fifteen were chosen, three of whom were in turn entrusted with the executive power, was maintained up till the tenth century, when Marseilles was brought under the dominion of the Counts of Provence. William I., Viscount of Marseilles, and his successors, retained sovereign power over the city till the twelfth century, and the change to a monarchical form of government would seem to have produced no bad effects on its industry, commerce, and arts. For some time after the restoration of republican institutions, Marseilles formed one of a confederation of similar smaller states, in which were included Arles and Grasse; but after a struggle which lasted for six years, the city was again compelled in 1243 to acknowledge the authority of the Counts of Provence. In a short time, however, Marseilles was involved in an unsuccessful war with Charles of Anjou, brother of Louis IX., who annexed it to his territory, and it remained in the possession of the house of Anjou till 1482, when Charles de Maine, the heir to the line of Anjou, bequeathed it to Louis XI., with a stipulation that the time-honoured liberties of the city should be respected. In 1524, Charles de Bourbon besieged the city with a large imperialist force, but the citizens, after a desperate struggle, succeeded in repelling their adversaries. Louis XIII. made Marseilles a station for the French navy, and provided it with a dock and arsenal; and one good effect that followed these measures was the dispersion of the pirates that had for many centuries infested the Mediterranean. A formidable insurrection broke out in the city, under the leadership of Noiselles, during the reign of Louis XIV., but the Grande Monarque personally suppressed the disaffection in 1660, and punished the Marseillaise by depriving them of their peculiar privileges. He at the same time built the citadel of St. Nicolas. Marseilles was frequently visited by the plague, and in the years 1720 and 1721 it suffered an attack of this fell disease which carried off between 50,000 and 60,000 of the inhabitants. Marseilles early and zealously espoused the cause of the first French revolution, and the celebrated patriotic and revolutionary hymn, composed by Rouget de Lisle, derives its name of the Marseillaise from the fact that it was first publicly sung by the Marseilles confederates in 1792. The revolutionary commotion, however, having nearly ruined the commerce of the city, its inhabitants in 1793 went over to the side of the Girondists. After the restoration the trade and industry of Marseilles revived.

The most famous of the old merchants of Marseilles was Jacques Cœur, who flourished in the first half of the fifteenth century. Jacques Cœur was born at Bourges in 1400, and was the son of a goldsmith and fur-dealer of that city, whose business he inherited and greatly extended. Throughout his whole career Bourges was the centre of the commercial connections that this merchant had formed with every district in France; but about the year 1429 he established a place of business in Marseilles, the ancient port affording excellent facilities for carrying on trade with foreign countries. For some twenty years he annually dispatched ten or twelve vessels to the ports lining the Mediterranean, to exchange the wares of France for the spices, silks, and other costly articles of the East. He was the original founder of the French trade with Egypt, and his dealings with that land were very extensive, the goods he obtained from thence being sold not only in his own but also in other countries. It was reported that he had at one period no fewer than three hundred agents in various parts of the world. Charles VII. gave him a grant of the mining districts surrounding Lyons, and so successful were his operations, that the common people believed that he was an astrologer, and had discovered the philosopher's stone. By commerce and mining this enterprising merchant amassed so much wealth, that "As rich as Jacques Cœur" became the French equivalent of the Latin proverb, "As rich as Crœsus." His sovereign appointed him Master of the Mint, first at Bourges, and afterwards at Paris, and he was subsequently made *Argentier*, or Treasurer to the Crown.

From the time of Jacques Cœur to the present day Marseilles has been the principal commercial emporium in the south of Europe. Some idea of the extent of its trade in the middle of the eighteenth century may be formed from the fact that in 1753 1,264 vessels entered its port, which was a large number for that date. A century later, however, its shipping had nearly increased fourfold in number, and considerably more in tonnage. In 1858, 4,787 ships, with an aggregate burden of 1,102,123 tons, entered, and 4,687 ships, with a collective burden of 1,030,077 tons, cleared the port. From the report of the British Consul at Marseilles, which has just been issued, we extract the following interesting statistics and notes relating to the commerce of the city in the years 1868, 1869, and 1870. Notwithstanding the disturbed state of France during the latter half of 1870, a larger amount of shipping visited the port in that year than in any preceding one. The aggregate burden of the sailing-vessels and steam-ships that arrived at Marseilles in 1868 was 2,171,463 tons; in 1869, 2,228,130 tons; and in 1870, 2,237,732 tons. For the same three years the sailing-vessels and steam-ships that left the port represented a total of 2,181,582 tons for 1868, 2,183,539 for 1869, and 2,190,854 for 1870. To show the rapid increase of steam-ships within the last ten years, it may be stated that the steamers entered and cleared at the port of Marseilles in 1861 represented an aggregate burden of 1,362,392 tons, while in 1870 they reached a total of 2,417,817 tons, or considerably more than one-half of the whole tonnage inwards and outwards during that year. In the latter year 364 British vessels, with an aggregate burden of 195,935 tons, and manned by 11,709 sailors, arrived at the port, and 352, with an aggregate burden

of 188,717 tons, and an aggregate crew of 11,480, left the port. In the foregoing numbers were included 148 British steamships, with a total burden of 122,519 tons, and a total crew of 9,263 men. Of these vessels 51 are the property of the Peninsular and Oriental Company, who at the end of the year quitted the Marseilles station, and adopted that of Brindisi for the Indian mail service. A very large passenger traffic has been carried on at this port for the past few years, the arrivals and departures fluctuating from 150,000 to 180,000 yearly. Marseilles now possesses 572 sailing vessels, collectively of 87,201 tons burden, and 119 steamers, of 94,872 tons. The custom-house revenue of the port for 1870 amounted to 18,009,370 fr., against 15,225,727 fr. for the preceding year. In 1864, which was an exceptionally brisk year, the total exports of Marseilles reached a value of 1,102,243,663 fr. The merchandise exported in the year 1867 was estimated to be worth 627,021,967 fr., and the precious metals 129,005,663 fr., giving a total value of 756,027,630 fr. Among the principal articles of export in that year were included woollen fabrics to the value of 37,000,000 fr.; silk goods, 32,000,000 fr.; cotton goods, 28,000,000 fr.; refined sugars, 35,000,000 fr.; and wines and spirits, 25,000,000 fr. A striking fluctuation in the importation of wheat into Marseilles for the past few years is noticeable in the returns. In 1870, 5,256,030 hectolitres (three hectolitres being equivalent to 1 quarter 0·254 bushels) came into the port; while in 1868 the quantity was 10,486,800, out of 15,918,500 hectolitres, which was the total importation of wheat into France in the same year. Of other grains, such as rye, barley, oats, and maize, 2,573,300 hectolitres were brought into the port in 1870. About 1,492,800 hectolitres of wheat and wheat flour were exported from Marseilles in the same year, 392,400 being sent direct to England. The raw sugar imported from abroad in 1869 amounted to 68,645 tons, and in 1870 to 76,390 tons; and in the former of these years 7,505 tons, and in the latter 1,911 tons of home-grown beet-root sugar were received in the city. In 1870, 44,214 tons of refined sugar were exported from Marseilles, of which 12,760 were sent to Turkey, 9,422 to Italy, 6,840 to Algeria, 2,358 to Egypt, and 2,888 to Greece; while about 4,000 tons of raw sugar were re-exported. Oil-seeds have recently acquired an important position in the commerce of Marseilles, the imports of this article for 1870 having amounted to 184,000 tons. These oil-seeds consisted of sesamum seed from the Levant, India, and the coast of Africa; linseed and cotton-seed from the Black Sea and Egypt; and cocoa and palm nuts from the coast of Africa. The oil-mills of the city turned out about 115,000 tons of oil-cake in 1870, 29,000 tons of which were shipped for England, out of a total exportation of 31,700 tons. There was a marked decline in the quantity of cotton imported into Marseilles in 1870 as compared with the three preceding years. In 1869, 150,572 bales came to the port, and in 1870, 98,884, about 19,000 only being brought from India. The annual value of the silk imported represents upwards of 100,000,000 fr., and the quantity landed at Marseilles in 1870 amounted to 32,039 bales, but a large portion of this and of the stock of silk at Lyons was re-shipped for England on the outbreak of the war. China, Japan, Bengal, Persia, Asia Minor, and the coast of Syria supply most of the silk brought to Marseilles. The wool trade of the city has fluctuated nearly to the same extent as the cotton trade, only 91,518 bales of wool having been imported in 1870 (the whole being brought from Mediterranean ports, with the exception of 4,654 bales from Buenos Ayres), against 139,910 bales in 1868. In 1870, there were imported into Marseilles 10,356 bales of sheep and lamb skins, nearly the whole of which came from the River Plate; 31,355 bales of goat-skins, mostly from Morocco; and 716,797 hides, of which 200,000 came from the River Plate, 60,000 from Brazil, and the remainder from other countries. The olive oil imported in the same year amounted to about 40,000 tons of ordinary quality for manufacturing purposes, and 5,000 tons of refined oil; and the oil-mills of the city produced 70,000 tons of oil from the various sorts of oil-seeds, 12,000 tons of which were exported. Owing to the direct importation of petroleum from the United States into the various Mediterranean ports which formerly drew their supplies from Marseilles, the trade in this article has recently declined, but 42,743 barrels of crude, and 32,797 of refined petroleum were landed in 1870. The exportation of wine from this port has considerably increased within recent years, 35,580 pipes having been shipped in 1869, and 26,963 in 1870; but the trade in spirits has fallen off, only 2,500 pipes having been shipped in 1869 and 1870 respectively, against 5,775 in 1866. About 15,000 tons of argentiferous lead were brought to the city in 1870, and a large portion of it was desilverised there. The blast-furnaces of Marseilles turned out about 30,000 tons of iron in 1870, from ore imported from Algeria, Spain, and Italy. Out of 627,000 tons of coal brought to Marseilles in the same year, 81,000 tons came from Great Britain; about 200,000 tons were consumed in the city, and the remainder was either used by the steam-shipping, or sent to the different countries of the Mediterranean. Some 70,000 tons of soap are annually manufactured in the city. The flour-mills of the district number about 100, and comprise 600 pairs of stones. Large quantities of flour are annually produced, and the exportation of this article is important, having amounted to 65,000 tons in 1870. About £600,000 worth of work was executed in the engineering establishments of Marseilles in 1867, which then employed 4,000 men, but there has since been a considerable falling off. Large quantities of cattle are annually imported into Marseilles from Algiers and Sardinia. From the former country 19,109 bullocks and 318,621 sheep were landed in 1868; and from the latter 16,173 bullocks and 715 sheep. In 1870 the figures were:—From Algiers 1,880 bullocks and 218,694 sheep; and from Sardinia 4,932 bullocks and 69 sheep. About a fourth of the sheep and a third of the bullocks are consumed in Marseilles, and the rest are driven into the neighbouring departments. The trade between Marseilles and Algeria is very extensive, as may be judged from the fact that 766 vessels, with an aggregate burden of 290,259 tons, left the port in 1867 for that colony, while 573 ships, of collectively 274,812 tons burden, arrived from it. Ship-building has almost entirely left the city, and little more than repairs are now done there. The sea-fishing, which a few years back occupied a considerable number of ships, now only occupies about a dozen, and between 300 and 400 men.

The harbour of Marseilles is one of the finest and largest in the world, being capable of accommodating 2,000 vessels. It comprises (1) the Old Port, which is 1,000 yards long, and 300 yards wide; and the Port of La Joliette, constructed in 1853, which is about 600 yards long and 460 yards wide, and is surrounded by spacious quays furnished with iron tramways; (2) the basins of Lazaret, Aren, and Napoleon, opened within recent years; (3) a very old and insufficient graving dock; and (4) two refitting docks constructed in the same canal that unites the Old Port with the Port of La Joliette. The latter port is formed by a breakwater 1,224 yards long, thrown out into the sea, running parallel with the shore, and at a distance of 1,312 feet from it. Marseilles is still deficient in quay-space, and ships have frequently to discharge their cargoes lying to three deep. The great dock warehouses, built of stone and iron, can contain some 40,000 tons of merchandise. Le Vieux Port is formed by an inlet of the sea which runs eastward into the heart of the city, and the roads are defended by the fortified islands of If (crowned with a castle, once a state prison), Pomeque, and Ratonneau.

In Marseilles, the western quarter, which is crowded with narrow, irregular streets, is the older, the poorer, and the seat of the principal industries. Connecting the old and the new towns is a beautiful street or promenade called Le Cours, planted with a double row of trees, adorned with fine fountains, and bordered with many elegant mansions. Here the shops and houses rival in splendour the finest of those in Paris. The new parts of the city are admirably laid out. A new town that sprang up with remarkable rapidity on the site of a hill removed in course of making the port of La Joliette, and on the land recovered from the sea, is known as the maritime city, and is capable of containing 60,000 inhabitants.

The city is healthy. There are few remarkable buildings or antiquities in Marseilles. The New Cathedral, which is supposed to be built on the site of a temple of Diana, is a basilica in the Byzantine style, shaped like a Greek cross, and surmounted by very picturesque domes. Marseilles is the capital of the department of Bouches du Rhone, and possesses a court of first jurisdiction, a court and chamber of commerce, an exchange, a royal naval observatory, a mint, an academy of sciences, belles-lettres, and art; schools of medicine, music,

drawing, and hydrography; a public library containing 60,000 volumes; botanical gardens, a picture gallery, and various learned societies. The population in 1861 numbered 219,984, or including the whole commune and the military, 260,910; and at present it is upwards of 300,000. There are about 900 *bastides* or villas in the vicinity of Marseilles.

CAPITAL AND LABOUR.—VI.

By J. E. Thorold Rogers, M.A., Tooke Professor of Economic Science.

COMBINATIONS OF LABOUR.

The possessors of property may unite together in order to make their property more useful to themselves, and so turn, in the language of economists, their wealth into capital. They may entrust the management of this capital to the hands of others, and they may, if they prefer it, manage their capital themselves. In the former case they will get interest, in the latter they will get profit as well as interest, or, as I have already explained the facts, they will get wages for the labour which they give in superintending their own property, together with a greater or less addition, according to the character of the business in which they are engaged, which will cover the risk of loss.

Now the labourer, when his economical position has been analysed, will be found, as has been generally stated before, to stand in exactly the same place that the capitalist does. His education and maintenance are, to all intents and purposes, an investment of capital for productive purposes. The duration of his powers is a matter of risk. He is engaged in an industry which will assuredly sooner or later wear him out, and therefore he does in his wages receive something which, over and above the risk which he incurs, will compensate for the inevitable exhaustion of the powers which make him an industrial agent. But as the remuneration of his labour, in the shape of wages, and of his employer in the form of profit, are really identical forms of economical distribution, there is a question which is constantly raised as to the relations between the employer and the labourer, and which is characteristic of them. I refer to the question as to whether the master gets too much and the workman too little, in the distribution of that which remains over and above in the market price of the article, after all necessary charges are liquidated.

A combination of labourers has for its object the appropriation to the labourer of a greater share in the surplus from which both wages and profit are derived. This object is not always assured, but it certainly subsists in all such combinations. It was historically the cause of these associations, for up to within fifty years ago the law inflicted serious penalties on all those who entered into combinations for the purpose of raising wages, and the law had adopted this policy for nearly five centuries. It was by no means surprising, when this law was repealed, that workmen entered into these mutual arrangements; for it is very natural that persons should think, as soon as they are permitted to do what they have been forbidden before, that there is some advantage to be gained by availing themselves of the permission.

But, apart from these historical circumstances, there are considerations, partly of principle and partly of fact, which justify the associations of working men for the purpose of bettering their condition, and obtaining an increase in their wages. It may be the case, as some persons of great judgment and experience have averred, that these arrangements can be proved to be superfluous, for that the rise in the wages of some kinds of labour may be explained by causes which are quite independent of trade combinations, that the power possessed by those who live by their labour of entering into such associations greatly varies, and that if the policy of these arrangements is expedient it ought to be available for all who might see good to take advantage of it. It may be proved too, perhaps, that the establishment of the system may in certain kinds of industry do great injury to the public at large, and in particular to that portion of the public which is least provided with the necessaries or conveniences of life. But even if these reasonings can be maintained, they will not militate against the justice of a combination of labourers, though they may disprove its expediency.

A labourer has something to sell. This is his labour. It is just as saleable an article as a pound of sugar or a yard of cloth, and its advantageous sale is as much a matter of interest to the labourer as the sale of sugar and cloth is to the grocer and the draper. Now, if it be admitted that capitalists can unite their capitals together in order to get advantage by mutual association, there can be in the nature of things no reason why labourers should not have and use the same liberty. A trade union is virtually a labour partnership. It may not be, and perhaps is not, the best form of labour partnership—we shall have occasion to recognise, hereafter, much more advantageous forms of association—but it is based on precisely the same principle as that which induces men to put their property together in order to found a bank, to construct a railway, or advance a loan to a government.

Part of the machinery by which a trade combination tries to enforce its regulations is a strike—that is, a refusal to work unless certain demands are conceded. Now such a course of action is very inconvenient, and occasionally very alarming. It may be very disadvantageous to the public, and still more disadvantageous to the persons who adopt the expedient. It may entail great loss, and may fail of its end. It may attain its end, and the public may suffer, because they may have to pay more for a service than the service has hitherto been worth. It may be superfluous, because the rise in wages which it is intended to achieve may come from natural causes. It may be even unfair, because it is possible that such a rise ought to come from natural causes only. But, judged by the ordinary practice of those who are engaged in business, it exactly corresponds with the line of action adopted by traders in goods. No one finds fault with a merchant because he speculates on a rise in the price of the articles in which he deals, and withholds his goods from the market in order that he may get a better price hereafter than the market offers him at present. Such speculations are justified on grounds of private right, and sometimes even on those of the public good. But a working man who, in concert with others, declines to work for wages which he thinks insufficient, is only doing that which is an admitted right in the conduct of business by a private merchant. No one would probably dispute his right to choose his own terms if he acted as an individual, and there is no reason in the nature of things why he should not act with others in seeking to obtain for all what he thinks will be for the good of all. On grounds of principle, then, combinations of working men have a clear economical defence.

They have a further justification in fact. There can be no doubt that in matters of bargain an individual workman is, as compared with an employer, in a weak position. The man who employs many hands has greater advantage in constraining a workman to accept terms, than an individual workman has of exacting them. There is not much doubt, whether they do so or not, that employers have naturally greater opportunities for uniting together, in order to adopt a common policy, than their workpeople have. Even if the men can be brought to act together, the power of endurance, however disastrous may be a trade difference, is greater on the part of employers than it is on the part of the men. The very fact that the employer is possessed of wealth which is generally saleable, while the workman is possessed of one kind of wealth only, which under the present circumstances he declines to sell, is positive proof of the superiority of position enjoyed by the employers.

In giving these economical excuses for those combinations and their action, I must not be supposed to think that such expedients are desirable, or under certain circumstances necessary. I only say that they are, under existing circumstances, defensible. They arise from causes which are in themselves exceptional. I may illustrate what I mean by a fact of my own experience. Before the outbreak of the American civil war, there were very few trade-unions in the United States. Just after the commencement of that war, a tariff was passed by the American Congress, of a highly protective character, in the interest of employers or manufacturers. I took occasion, in conversation with an American of eminence, to predict that speedily, under that tariff, the States would swarm with trades-unions. Events proved that I was right. But my prediction was based on the principle which I have often insisted on, that where there are employers and working hands there is always a question afoot, whether the profits of the employer do not take over-much from the wages of the workman.

ENGLISH CARRIAGE-BUILDING.—I.

BY A LONDON COACH-BUILDER.

INTRODUCTION—HISTORY OF CARRIAGE-BUILDING—ESSENTIALS—LUMBER AND PANEL STUFF—WORKING DRAUGHT—CANT-BOARD—STANDING PILLAR.

It is a moot point whether carriage-building is to be regarded as one of the fine arts, or whether it is to be classed among the branches of industry which are included in the list of mechanical trades. The question is well worth the consideration of all those who adopt carriage-building as their vocation in life, because on the conclusion at which they arrive depends, to a great extent, their chances of success; for the higher the opinion men entertain of their occupation, the more are they likely to pursue it as a labour of love. On the one hand, it is said that, although essentially and of necessity for its practical purposes a mechanical occupation, it nevertheless includes so much of what is termed *art* in the higher sense of the word, that it may justly claim to be considered more than a mere industrial manufacture. On the other hand, it is contended that this branch of industry is of so multiform and composite a character, that it cannot in any sense lay claim to individuality which is the characteristic distinction of an art.

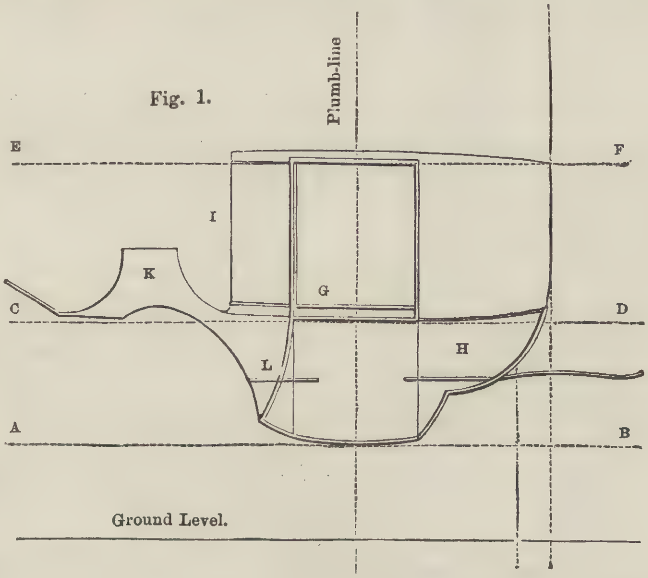

Fig. 1.

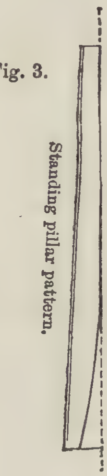

Fig. 3.

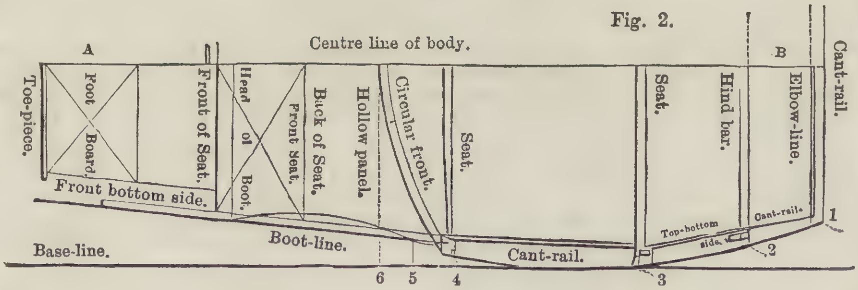

Fig. 2.

It is quite true that the occupation of the coach-builder differs widely in this respect from that of the sculptor, the painter, or the architect, or even from the pursuits of the goldsmith or the potter, inasmuch as each of these has to deal only with one substance, or one class of substances, and is dependent alone on his own efforts and skill; while the former has to deal with a great variety of materials of very opposite natures, and to command a whole train of auxiliaries, every one of whom must be well skilled in his department, or the work when completed will be marred, notwithstanding the superior abilities of the superintending head; but it is equally certain that if this same superintending head possess not in a high degree the distinguishing characteristics of the sculptor, the artist, and the architect, he will inevitably fail to make a proper use of the mechanical skill that is placed under his control, or to obtain a high position.

In the earlier ages of carriage-building, and even to a comparatively recent period, little was necessary to those engaged in it, beyond some rude knowledge of the laws of mechanics. No doubt the war-chariots of the ancient Greeks, described in the classic language of Homer, were very primitive constructions; the state carriage of our own Elizabeth, judging from the descriptions we have of it, must have been a very lumbering contrivance; and even the state-carriage in which "Mr. Speaker," only a few years ago, proceeded to St. Paul's Cathedral to take part in the thanksgiving service offered on the occasion of the recovery of the Prince of Wales from his severe illness, is little more than a venerable piece of gilt gingerbread. But the wonderful development of this elegant and useful branch of industry during the present century, especially during the last five-and-twenty years, has rendered far higher qualities essential for its successful prosecution, and under whatever heading it may be classified in the world's industries, the more eminent of our builders quietly pursue it as an art. That it is so considered in many European states is shown by the fact that in France, Belgium, and Germany, the respective governments have established technical schools, where youths intending to follow it are instructed in drawing, modelling, in the harmonious arrangement of colours, in chemistry, in metallurgy or the proper working of metals, and in the principles and applications of mechanics and mathematics to manufactures. It is to be regretted that more pains are not taken in this respect with our English apprentices, who mostly pursue their study of the different branches in which they are destined to labour with very little knowledge of the qualities or properties of the materials that are placed in their hands. But, notwithstanding our remissness, many of the heads of our large establishments have, by their own technical knowledge, and their taste and experience, overcome the difficulties that the want of a better system might be expected to give rise to, and if we pay a visit to their factories or show-rooms, we shall see at once to what perfection carriage-building has been brought in this country. We shall, moreover, be convinced not only that it is an art, but one calling forth no ordinary skill, for the carriage-builder has to combine in one harmonious whole a great variety of essentials, over each of which he must possess a mastery before he can succeed.

The art of carriage-building is of very high antiquity, and was still of ancient date in the days of Homer, who flourished about 900 years before the Christian era. The war-chariots of the Pharaohs are mentioned by Moses in the sacred writings, and it may be flattering to the pride of our English manufacturers to know that the scythe-armed chariots of the ancient Britons were copied and adapted by the Romans for purposes of luxury and convenience. But however much the Greeks or Romans may have elaborated their system of carriage-building, they made very little improvement upon the vehicles used by the ancient Egyptians, and after the fall of the Roman empire the art slumbered altogether for many centuries.

On its revival in the fifteenth century, it became rapidly a lucrative branch of industry, and attained great excellence, first

in Italy, and afterwards in Spain, France, and England. In 1668 Charles II. granted a charter incorporating the Worshipful Company of Coach and Coach-harness Makers in the City of London, conferring on them certain privileges and rights in order to encourage and protect a trade that had not been very long established in this country, and which was thought to require support. At that period trades were mysteries and their processes secret, and protection and support was required by that company in order to preserve those mysteries and processes inviolate.

For a long period none who embarked in this business was regarded in the trade as a legitimate carriage-builder, but he who had been brought up to the art of framing bodies or carriages. But in process of time it was shown that taste was the chief requisite, and as taste is not a necessary result of peculiar instruction, it followed that it must be had wherever it could be obtained; and others who had been brought up in different departments of the trade, such as painters, harness-makers, or smiths, were found to exercise the business with success. At the present day many men are engaged in it who have been brought up to professions or occupations entirely unconnected with carriage-building, and by their natural abilities, combined with excellent taste, they have often done more towards raising their adopted calling to the dignity of an art than some others who are able to boast of their practical experience and early training in the mysteries of the craft.

The protective theories of the "Worshipful Company" have long since exploded, but the company still exists, and, advancing with the times, its worthy representatives recently lent their hall for the purpose of an industrial exhibition of the operative coach-makers, the object of which was the very opposite of that for which the company was originally formed—namely, to court inquiry, comparison, and inspection of their work, with the enlightened desire to interest the public, by showing how much ingenuity, patience, and care are necessary for the production of a first-rate carriage. The mysteries and processes of the trade may therefore fairly be said to be thrown open, and without any violation of principle we are enabled to place before our readers some interesting details of the manner in which the elegant equipages of modern days are produced and turned out from our best establishments.

The first essential in a well-appointed carriage factory is a plentiful stock of well-seasoned timber, and of the different woods that are required in the process of carriage-building. There should be no timber used in a body or anywhere about a carriage that has not had at least one year in seasoning to every inch in thickness. After it has been cut into planks, it should be kept in a place where it will have a free current of air, each plank separated half an inch apart, with slips placed directly over each other, or the planks will be liable to warp.

Panel stuff should be treated in a similar manner, with the addition that it should be secured at the ends to prevent splitting; and when a body-maker commences his work, his first care should be to look after his panel, roof, bottom, side stuff, and lining boards, get them all planed up to their proper thickness, and put them up in some safe place where they will get a moderate degree of heat, each panel separated by slips; and all other stuff that will be required for the piece of work in hand, should be selected and put aside. If all these things be strictly attended to, there need be no trouble about bad joints; and it will be to the employer's interest to look after such workmen as do not know enough to see to these things themselves, and have these rules strictly enforced; but an intelligent workman will soon appreciate the advantage of getting his stuff ready at the commencement, instead of waiting till he wants to use it.

The timbers and woods commonly in use in our carriage factories are English ash plank, which is used for the framework of bodies and the timbers of carriages, Honduras mahogany for panelling, white pine for roofing, seat-boards, and the under parts of bodies, and birch for boot sides; but of late years Canadian black walnut wood has been advantageously introduced, and is often used in the place of birch, or being cut into panels is found, for many purposes, an excellent substitute for Honduras mahogany; the sapling oak or hickory is used for the spokes of wheels, and other woods are used for minor purposes. Many schemes have been tried for forcing the desiccation of timber, but we have no faith in any of them. The well-ventilated timber-shed, which gives alike protection against damp and the direct rays of the sun, offers the surest and safest means of seasoning or drying timber. Subjected here to atmospheric influence, the process may be slow; but while the moisture evaporates, the fibrous texture of the wood gradually consolidates, and none of its virtue is lost; while by any forced process the too rapid evaporation of moisture leaves the grain open and porous, and the virtue of the timber is more or less destroyed.

But before these timbers can be brought into use, it is necessary first to design the carriage that is to be built, and here we find at the outset that the eye and hand of the artist are wanted, for on the manner in which the carriage is first placed on the canvas entirely depends its appearance when finished: the importance, therefore, of a good draughtsman is at once apparent. In view of this vital necessity in the art of modern carriage-building, the Worshipful Company of Coachmakers annually offers prizes of silver and bronze medals for the best specimens of freehand drawing, as well as for practical mechanics; and, in addition, two silver and two bronze medals for drawings of carriages *to any scale*, for competition among foremen, workmen, or apprentices engaged in the trade. It is gratifying thus to see this ancient City guild striving to promote the best interests of the trade, for the special benefits of which it was originally established, while all others similarly called into existence have outlived everything connected with the industry they represent, except the name.
